(received 11 June, revised 11 O ctober, 1997)

We show that the quantum relaxation process in a classically chaotic open dynamical system is characterized by a quantum relaxation time scale t_q . This scale is much shorter than the H eisenberg time and much larger than the Ehrenfest time: t_q / g where g is the conductance of the system and the exponent is close to 1=2. As a result, quantum and classical decay probabilities remain close up to values P exp $p = \frac{p}{g}$ similarly to the case of open disordered system s.

PACS num bers: 05.45.+ b, 03.65.Sq

Recently there has been a considerable interest in the statistical properties of the poles of the S m atrix in m esoscopic quantum dots coupled to conducting m etallic leads [1,2]. The statistical properties of these poles determ ine the e ective life tim e of particles inside the dot and therefore are directly related to the conductance uctuations and current relaxation inside the dot. In fact, the problem of current relaxation in di usive m esoscopic sam ples connected to leads has been addressed long time ago [3]. Recently the interest to this problem was renewed and new e ective m ethods based on the supersymmetry approach have been developed to study the problem in more detail [4]. For quasi one-dim ensional m etallic samples the results of [3,4] predict that the current in the sam ple, being proportional to the probability P (t) to stay inside the sample, will decay, up to a very long time, in an exponential way according to the classical solution of di usive equation which describes the electron dynam ics in disordered m etallic sam ples: P (t) exp (t=t): Here $f_{\rm p} = N^2 = D$ is the diusion time for a system of size t_c N with diusion coe cient D.

According to [3,4] the strong deviation of quantum probability P_q from its classical value P takes place only for $t > t_H$ where the quantum probability decays as P_a(t) exp ($g \ln (t=t_H)$). Here, $t_H = 1 = (h = 1)$ is the Heisenberg time, is the level spacing inside the sample and $g = t_H = t_c = E_c = is$ the conductance of the sample with Thouless energy $E_c = 1 = t_c$. At time t_H , $\ln P_q$ (t_H)= $\ln P$ (t_H) 2. As it was pointed out recently [5], less strong deviations $(\ln (P_q(t_q)=P_t_q))$ 1) t^P g due to should take place at a shorter time t_q weak localization corrections according to equations obtained in [4]. Up to now these theoretical predictions for open systems have not been checked neither by num erical computations nor by laboratory experiments. A lso the above results are based on an ensemble averaging over disorder and their validity for a quantum dynam ical system which has one xed classical lim it is not evident. The investigation of this problem is also interesting from

the view point of sem iclassical correspondence in a regime with exponentially fast spreading of narrow wavepackets due to which the Ehrenfest time scale [6] is very short: t_E ln N = where is the Liapunov exponent.

In this paper we study the quantum relaxation process in a dynam ical model of quantum chaos where di usion is caused by the underlying classical chaotic dynam ics. This model, introduced in [7], describes a kicked rotator with absorbing boundary conditions (when the momentum is larger than some critical value). This open system can be considered as a model of light trapped in a sm all liquid droplet with a deform ed boundary in which the rays, with orbital momentum less than some criticalvalue, escape from the droplet because the refraction angle exceeds the critical value [8].

Contrary to the standard kicked rotator model [6] in which the matrix of the evolution operator is unitary, the absorption breaks the unitarity of the evolution matrix so that all eigenvalues move inside the unit circle. In other words, each eigenvalue can be written in the form $= e^{i} = \exp(iE = 2)$ where characterizes the decay rate of the eigenstate. In this way absorption corresponds to ideal leads without rejections back to the sam – ple. A similar approach, in which coupling to continuum was studied on the basis of non Herm itian Ham iltonians, has been developed and widely used by W eidenmuller et al. (see for example [9]).

In our model the quantum evolution of the wavefunction is described by the following quantum map:

$$= \hat{U} = \hat{P} e^{iT \hat{\pi}^{2} = 4} e^{ik \cos^{2} e^{iT \hat{\pi}^{2} = 4}}; \quad (1)$$

where \hat{P} is a projection operator over quantum states n in the interval (N =2; N =2). Here, the commutator is $[\hat{n}; \hat{}] =$ i and the classical limit corresponds to k ! 1, T ! 0 while the classical chaos parameter K = kT remains constant. In the classical limit the dynamics is described by the Chirikov standard map [6]:

$$n = n + k \sin + \frac{Tn}{2}$$
; $= + \frac{T}{2}(n + n)$: (2)

