Abstract

The persistent current I in integrable models of multichannel rings with both short- and long-ranged interactions is investigated. I is found to oscillate in sign and increase in magnitude with increasing interaction strength due to interaction-induced correlations in the currents contributed by different channels. For sufficiently strong interactions, the contributions of all channels are found to add constructively, leading to a giant enhancement of I . Numerical results confirm that this parity-locking effect is robust with respect to subband mixing due to disorder.

The absence of macroscopic persistent currents in normal metal rings even at $T = 0$ is a consequence of a parity effect stemming from Fermi statistics, first discussed by Byers and Yang [1]: For N spinless electrons in a purely one-dimensional (1D) ring, the persistent current I is diamagnetic if N is even and paramagnetic if N is odd, independent of disorder and interactions [2,3], and takes a maximum value $I_0 = ev_F/L$ for a clean ring, where v_F is the Fermi velocity and L the circumference of the ring. In a ring with many independent channels, I is the sum of many such diamagnetic and paramagnetic contributions, and is thus very small [1]. Buttiker, Imry, and Landauer [4] argued that persistent currents should, nonetheless, exist at the mesoscopic level, and calculations with noninteracting electrons [5] predicted typical currents of order $I_0 \sim L$ for a disusive metallic ring, where ℓ is the elastic mean free path. Subsequently, persistent currents were observed experimentally in both normal metal [6,7] and semiconductor [8,9] rings. Surprisingly, the persistent currents observed in metallic rings were roughly two orders of magnitude larger than those predicted by theories neglecting electron-electron interactions [5,10], being of order I_0 in individual rings [7]. Mean-field calculations [11-13] for multichannel rings, renormalization group results for 1D rings [14], and exact diagonalization studies [15] found that the persistent current in disordered systems can be enhanced by repulsive interactions due to the suppression of charge fluctuations, but were unable to account for the experimentally observed magnitude of I .

In this Letter, we propose a novel interaction effect which can lead to a large enhancement of I in multichannel rings, even in the ballistic regime, due to the fact that the parities of different channels are no longer independent in an interacting system. We investigate two integrable models of interacting M -channel rings, $SU(M)$ fermions with inverse-square $V(x) = g/x^2$ and delta-function $V(x) = U \delta(x)$ interactions. In the prior model, we show that for $g > 0$ the persistent currents of all channels add constructively provided $k_F L > 2M$, leading to a large persistent current whose parity depends only on the total number of electrons N . In the $SU(M)$ delta-function gas, I is found to oscillate in sign and increase in magnitude with increasing U due to a progressive condensation of electrons into the lowest subband, leading to a parity-locking effect for $U > 16M^4 \hbar v_F/3$, where v_F is the Fermi velocity. A disordered two-channel ring with interchannel interactions is also investigated numerically, and shows, importantly, that the parity-locking effect persists even when the subbands are mixed strongly by disorder. Qualitatively, the parity-locking effect arises in a thin ring because for sufficiently strong repulsive interactions, electrons can no longer pass each other. The elimination of transverse nodes in the many-body wavefunction (which are necessary for two electrons to pass each other) leads to a state whose parity depends only on the total number of electrons, as discussed by Leggett [2], and whose persistent current is consequently large.

Interacting spinless electrons in a non-disordered ring with M transverse channels, threaded by an Aharonov-Bohm flux ($\hbar c = e$), may be represented by 1D $SU(M)$ fermions. The transverse degrees of freedom may be represented by an $SU(M)$ spin variable $\sigma = 1, \dots, M$. In the absence of disorder, and for interactions which depend only on the electrons' coordinates along the ring (i.e., for thin rings), the number of electrons K_σ in each channel is conserved. The Hamiltonian of the system is

$$H = \frac{1}{2} \sum_{i=1}^N \frac{\partial^2}{\partial x_i^2} + \sum_{i < j}^N V(x_i - x_j) + \sum_{\sigma=1}^M K_\sigma \sigma; \quad (1)$$

where $N = \sum_{i=1}^M K_i$ is the total number of electrons and ϵ_i is the energy minimum of subband i . Units with $\hbar = m = 1$ are used. The Aharonov-Bohm flux leads to the twisted boundary condition [1]

