M anifestation of spin degrees of freedom

in the double fractional quantum H all system

A bstract : The double fractional quantum Hall system of spin 1/2 electrons is numerically studied to predict that there exists a novel spin-unpolarized quantum liquid speci c to the multi-species system, which exemplies a link between the spin state and the inter-layer electron correlation. Even when the ground state is spin-polarized, the lowest charge-excitation mode involves the spin when the interlayer tunneling is considered.

PACS numbers: 73.40 Hm.

Recently, much attention is focused on the double fractional quantum Hall (FQH) system, in which two layers interact with each other as realized in double quantum wells[1] or in wide single quantum wells[2]. Speci cally, E isenstein et al have observed a FQH state at total Landau level lling of = 1=2 in a structure in which the inter-layer tunneling is prohibited due to a barrier separating the two layers and yet the two layers are coupled via C oulom b interactions.[3] U sual practice in considering a double FQH system is to introduce a pseudospin describing the layer degrees of freedom, while the real spin is neglected under the assumption that they are fully polarized. Then the spin-polarized double FQH system m in icks the single FQH system of spin 1=2 electrons.

However, already in single-layer FQH system s,[4] the real spin degrees of freedom dom inate the electron correlation via Pauli's principle. N am ely, the ground state is spin fully polarized for odd-fraction Landau level lling factor, while the ground state is spin unpolarized for some other fractions as detected in tilted- eld experiments. Thus the real question for the double FQH system is that how the inclusion of the spin degrees of freedom dom inate the physics, in which the total spin should crucially a ect the interplay of the intra-layer and inter-layer electron correlations, which is controlled by the layer separation (d=`) norm alized by the magnetic length (`= $\frac{q}{dh=eB}$).

M otivated by this, we consider double-layer FQH systems of spin 1=2 electrons. We shall show from a numerical study for nite systems that we do have spin-unpolarized FQH state speci c to the double-layer system of spin 1=2 electrons. A nother motivation of the present Letter is to look into the low-lying excitations in the coexistence of real and pseudo spins in view of the recently emerged measurements of the excitations in the FQH system from the inelastic light scattering.[5, 6, 7]

W e consider the H am iltonian, rst in the absence of inter-layer tunneling, given by

$$H = \frac{1}{2} \sum_{m_{1} m_{4}}^{X} \sum_{m_{1} m_{4}}^{X} m_{1} i^{m_{2}} j^{q} \frac{e^{2}}{jr_{1} r_{2}j^{2} + (z_{1} z_{2})^{2}} jm_{4} i^{m_{3}} ja_{m_{1}}^{Y} a_{m_{2}}^{o} a_{m_{3}}^{v} a_{m_{4}}^{o} i^{m_{4}} i^{m_{4}} i^{m_{3}} ja_{m_{1}}^{Y} a_{m_{2}}^{o} a_{m_{3}}^{v} a_{m_{4}}^{o} i^{m_{4}} i^{$$

where a_m^y is the creation operator for the m-th in-plane orbit of real spin with pseudospin (= layer 1;2), r the in-plane position and the dielectric constant.

We have obtained the ground-state wavefunctions from the exact diagonalization of nite systems in both torus and spherical geometries. Since the total spin, S_{tot} , of the system is conserved, we concentrate on the subspace of $S_z^{tot} = (N \cdot N_{\#}) = 2 = 0$. Still, the inclusion of the spin in the double-layer system enormously increases the dimension of the H am iltonian matrix (to typically 8 10^5 for = 4=7 with four electrons per each layer), which has been diagonalized here by the Lanczos method. We have determined S_{tot} and the intra- and inter-layer electron correlations for various values of total and d.

To characterize the numerically obtained wavefunctions we have boked into, in addition to the radial distribution function, the overlap with trial wavefunctions: we can extend the G reek-R om an wavefunction [3] proposed for the single-layer system of spin 1=2 electrons to the double-layer system, which is feasible in the absence of inter-layer tunneling with the xed number of electrons in each layer.[9] The double G reek-R om an' wavefunction is given (in the symmetric gauge) for N electrons as

$$\lim_{m \to \infty} A = A \left[\lim_{m \to \infty} (z) (u)_1 + (\underbrace{u}_4 (u)_1)_1 + (\underbrace{u}_4$$

$$\lim_{m \to \infty} z = \lim_{m \to \infty} \lim_{m \to \infty} \lim_{m \to \infty} \lim_{m \to \infty} \exp \left(\sum_{i=1}^{x} \dot{z}_{i} \dot{z}_{i}^{2} = 4^{x^{2}} \right);$$
(3)

$$\prod_{i=1}^{intra} = \sum_{\substack{1 \ i < j \ \frac{N}{2}}}^{Y} (z_i \ z_j)^1 (z_i \ z_j)^1 (i_j)^1 (i_j)^1;$$
(4)