For the classical computations, in analogy with the quantum model, all classical trajectories escaped from the interval (N = 2; N = 2) are absorbed and never return back. Due to this absorption, in the regime of strong chaos (K 1) with one chaotic component (no islands of stability), the classical probability to stay inside the interval (N = 2; N = 2) decays exponentially with time: P (t) exp($_{c}$ t). The time scale $t_{c} = 1 = c$ t, is determ ined by the diusion time t_D required to reach the absorbing boundary from the center. Since the di usion rate is $D = \langle n^2 \rangle = t$ $k^2 = 2$ then $c = E_c$ 1=t, = $k^2 = N^2$. In order to study the quantum relaxation we xed the classical chaos parameter K = 7 and the ratio N = k = 4. In this way the di usion time t_D is constant when N ! 1 and this allows to investigate the sem iclassical behavior. Moreover $t_D >> 1$ which justi es the di usive approximation. We note also that the system (1) with N = 2 < n < N = 2 and $\hat{P} = \hat{1}$ coupled to open leads (T = 0 for $n_j > N = 2$) had been studied in [10]. The results obtained there showed that this model has universal conductance uctuations [11] and other properties very sim ilar to m esoscopic m etallic sam ples.

The num erical solution of the classical problem was obtained by iterating m ap (2) for M = 9 1°0 di erent in itial conditions hom ogeneously distributed on the line n = 0. The results dem onstrate a clear exponential decay P(t) = $exp(_{ct} b) w \pm h_{c} = 0:101882(1); b = 0:17774(5)$ (see Fig.1). This exponential decay shows that for K = 7the phase space is completely chaotic without any island of stability. Even with such a high number of orbits, the classical computations allow to obtain directly the probability P (t) with 10 % accuracy only up to the level Ρ 5 10 (t 165). This limitation is due to statisticalerrors appearing for nite num ber of trajectories. In spite of this, the decay rate _c can be found with very high precision which allows to extrapolate the probability behaviour to larger tim es.

For the quantum evolution we choose the corresponding initial condition in which only the level n = 0 is populated and we studied num erically the quantum dynam ics (1) for dierent N . We have found that the quantum probability P_q (t) follows the classical one up to a time t_q after which it starts to decay at a slower rate (Fig.1). We determ ined the quantum relaxation time t_{α} by the condition $\ln [P_q(t_q)=P(t_q)] = 0:1$ which corresponds to 10% deviation. The comparison of quantum and classical probabilities is shown in Fig.1. The values of t_q, obtained in this way, strongly uctuate with changing the system size N as is typical for mesoscopic systems (Fig.2). These uctuations are satisfactory described by a log norm al distribution (insert in Fig.2), but a more detailed analysis is required to determ ine precisely their statistical properties.

To suppress the uctuations, we average $\ln P_q$ (t) over di erent system sizes by changing N in a small interval N around a given N. Typically we averaged up to 500 di erent N values. This allows to determ ine the averaged ratio R (t) = hln (P_q (t)=P (t))i of quantum to classical probability. For all these N values the classical dynam ics is exactly the same since we kept K = 7 and N = k = 4. Then the quantum relaxation time t_q (averaged) at 10% level, is determined by the condition R (t_q) = 0:1. The dependence of R (t) on time, for dierent N, is shown in Fig.3. It is clearly seen that $t_{\rm q}$ grows as we approach the sem iclassical lim it N ! 1 . The rescaling of data for R (t) as a function of $t=t_q$ shows a satisfactory global scaling behaviour of quantum probability (see insert in Fig.3). The dependence of t_q on N is shown in Fig. 4 for the sem iclassical regim e 500 < N130001. This regime corresponds to a variation of conductance $g = N = t_c$ in the interval 50 < g 13000. The tofnum erical data gives a power law dependence t_q 0:19 ct N with

0:41. This power remains the same for 5% deviation level (Fig.4).