$$(\psi_{i+1}, \dots, \psi_N) = e^{i\theta} (\psi_1, \dots, \psi_N) \quad (2)$$

For simplicity, let us consider equally spaced subbands $\epsilon_{i+1} - \epsilon_i = E_F/M$. The subband splitting plays the role of an $SU(M)$ magnetic field. As we shall see, the effect of repulsive interactions is to renormalize this effective field, causing a condensation of electrons into the lowest subband. At $T = 0$, the equilibrium persistent current is given by $I(\theta) = (e\hbar/4\pi) \partial E_0 / \partial \theta$, where $E_0(\theta)$ is the ground state energy of Eq. (1), subject to the boundary condition (2). For simplicity, we consider the case $\theta = 2\pi(1/4 + \text{flux quantum})$ in the following.

Let us first consider a model with long-range interactions: $V(x) = g/d(x)^2$, where $d(x) = (L - |x|)\sin(|x|/L)$ is the chord length along the ring. This model was introduced and solved by Sutherland [16] for the case $M = 1$ and $\theta = 0$, and is integrable for $g \neq 0$. For $g = 0$, this model reduces to noninteracting electrons, and one finds

$$I(\theta=4\pi) = \frac{e\hbar}{2mL^2} \sum_{k=1}^N (1)^k K_k \quad (3)$$

For $M = 1$, this leads to the well-known [5] result $|J| = M^{1/2} I_0$ due to the random parities of the different channels. For $g > 0$, on the other hand, the ground state is highly degenerate in the limit $L \rightarrow \infty$ in the absence of $SU(M)$ symmetry breaking ($\theta = 0$) due to the strong repulsion of the potential at the origin, which prohibits particle exchange. In a finite ring, these states differ in energy by at most $\hbar v_F/L$ due to boundary effects; all electrons will thus be condensed into the lowest subband for $\theta > \hbar v_F/L$, i.e., for $k_F L > 2M$, which is satisfied provided the ring is sufficiently thin. The ground state of the system in this "ferromagnetic" state has the Jastrow product form

$$(\psi_g) = \exp \left[i \sum_{k=1}^N \frac{a^{x_k}}{L} \prod_{1 \leq i < j \leq N} \sin \frac{x_i - x_j}{L} \right] \quad (4)$$

for $0 < \theta < \hbar v_F/L$, where $a = 0$ if N is odd and $a = \frac{\theta}{\hbar v_F/L}$ if N is even. Here $\frac{\theta}{\hbar v_F/L} = g + 1/4$, $1/2$. One readily verifies that ψ_g is an eigenstate of Eq. (1), has the correct symmetry, and obeys the twisted boundary condition (2). This eigenstate is a positive vector when the particles are ordered, and is therefore the ground state of the system. The ground state energy is found to be

$$E_0(\theta) = \frac{\hbar^2 (\frac{\theta}{\hbar v_F/L} + 1)^2 N (N^2 - 1)}{6L^2} + \frac{N}{2} \frac{a^2}{L} \quad (5)$$

The corresponding persistent current is

$$I(\theta=4\pi) = (1)^N \frac{e\hbar N}{2mL^2} = (1)^N M I_0 \quad (6)$$

The condensation of all electrons into the lowest subband caused by the strong repulsive interactions thus leads to an enhancement of the typical persistent current by a factor of $M^{1/2}$ in the ballistic regime, due to the suppression of the parity effect of Byers and Yang.

Let us next consider a model with short-ranged interparticle interactions $V(x) = U \delta(x)$. This system is integrable for arbitrary U , and the eigenenergies with twisted boundary conditions may be determined from a straightforward generalization of the nested Bethe ansatz of Sutherland [17] to the case $\epsilon \neq 0$. The energy of the system may be expressed as

$$E = \sum_{j=1}^N k_j^2 + \sum_{\alpha=1}^M K_\alpha; \quad (7)$$

where the pseudomomenta k_j are a set of N distinct numbers which satisfy the coupled equations

$$\exp[i(Lk_j - \epsilon)] = \prod_{\alpha=1}^M \frac{k_j^{(1)} + iU/2}{k_j^{(1)} - iU/2}; \quad (8)$$

