Random bond Ising chain in a transverse magnetic eld:

A nite-size scaling analysis.

Abstract

We investigate the zero-tem perature quantum phase transition of the random bond Ising chain in a transverse magnetic eld. Its critical properties are identical to those of the M cC oy-W u m odel, which is a classical Ising m odel in two dimensions with layered disorder. The latter is studied via M onte C arlo simulations and transferm atrix calculations and the critical exponents are determined with a nite-size scaling analysis. The magnetization and susceptibility obey conventional rather than activated scaling. We observe that the order parameter{ and correlation function {probability distribution show a nontrivial scaling near the critical point which im plies a hierarchy of critical exponents associated with the critical behavior of the generalized correlation lengths. 75.10H k,75.50L k

Quite recently there has been a growing interest in the zero-tem perature quantum critical behavior of disordered spin systems. Therm all uctuations are absent here and the phase transition is driven by the interplay between randomness and quantum uctuations. In order to tune the system to criticality one can either vary the strength of the disorder, as for instance in spin $-\frac{1}{2}$ XXZ (chains [1], or one can control the strength of the quantum uctuations directly by an external transverse magnetic eld in spin models with a strong Ising anisotropy. The latter case is particularly interesting since experimentalists became e able to investigated the elect of a transverse eld on the glass transition in the Ising spin glass LiHo_xY_{1 x}F₄ at low temperatures [2]. On the theoretical side much progress has been made since then: the in nite range model has been solved analytically [3{5], a M igdal-K adano renorm alization group calculation has been made [6], the critical exponents in 2 and 3 dimensions have been determined via M onte C arbo simulations [7,8] and new results for the one-dimensional case have been derived via a renorm alization-group analysis [9].

In the latter papers focusing on the critical behavior in nite dimensions of these quantum models it has been pointed out that their universal properties are identical to those of classical Ising models with layered disorder [10]. Especially the Ising spin chain in a transverse eld can be mapped onto the M cC oy-W u model [11{13}, for which various exact results have been derived. The critical exponents of the order-parameter and the correlation length as well as the dynamical exponent z has been found recently via a renorm alization-group (RNG) analysis by D.Fisher [9].

The aim of the present paper is to perform a numerical investigation of the nite-size scaling behavior of the Ising spin chain in a transverse magnetic eld. Such an analysis has not been performed yet for this model and bears some new features concerning the nite-size scaling of anisotropic systems [14]. It can also be seen as a test-ground for numerical methods applied to systems, for which | in contrast to this model | no quantitative theoretical prediction are at hand (e.g. for the cases considered in [7,8]). And nally it provides a check to what extend analytical predictions, like those made in [9] and which are valid asymptotically for an in nite system with rather unusual properties, can be detected

2

in systems of nite size.

The model under consideration is described by the quantum Hamiltonian

$$H_{Q} = \begin{array}{ccc} X & X & X \\ J_{i} & i & i+1 \\ i & i \end{array} \begin{array}{c} X & X \\ i & i \end{array}$$
(1)

where are spin { $\frac{1}{2}$ Paulim atrices, is the transverse eld strength and the exchanges J_i are quenched random variables obeying a distribution P (J). At zero tem perature the system (1) has a ferrom agnetic phase transition to long{range m agnetic order at a critical value $_c$, which depends on the bond distribution P (J). We are interested in the critical properties of this transition. However, as shown in [9,11,13], the m agnetization behaves already non-analytically at higher values of $_c$ giving rise to e.g. a divergence of the longitudinal susceptibility at higher values of .

The ground state energy of this one-dimensional quantum model (1) is equal to the free energy of the two-dimensional classical Ising model [15]

$$H = \int_{i;j}^{X} J_{i}S_{i;j}S_{i+1;j} K \int_{i;j}^{X} S_{i;j}S_{i;j+1}$$
(2)

at a certain nite temperature T. Here $S_{i,j} = 1$ are classical Ising spins, the site index i nuns along the x (space) direction and the index j along the (imaginary time) direction of a two-dimensional square lattice. Following [7,8] we can rescale the bond strengths J_i and coupling constant K without changing the universal properties. For numerical convenience we set K = 1 and take a binary distribution

$$P(J) = \frac{1}{2} (J' - j_1) + \frac{1}{2} (J' - j_2); \qquad (3)$$

where we put $j_1 = 1$. The layered random bond Ising model (2) with the bond distribution (3) has a ferrom agnetic phase-transition at a critical tem perature T_c de ned by [11]

$$\log \operatorname{coth} (1=T_c) + \log \operatorname{coth} (j_2=T_c) = 4=T_c$$
(4)