Here we propose a qualitative explanation of value based on the fact that in the open system the physics is a ected not by the level spacing but by the distribution of poles of the scattering matrix S which describes the coupling to the leads. These poles are located in the complex energy plane and their in aginary parts determ ine the decay probability of eigenmodes inside the sample. For our model, the poles are simply given by the evolution operator (1). The eigenvalues of \hat{U} are distributed in a narrow ring of width E_c inside the unitary circle [7]. This is typical for di usive sam ples coupled to strongly absorbing leads. As a result, N com plex eigenvalues are hom ogeneously distributed in a ring of total E_c and the distance between them , in the com area A $\overline{\mathrm{E}_{\mathrm{c}}}$ = N . In the classical lim it this plex plane, is spacing goes to zero and one obtains a continuous density of poles. However, for nite N, the separation of poles is nite and can be resolved after a time t_a 1= . A coording to this argum ent, which is independent of the symmetry and dimensionality of the problem, the deviation between quantum and classical probabilities will take place at

$$t_{\rm q} = 0.38 \frac{p}{t_{\rm c}N} = 0.38 t_{\rm c}^{\rm p} \overline{\rm g}$$
(3)

where the numerical coe cient has been extracted from Fig.4. The theoretical dependence (3), which corresponds to = 1=2, is di erent but close to the numerical value = 0.41. We attribute this di erence to a not sufciently large value of $^{p}\overline{g}$. Indeed, neglecting the values with $^{p}\overline{g} < 15$, we obtain = 0.44 for 10 % deviation and = 0.45 for 5% deviation; these values are closer to the theoretical prediction = 0.5.

The scale t_q can be also explained in a more standard way based on weak localization corrections [5,4]. Indeed, the quantum interference gives a decrease of the di usion rate 1=t_c / D ! D (1 at=t_H) where a is some constant (di usion stops at time t_H). As a result ln (P_q=P) at_{H}^{2} = (t_c t_H) 1 and one gets (3).

For very large times, the decay of P_q (t) is determined by the eigenvalue = E $i = 2 \text{ with minimal} = m_{\text{in}}$. This asymptotic behaviour should start from some time scale t_f, which can be estimated in a following way. Sim ilarly to the results obtained for complex matrices [12], the eigenvalues should be distributed in a region with smooth boundary in the complex plane with approxim ately constant density of points for c. Typically this boundary is parabolic near the extrem al 0 close to m in. Due to this, the relative num ber of eigenvalues dW $_{0}) = _{c}^{3=2}$. in the intervald is given by dW = d(The total probability in the interval = ₀ is $(=_{c})^{3=2}$. The distance between the two lowest W values of can be estim ated from the condition W 1=N $_{\rm c}N$ $^{2=3}$. Then $t_{\rm f}$ $0:4tN^{2=3}$ which which gives ism uch larger than tq. The num erical factor here was determ ined from the two lowest values of for N = 5001: $m_{in} = 1 = 0.065309$ and nearest 2 = 0.066203. These values were obtained by direct diagonalization of the matrix U. The rate of the asymptotic decay of P_{q} (t) for N = 5001 (Fig.1) agrees, up to 6 digits accuracy, with the above value of $\mbox{ }_{m \mbox{ in }}$. We note that a typical size of uctuations for poles is and so we expect that 1=t. Since in our model t_f t_H С m in and the classical limit is xed we do not see the quantum deviations discussed in [3,4] for $t > t_{H}$. At large g one should average over exponentially large num ber of realizations to observe them .

The largest value of t_q we have num erically obtained (at N = 1:3 150 is $t_q = 254$ which corresponds to a 5 $1b^2$. On the other hand, the probability $P_q(t_q)$ classical simulation with M = 9 1°0 orbits allows to directly compute the classical P (t) with 10% accuracy 165 which corresponds to a probability only up to t Ρ 5 10. In order to reach the above level of quan-10⁴ orbits, which tum accuracy one should iterate M is already out of the possibility of present day com puters. M oreover, the value of P_g at 10 % accuracy level can be easily increased by orders of magnitude since according to (3) t_q grows proportionally to N. Instead, for classical com putations, the num ber of required orbits M will increase exponentially (P 1=M). This dem onstrates that quantum com putations of exponential relaxation processes are much more e cient than classical simulations with large number of orbits. The possibility to e ciently compute the quantum probability $P_{\rm q}$ (t) up to very long times $t_{\rm q}>>~1=$, allow s to num erically estim ate the measure of the integrable component

in the phase space of the classical system . Indeed, for > 0, the existence of integrable islands leads to an asymptotic power law decay of correlations P (t) / t^{0:5} [13]. Since in our num erical data the quantum probability decays exponentially up to $P_q(t_q) = 5 - 1b^2$ we assume that the measure of the integrable component is $< P_q(t_q) = 5 - 1b^2$ (1 0:1) being much smaller

than the relative size of quantum cell 1=N . Here, the error bar gives the average $\,$ uctuation of P $_q$ (t $_q$ = 254) obtained for 77 values of N .