$$\prod_{\alpha=1}^{N_Y-1} \frac{k_j^{(n)} - iU/2}{k_j^{(n)} + iU/2} = \prod_{\alpha=1}^{N_Y+1} \frac{k_j^{(n)} - iU/2}{k_j^{(n)} + iU/2} = \prod_{\alpha=1}^{N_Y} \frac{k_j^{(n)} - iU/2}{k_j^{(n)} + iU/2}; \quad n = 2, \dots, M; \quad (9)$$

where $k_j^{(n)}; j = 1, \dots, N_n = N - \sum_{\alpha=1}^P n_\alpha K_\alpha$ are distinct numbers, with $k_j^{(1)} = k_j$. For $\epsilon = 0$, the ground state is an $SU(M)$ singlet when N is an odd multiple of M . As ϵ increases, electrons in the higher subbands are transferred to lower subbands, until all electrons are condensed into the lowest subband for $\epsilon > \epsilon_c$. This phenomenon is analogous to the spin-polarization transition of the 1D Hubbard model in a magnetic field, studied by Carmelo et al. and by Frahm and Korepin [18]. Using the techniques of Ref. [18], one finds

$$\epsilon_c = (1/4) [U^2 + (2n)^2] \tan^{-1}(2n/U) \quad U n = 2; \quad (10)$$

where $n = N/L$. For $\epsilon > \epsilon_c$, the system is in a parity-locked state, with persistent current given by Eq. (6). It is useful to consider some limiting cases of Eq. (10): Using $k_F' = n/M$, one finds $\epsilon_c' = M^2 E_F$ for $U = 0$ and $\epsilon_c' = 16M^3 E_F v_F = 3U$ for $U = v_F M$. For fixed ϵ , the critical interaction strength required to enforce parity-locking is thus

$$U_c' = 16M^4 v_F = 3 \epsilon; \quad (11)$$

For $M \gg 1$, very strong interactions are thus required to cause complete parity-locking, which would lead to a macroscopic persistent current. This result is in contrast to that for the preceding model, which exhibited parity-locking for any value of the interaction $g > 0$, provided the ring was sufficiently thin.

In order to see how the parity-locking effect develops as a function of interaction strength, let us consider the simple case of a two-channel ring with N odd; then the parities of the two channels are necessarily opposite. For mesoscopic rings, $SU(2)$ excitations of the type considered by Kuzmartsev [19] and by Yu and Fowler [20], which lead to a $\phi_0 = N$ periodicity

of the persistent current, can be neglected [20]. The persistent current for $M = 2$ is then given by

$$I(\mu_0=4) = (-1)^{K_1} (K_1 - K_2) I_0 = N : \quad (12)$$

For $\mu_0 = 4$, the polarization $(K_1 - K_2) = L/2$, where the susceptibility may be evaluated from Eqs. (7-9) using the method of Shiba [21]; one obtains $\chi = 2/v_F$ for $U = 0$ and $\chi = 3U/(2v_F)^2$ for $U \gg v_F$. The magnitude of the persistent current is thus given by $|I| = 4e/hN$ for $U = 0$, and is increased by the factor $3U/8v_F$ for $v_F \ll U \ll U_c$. As U is increased, the persistent current thus oscillates in sign and grows roughly linearly in magnitude due to the progressive transfer of electrons from the upper to the lower subband. For $M = 1$, the evolution of the system toward the parity-locked state as U is increased will of course be more complicated, but one nonetheless expects I to fluctuate in sign and increase in magnitude as electrons condense into the lowest subband.