and the universal properties (like exponents etc.) are identical to those of the quantum chain (1) at $_{c}$ and zero tem perature. Therefore we study model (2) at $T_{c}(j_{2})$ by M onte-C arb simulations of rectangular lattices of size L L. The largest size in the -direction was L = 160 whereas that in the space direction x, which corresponds to the length of the quantum chain (1), was L = 16. Hence the disorder average over the distribution (3) could be done exactly by generating all, non-equivalent bond-con gurations (whose number is approxim ately 2^{L} =L). To have more con dence on the data from the M onte-C arlo simulation we have compared our results to those obtained from transfer m atrix calculations. The advantage of the latter m ethod is that the results are exact, but the drawback is that one is lim ited to sm all system sizes L 10. In all cases we found no signi cant deviations between the results of the two m ethods.

The correlation length of the quantum chain (1) diverges as ($_{\rm c}$) when approaching the ferror agnetic transition. The characteristic relaxation time of the quantum dynamics is expected to diverge as $^{\rm z}$, with z being the dynamical exponent. These two diverging scales can naturally be found in the classical model (2): due to the extrem e anisotropy one expects the correlation length in the space (or x) direction to diverge like (T T_c) and the correlation length in the imaginary time (or) direction like

(T T_c)^z. Following a nice argument by L.M ikheev [16] one might in agine the system close to T_c as being composed of roughly rectangular, ferrom agnetic/param agnetic domains, which are located (in the space direction) at segments of the chain where strong/weak bonds are dominating. The correlation length in the time direction is then given by the average distance of domain walls in semi-in nite strips of width being ferrom agnetically ordered, thus / exp(a) (see e.g. [17]). This supports very much an activated dynamics scenario with z = 1, as found in the RNG analysis [9]. However, we begin the analysis by assuming a nite z and will see how far we get.

At the critical point (i.e. $T = T_c$) various them odynam ic quantities are expected [14] to depend only on the scaling variable L=L, the aspect ratio or the shape of the system. For instance we would have for the averaged spontaneous magnetization

$$M = [m i]_{av} \quad L^{=} m (L = L^{z});$$
(5)

where m = (L L) 1 ${}^{p}_{irj}$ S_{irj} j is the magnetization per site, h imeans the therm allowerage and [${}_{av}$ m eans the disorder average. In gure 1 we show a scaling plot according to (5) obtained by M onte-C arlo simulations for di erent shapes and sizes (note that the disorder average is done exactly) at ${}^{1}_{2}$ = 0:1 and T = T_c = 1:32038. It yields = = 0:17 0:01 and z = 1:65 0:05. We also looked at ${}^{1}_{2}$ = 0:05 for which T_c = 1:14710, and obtain z = 1:70 0:05 and = = 0:18 0:01. The RNG prediction is = 2 (for the averaged correlation length) = (3 ${}^{p}_{5}$ 0:38 [9], which yields a ratio = 0:19 that agrees roughly with our estimate.

The exponent z decreases as j_2 increases approaching z = 1 for $j_2 = 1$ and indicating the crossover to the pure case. This is the reason why we used sm all values for j_2 to ensure that what we see is the critical behavior of the disordered model. On the other hand we tried to avoid too sm all values of j_2 in the M onte-C arb simulations, since then the critical tem perature decreases too much and equilibration becomes more di cult.

The insert of gure 1 shows the scaling behavior of the susceptibility at $j_2 = 0.1$,

$$(L;L) = L L [m2i]av L0 ~ (L = Lz);$$
(6)

for which we nd 0 = 2.3 0.1 (we used the value z = 1.65 that was obtained from the scaling of the magnetization). Note that 0 is not the critical exponent that describes the divergence of the susceptibility in an in nite system by approaching the temperature T_c from above, since this quantity is expected to diverge already at a temperature higher than T_c [9,11]. The prediction for an anisotropic system obeying hyperscaling [14] is 0 = +2 = = d+ z. Inserting d = 1 and the values for = and z given above this relation is full led very well. For the magnetization and the susceptibility conventional scaling seems to work well for these system sizes.

The averaged cumulant $g_{av} = 0.5$ [3 $m^4 i=m^2 i^2 l_{av}$ is expected to scale like

$$g_{av}(L;L) = g(L = L^{z})$$
(7)

and a scaling plot is shown in gure 2 with z = 1.55 0.05 for $j_2 = 0.1$, which is slightly lower than the estimate from the spontaneous magnetization. Furtherm ore the data collapse

is not as good as in gure 1. Even worse is the scaling behavior of the cumulant $\overline{g} = 0.5$ (3 $[m i^4]_{av} = [m i^2]_{av}^2$). A system atic shift in the maximum to smaller values for increasing system sizes L indicates that this quantity is not dimensionless as expected naively. The natural scaling assumption $[m i^k]_{av}$ L $^{k} = \mathfrak{m}_k (L = L^z)$ does not seem to be correct here. As a consequence, the order parameter probability distribution P (M) = [(m i M)]_{av}^1 does not scale in a trivial way like P (M) L = P^{e} (M L = $;L = L^z$) | as it does e.g. in conventional spin glasses [18] | which we checked explicitly by looking at the magnetization histogram s for system s with constant aspect ratios L L^z .