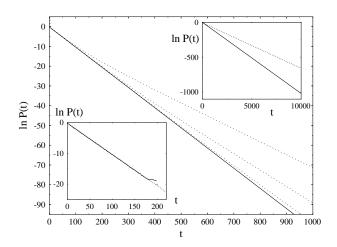

A lso it is interesting to note that the Ehrenfest time scale t_E is much smaller than the quantum relaxation $\ln N = \overline{N} << 1$. For example for $time t_q: t_E = t_q$ N = 1:3150 we have $t_{\alpha} = 254$ while $t_{E} = \ln N =$ 9:4 ln K =2 1:25). This shows that the agree-(m ent between quantum and classical relaxation continues for a time scale which is much larger than the time of wave packet spreading. However, for $t > t_E$ there is no exponential instability in the quantum motion [6,14]. As a result, correlation functions of the type C() = hsin (t) sin (t+)iw hich, in the regime of strong chaos, decay exponentially in the classical case (In t j), in the quantum case decay only during the E hrenfest time lnN (ŧ scale up to ln jC j t_c). This is sim ilar to what happens in closed (unitary) systems such as the kicked rotator [14]. This example shows that exponential relaxation is not necessary related to exponential local instability and positive Kolm ogorov-Sinai entropy.

A fier the submission of this paper the scale t_q has been obtained on the basis of random matrix theory and supersymmetry for kicked rotator with random phases [15]. The related results for pre-localized states in closed systems were discussed in [16].

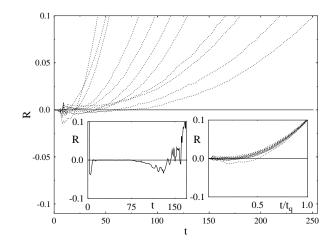

FIG.1. Classical and quantum probability decay for K = 7 and N = k = 4. The full line shows the t to the classical decay. D otted lines give the quantum probability P_q (t) for N = 5001;20001;130001 (upper, m iddle and lower curves respectively). The lower insert shows the classical probability actually computed from M = 9 10 orbits and the t is shown by the dotted line. The upper insert shows the classical (full line) and the quantum (dotted line) asymptotic decay for N = 5001.

FIG.3. The average ratio R (t) = hh ($P_q(t)=P(t)$)i as a function of time for di erent N from N = 2500 (left curve) to N = 129500 (right curve). The horizontal full line corresponds to $P_q(t) = P(t)$. The probability P(t) is given by numerical data obtained with M = 9 10 orbits for t 70 and by the t from Fig.1 (see text) for t > 70. The left insert shows the ratio of the numerically computed classical probability P(t) to the t function. The deviations from the t, for t > 70, are due to statistical errors related to nite M. The right insert demonstrates the scaling behaviour of $P_q(t)$ on the variable t=t_q where the t_q values are determined by condition R (t_q) = 0:1.

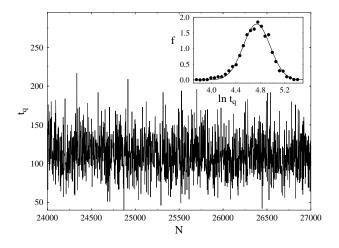

FIG.2. Mesoscopic uctuations of the quantum relaxation time t_q for di erent system sizes N. The insert shows the statistical distribution of uctuations fwhich is close to a log norm all distribution of width 0.22.

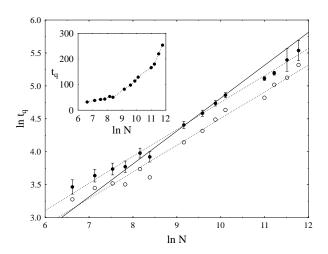

FIG.4. Dependence of the quantum relaxation time $t_{\rm q}$ on the system size N = gt_c in logarithm ic scale. Points refers to 10 % deviation level (R = 0:1) while circles refer to 5% deviation (R = 0:05). The two dotted lines give the t $t_{\rm q}$ = 1:9N $^{0:41}$ and $t_{\rm q}$ = 1:5N $^{0:41}$ respectively. The full line gives the theoretical prediction with = 1=2 (3). The insert shows the 10 % data in a semilog scale.