A peculiarity of the integrable models considered to this point is that the number of electrons in each channel is a constant of the motion. Both disorder and more realistic interactions which depend on the transverse coordinate will break this symmetry, and it is therefore important to verify that the parity-locking effect is not destroyed. To this end, we have considered a disordered two-channel ring, modeled in the tight-binding approximation, with a nearest-neighbor interchain interaction V included to induce interchannel correlations. The Hamiltonian is

$$H = \sum_{i=1}^L \sum_{\alpha=1}^2 \epsilon_i^{\alpha} c_{i\alpha}^\dagger c_{i\alpha} + H_{\text{dis}} + \sum_{i=1}^L \epsilon_i c_{i1}^\dagger c_{i1} + \frac{1}{2} \sum_{i=1}^L c_{i1}^\dagger c_{i2} + H_{\text{dis}} + V \sum_{i=1}^L c_{i1}^\dagger c_{i2} ; \quad (13)$$

where $c_{i\alpha}^\dagger$ creates a spinless electron at site i of chain α , $\epsilon_i^{\alpha} = \epsilon_i + \epsilon_i^{\alpha}$, and ϵ_i is a random number in the interval $[-2, 2]$. The interchain hopping determines the subband splitting. Fig. 1 shows the persistent current for rings with 5 spinless electrons on 18 sites as a function of V , calculated using the Lanczos technique. Both the ensemble average of I for 500 systems (squares) and the persistent current of a typical system (solid curve) are indicated. The error bars indicate the standard deviation $\Delta I = (\overline{I^2} - \overline{I})^2$ over the ensemble (not the statistical uncertainty in the mean value). The subband splitting $\epsilon = 0.8$ is chosen so that in the absence of disorder and interactions, $K_1 = 3$ and $K_2 = 2$, leading to a large cancellation of the persistent current due to the different parities of the two channels. The on-site disorder $\epsilon = 2 > \epsilon$; E_F mixes the two channels, but does not lead to strong backscattering. For $V = 0$, the sign of I is essentially random, and \overline{I} is slightly diamagnetic. As V is increased, \overline{I} oscillates in sign and increases in magnitude, becoming strongly diamagnetic for large V . \overline{I} is increased by a factor of 10 as V is increased from 0 to 20, while $\overline{I^2}$ is increased by a factor of 3. How can we understand this behavior, so analogous to that of the ballistic system with delta-function interactions described above, given the strong intersubband scattering? While the subband occupancies are no longer constants of the motion, there is a corresponding topological invariant in the disordered system, namely, the number of transverse nodes in the many-body wavefunction [2] (i.e., nodes which encircle the Aubry flux). The lowest subband has no such nodes, while each electron in the second subband contributes one transverse node. In order for two electrons to pass each other as they circle the ring, such a transverse node must be present. As

V increases, it becomes energetically unfavorable for electrons to approach each other, so transverse nodes in the many-body wavefunction will tend to be suppressed. In the strongly-correlated limit, all such nodes will be eliminated, leading to a state whose parity depends only on the total number of electrons. In such a state, the persistent currents of all channels add constructively, leading to a large persistent current (see Fig. 1). It should be emphasized that while the enhancement of the persistent current shown in Fig. 1 is relatively modest, a much larger enhancement would be expected in a system with $M \gg 1$, based on the above arguments.

In conclusion, we have proposed a novel interaction effect which leads to a large enhancement of the persistent current in multichannel rings due to correlations in the contributions of different channels. It was shown that even when interactions are weak compared to those necessary to enforce complete parity-locking, as is likely to be the case in metallic rings such as those studied in Refs. [6,7], the persistent current may still be substantially enhanced by interchannel correlations. It should be emphasized that the parity-locking effect holds in both ballistic and disordered systems; it is therefore complementary to mechanisms previously proposed for the enhancement of the persistent current [11-15], which rely on the competition between disorder and interactions. It is likely that both such mechanisms are important to explain the anomalously large observed value [6,7] of the persistent current in disordered metallic rings.

FIGURES

FIG. 1. Persistent current $I = \frac{e}{h} \partial E_0 / \partial j = \partial E_0 / \partial \phi$ of a disordered two-channel ring with 5 spinless electrons on 18 sites as a function of the interchain interaction V . The current is given in units of $I_0 = ev_F/L$. The amplitude of the on-site disorder is $W = 2$ and the subband splitting is $\Delta = 0.8$. Solid curve: persistent current for one realization of disorder. Squares: ensemble average $\langle I \rangle$ for 500 systems. The error bars indicate the width $\Delta I = (\langle I^2 \rangle - \langle I \rangle^2)^{1/2}$ of the current distribution. Note that the persistent current is diamagnetic for large V , as expected for a system with N odd due to parity-locking; this is true for all realizations of disorder.