$$\stackrel{\text{intra}}{\overset{\texttt{m}}}_{\texttt{m}} = \begin{pmatrix} Y \\ (z_i \quad Z_j)^{\texttt{m}} (i_j \quad j)^{\texttt{m}}; \\ 1 \quad \frac{1}{2}; j \quad \frac{N}{4} \end{pmatrix}$$
(5)

$${}^{\text{inter}} = {}^{Y} (z_{i} \ _{j})^{n} (Z_{i}$$

Here $z_i = x_i$ iy_i is the position of an "-spin electron in layer 1, Z_i for a #-spin in layer 1, $_i$ for a "-spin in layer 2 and $_i$ for a #-spin in layer 2. \hat{A} is the antisymmetrization operator, u=d are the spinors for layer 1/2, = are the spinors for real spin up/down. The exponents in the Jastrow factors specify the orbital correlation (m inimum relative angular momentum) for intra-layer like spins (1), intra-layer unlike spins (m) and inter-layer electrons (n).

Ferm i statistics requires 1 to be odd. In addition a wavefunction must be an eigenstate of S_{tot} . Since the total spin of each layer is conserved in the absence of inter-layer tunneling, we should impose the usual Fock condition upon each layer, which is satisfied only when m = 1

(spin-polarized) or m = 1 1 (spin-unpolarized) for $S_z^{tot} = 0$. The lling factor is given by = 4=(1+ m + 2n); since we have N = (1+ m + 2n)N=4 l in a spherical system with the number of ux quanta being N, which is in turn related to the Landau-level lling via N = 1N where is an integer.

We have previously obtained the result for total = 1.[9] The result shows an existence of a spin-polarized/spin-unpolarized transition at $(d=`)_c = 1.43$. A change in the inter-layer radial distribution function, which is quantitatively slight but discontinuous, signals the transition at d_c . The spin-polarized ground state for = 1 has a large overlap with $_{111}$. This is in fact expected, since we have an obvious limit of d = 0 at which both the pseudospin and real spin should be polarized with all the correlations between like/unlike layers and like/unlike spins becoming equivalent as realized in $_{mmm}$.

Now we turn to the case where the role of spin is truly dram atic. The double G reek-R on an traial function predicts the simplest spin-unpolarized state to be = 4=7 = 4=(3+2+2) 1), for which $_{321}$ becomes an eligible function. This state is thus in sharp contrast with the extensively studied = 1=2 state, in which case the only eligible function among $_{\ln n}$'s with a nite inter-layer correlation (n \in 0) is spin-polarized $_{331}$. W hile for = 1=2 Yoshioka et al have pointed out, for spinless electrons, a large overlap between the ground state and the (spinless counterpart of) $_{331}$ around d=`' 1.5 from the numerical calculation [10], followed by an experimental identication of the state by E isenstein et al, [3] the = 4=7 state thus exemplies a novel, spin-unpolarized class in the coexistence of real and pseudo-spins.

As seen in Fig.1 (a), prelim inary reported in [9], the overlap between the exact ground state at = 4=7 and $_{321}$ num erically calculated in the spherical geom etry has indeed a maximum value, 0.968, around d= ' 1:0. $_{321}$ has the intra-layer correlation similar to that of the = 2=5 single-layer state with S_{tot} = 0 proposed by Halperin, [8] but incorporates a signi cant

inter-layer correlation as well. N am ely, given the fact that three of the intra-layer correlation of parallel spins, intra-layer correlation of antiparallel spins and inter-layer correlation cannot vary independently in a quantum liquid, ₃₂₁ provides a simplest example in which all the three correlations di er from each other. The state is realized for a nite range of d because, as d

is increased, the di erence between the intra-layer and inter-layer interactions (or the Haldane pseudopotentials for the spherical geometry) increases, thereby giving a chance for the interlayer correlation to deviate from the intra-layer correlation, while the system will eventually reduce to independent layers for larger d.

Experimentally the quantization at = 4=7 in double FQH systems has not been observed so far. This may be because the layer separation has not been made small enough. Another factor is that a spin-unpolarized state will be unfavored when the Zeem an energy, E_{Zeem an}, is taken into account. Hence it is imperative to con m the = 4=7 state can survive the Zeem an e ect. We have calculated the energy di erence per particle, E, between the lowest of the spin-polarized states and the ground state as a function of d='. The result in Fig1 (b) shows that it has a peak of 0.0058 e²= ', which is ' 1.0K for G aAs (with = 12.6) in B = 10T and is in fact comparable with the Zeem an energy g B B s ' 1.5K, where g (= 0.44 for G aAs) is Lande's g factor.[11] The gure may also serve as a phase diagram, if we norm alize the vertical axis to regard it as the ratio, $E = E_{Zeem an}$ (the right scale in the gure): in the region where the curve exceeds unity the spin-unpolarized ground state survives the Zeem an energy. Since $E = E_{Zeem an} / (g = 0)^{-1}$ we predict that the = 4=7 FQH state should be observable for sm aller B (with sm aller density of electrons to retain = 4=7), or for sm aller g-factor possibly realized in high-pressure experiments [12].