To have an independent check of this scenario we have compared the above results with those obtained from the transfer matrix calculation. We have used the method recently introduced in [19] for the exact calculation of the free energy derivatives. The method has been extended to a nite rectangular lattice with periodic boundary condition in both directions. By expressing the cumulants of the magnetization as derivatives of the free energy, we have computed g_{av} and \bar{g} for systems sizes up to 8 256. Since there are no num erical derivatives involved and the average over disorder is performed by summing over all possible con gurations, the calculation yields the exact values. In all cases we did not nd signi cant di erence between these results and those of the M onte-C arlo simulations.

We have also calculated the averaged spin-correlation function at T_c, which is de ned as

$$C(r;t) = [hS_{i;j}S_{i+r;j+t}i]_{av}$$
: (8)

For the averaged correlations in the time direction C (0;t) one expects [14] for L / L^z a behavior

$$C(0;t) / t^{2} + (L t)t^{2};$$
 (9)

where the second term on the rh.s. takes into account the periodic boundary conditions. In the insert of gure 3 we have depicted C (0;t) for various system sizes L with L chosen at the maximum of g_{av} (L), so that L / L^z . From the two conclude that $_2 = 0.23 - 0.01$.

Concerning the spatial correlation function C (r; 0) Shankar and M urthy report a result (see equations 3.39 and 3.43 in [13]), which is

$$C(r;0) / exp(ar) + exp(aLr);$$
 (10)

where the second term on the r.h.s. takes again into account the periodic boundary conditions. This form yields a nice least square t to our num erical data, as shown in gure 3. Note that comparing (9) and (10) one observes that space and tim e seem to scale like r $(\log t)^2$, as predicted in [9].

D. Fisher argues [9] that the result (10) holds for the typical correlations (i.e. those corresponding to the maximum of their probability distribution), whereas the average should decay algebraically, since the latter should be dom inated by rare, strongly correlated regions of the spin chain. We tried to tC(r;0) to an algebraic decay similar to (9) with a dimension exponent k, which gave much worse results. However, stipulating

$$C(r;0) \quad r^{k}e(r=L;L=L^{2}); \qquad (11)$$

the relation C (L=2;0) L $*\overline{c}(L = L^z)$ should hold, which gives indeed an acceptable datacollapse for $_k = 0.40$ 0.02 (using our estimate z = 1.70). The latter result agrees well with the result $_k$ 0.38 obtained in [9]. Furthermore it is consistent with the scaling relation $_2 = _k = z$ (within the errorbans) and $_k = d + z$ $_0^2 = 2 = .$ We would like to stress that our data are compatible with both equations (10) and (11), which, however, are based on assumptions excluding each other.

Next we study the probability distribution of correlation functions in the spatial direction through the analysis of the associated generalized correlation lengths [20,21]. The analysis is carried out using the transferm atrix approach, form one details see [21,22]. We focus on the spatial correlation function for which we can use the general results for products of random m atrices. In this case the latter consists of a succession of transferm atrices from row i to row i+ 1 in the spatial direction, each of which is made by L spins. Since the generalized correlation lengths to be de ned below are related to the rst two Lyapunov exponents of an in nite product of transferm atrices we have to choose L very large (10^6). An advantage of this approach is that one is left with only one scaling variable at the critical point since L =L² is zero.

7

In general each m om ent of the probability distribution of the correlation function de nes a characteristic length scale which we denote by $_q$ where q is the order of the m om ent [20,21]:

$$_{q}^{1} = \lim_{r! = 1} \frac{1}{rq} \ln [G_{i}(r)^{q}]_{av}$$
 (12)

where $G_{1}(\mathbf{r})$ is the connected correlation function between the row i and the row i + r. For example $_{1}$ is the characteristic length scale of the average correlation function, while $_{0}$ is that of the typical correlation function. We shall then call $_{0}$ the typical correlation length and $_{1}$ the average correlation length. It can be shown that if $q > q^{0}$ then $_{q} = q^{0}$ [22]. Taking into account this hierarchy, the usual nite-size scaling hypothesis [14] for the spatial generalized correlation lengths would be

$$_{q}^{1} = L \stackrel{1=z_{q}}{=} \stackrel{e}{_{q}} ((T \quad T_{c}) L^{1=z_{q}})$$
(13)

where the z_q can be called \generalized dynamical exponents". From the relation $q q^0$ for $q > q^0$ it follows that $z_q z_{q^0}$ and $q q^0$. In the scaling form (13) it is assumed that the q diverges all at the same temperature T_c , which in general need not to be the case, see for instance [20]. As consequence, especially for large q (13) should be modiled allowing for a q-dependent T_c . However, we stick to the scaling form (13) with T_c given by the ferrom agnetic phase transition temperature.