We have also calculated the energy gap between the ground state and the rst excited state as a function of d=`. The result in Fig.1 (a) has a peak of $0.027e^2 = `, which has a magnitude$ sim ilar to the gap for the single-layer = 1=5 state. A llof the three curves in Fig.1 are peakedin the same region of d, which con rm s the existence of an intrinsic state in this region.

We can further show that, even when the ground state is real-spin polarized, the discussion of charge excitations has to include the spin degrees of freedom when we take the interlayer tunneling into account. The tunneling adds a term, $H_t = (SAS = 2)^P_m$; $(a_m^Y a_m^Z + h c)$, to the H am iltonian. The single-particle wavefunctions then split into symmetric and antisymmetric ones about the center of the structure, and the gap, SAS, enters as another energy. For spin 1=2 electrons in a double layer, we have then to consider the excitation mode in

which pseudospin-ip and real-spin-ip simultaneously take place (which we call SPS-mode) in addition to the spin-wave (S) and pseudospin-wave (PS) excitations.

This is expected from the e ective spin/pseudospin Hamiltonian for the system, which comprises the pair creation/annihilation of the PS mode, the S \$ PS + SPS and SPS \$ S + PS processes on top of the free boson piece. Because of these processes, the e ective Hamiltonian cannot be diagonalized by a Bogoliubov transformation, unlike the spinless case where the PS mode may be nicely tted by the single-mode approximation. Brey has discussed an SPS excitation in the Hartree-Fock approximation.[13] However, this problem has to be investigated rigorously, because we are dealing with a strongly correlated system.

Here we look into the case of = 1 because of the recent interests for this situation in the presence of inter-layer tunneling. M urphy et al have experimentally investigated the double-layer system [14] to probe the phase diagram, in which the = 1 QHE region' exists with the ground state being both real-spin polarized and pseudospin polarized throughout. There the nature of the ground state evolves continuously, as $_{SAS}$ is increased, from $_{111}$ dom inated by the inter-layer C oulomb interaction ((a) in the inset of F ig 2) down to the fully-occupied symmetric state, $_{sym}^{=1}$, dom inated by single-particle tunneling (b).

We present in Fig 2 the numerical result for the low-lying excitations for three typical points in the QHE region, which includes the case (c) of a large d=' for which a dip evolves in the pseudospin-wave dispersion precursing an instability of $_{sym}^{=1}$. When $_{SAS} \in 0$, the spin-wave excitation is a gapless G oldstone mode restoring the SU (2) symmetry of the spin if the Zeem an shift is neglected, while both the PS mode and the SPS modes have gaps. A new noting here is that the energies of the three modes satisfy $E_S < E_{SPS} < E_{PS}$ for k < 1= ' for cases (a-c), which persists when the Zeem an energy is considered. Nor each the charge excitation costs smaller energy ($_{SAS}$) when the spin excitation is exploited simultaneously. Thus the SPS-mode can be a candidate for the thermal gap, but this would contradict with the experimentally reported gap much larger than $_{SAS}$ for sam ples having a small $_{SAS}$ [14]. The problem is thus still open. For the spin-polarized case, the pseudospin-wave excitations from the ground state have been shown to have multiplet structures of weakly-interacting bosons (pseudom agnons) for sm all layer separations.[15] Extension of this picture to spin 1/2 electrons in a double-layer is another future problem .

W e are grateful to Prof. D. Yoshioka and Koichi Kusakabe for valuable discussions. The num erical calculations were done on HITAC S3800 in the Computer Centre, the University of Tokyo. This work was in part supported by a Grant-in-Aid from the Ministry of Education, Science and Culture, Japan.

Fig.1. (a) The overlap between the exact ground state at = 4=7 and $_{321}$ against the layer separation, d for eight (four per layer) electrons in the spherical geometry. The energy gap per particle between the ground state (which is spin-unpolarized) and the lowest spin-polarized state (b) or the gap between the ground state and the rst excited state (a, right scale) are also plotted. The right scale in (b) represents the ratio, ($E_{Sm ax} = E_0$)= $E_{Zeem an}$, where $g = g=g_{GaAs}$ and $B^{*} = B=10T$: in the region where the line exceeds unity the spin-unpolarized ground state survives the Zeem an energy. The lines are quice to the eye.

Fig.2. The excitation modes for the double-layer system of spin 1=2 electrons having six electrons at = 1 for (a) d=' = 0.5, $_{SAS}/(e^2 = ')= 0.05$, (b) d=' = 0.5, $_{SAS}/(e^2 = ')= 0.20$ and (c) d=' = 1.5, $_{SAS}/(e^2 = ')= 0.20$ in the absence of the Zeem an energy. The modes comprise the spin-wave excitation (S, dotted line), pseudospin-wave excitation (PS, broken line), and pseudospin-wave excitation with one-spin- ip (PSP, solid line). The lines are guide to the eye. The inset indicates the positions of the three sets of parameters on a plot of the num erically obtained overlap between the exact wavefunction and the fully-occupied symmetric state against d=' and $_{SAS}$.