We have calculated (for technical details see [21,22]) the z_q by computing the exponents $_q$ at the critical point T_c for di erent j_2 for system s of sizes up to L = 8. The length of the product was 10^6 . The exponent z_q increases as j_2 decreases. We get (with at least 10 percent accuracy)

In all cases we found a good scaling at the critical tem perature T_c given by (4). Our statistics is not accurate enough to investigate higher correlation lengths. The dynam ical exponents increase system atically with decreasing j_2 and it cannot be ruled out that $z_q ! 1$ for $j_2 ! 0$. Since the other exponents (as q, see below, or see above) are less susceptible to a variation in j_2 we have to leave it open here, whether this behavior indicates a cross-over or an actual non-universality of z_q with respect to j_2 .

The exponent $_{q}$ are obtained from the data collapse using (13). In this case we computed the generalized correlation lengths for temperatures $T > T_{c}$ and for system sizes up to L = 7. Again the length of the product was 10^{6} . W ith this statistics we were able to estimate only the rst two exponents. The data for $j_{2} = 0.1, 0.05$ and 0.01 leads to $_{0}$ ' 0.7 and $_{1}$ ' 1, in agreement with the analytical result of [13] but disagrees with the RNG result $_{1} = 2$ [9]. In gure 4 we show a scaling plot for $_{0}$.

We brie y discuss the time-correlation length for which we consider a sem i-in nte strip in the time-direction (L ! 1). While for the spatial correlations we have an in nite product of random matrices, in the case of time-correlations the transfer matrix is always the same since the random ness is only in the spatial direction. In this situation for each realization of disorder the correlation length is given by the inverse of di erence between the rst two eigenvalues of the transfer matrix and yields, if averaged, the inverse of the typical correlation length, $_0^{-1}$ (note that this is equivalent to averaging the logarithm of the correlation function). For the typical time-correlation length we stipulate again the usual nite-size scaling form [14]

$${}_{:0}^{1} = L {}^{z_{0}} {}^{e} {}_{;0} ((T {}^{T} {}_{c}) L^{1=\sim_{0}}):$$
(15)

For $j_2 = 0$:1 we found, for example, $z_0 = 1$:3 and $e_0 = 1$. Note that $z_0 \notin z_0$ and $e \notin .$

To sum marize we perform ed a detailed nite-size scaling analysis of the zero-tem perature phase transition occurring in a random bond Ising chain by tuning the transverse magnetic eld to some critical value. For this model many analytical results are known and our analysis shows a good agreement with the results of Shankar and Murthy [13] and concurs also with the RNG prediction of the existence of di erent length scales with di erent critical exponents [9]. However, we do not not the same values as those reported in the latter. O ne possible explanation of this fact m ight be the following: D. Fisher [9] estimated the average correlations by only taking into account the very rare events, which, in our notation (12) for the generalized correlation length $_{q}$ corresponds to the limit q ! 1 . C onsequently his result = 2 should an upper bound of our $_{q}$. W hat is denoted by typical correlations in [9] seem s to us m ore related to our averaged correlation functions.

Our nite-size analysis leads to nite values for the dynam ical exponent z, which m ight be due to the small system sizes we were conned to. However, for $j_2 \, ! \, 0$ wend z ! 1 in agreement with a RNG-picture [9]. Furthermore wend that the order-parameter probability distribution scales non-trivially at the critical temperatures. We made this observation also in connection with the cumulants of the probability distribution of correlation functions and we found a hierarchy of critical exponents for the generalized correlation lengths. D expite these facts the numerical value = for the nite-size scaling of the averaged spontaneous magnetization concurs with the prediction made in [9].

All these phenom ena merit further investigation (a more detailed discussion on these results will be given elsewhere [23]), especially with respect to the Gri the singularities occurring already at temperatures above T_c [9,13]. Finally we would like to mention that there is also a large overlap of the scenario we have encountered here with what might occur in two- and three-dimensional Ising spin glass in a transverse eld [7,8].

ACKNOW LEDGMENTS
