Theoretical design of global optimization algorithms can profitably utilize recent statistical mechanical treatments of potential energy surfaces (PES's). Here we analyze a particular method to explain its success in locating global minima on surfaces with a multiple-funnel structure, where trapping in local minima with different morphologies is expected. We find that a key factor in overcoming trapping is the transformation applied to the PES which broadens the thermodynamic transitions. The global minimum then has a significant probability of occupation at temperatures where the free energy barriers between funnels are summable.

Global optimization is a subject of intense current interest, since better optimization techniques can produce cost reductions and greater efficiency. It is therefore important to understand the key requirements for a successful global optimization method, rather than proceeding on purely empirical or intuitive grounds.

One of the difficulties associated with global optimization is the exponential increase in the search space with system size. For example, the number of possible conformations of a typical protein is so large that it would take longer than the age of the universe to find the native state if the conformations were sampled randomly (Levinthal's paradox [1]). This problem can be more rigorously defined using computational complexity theory; finding the global minimum of a protein [2] or a cluster [3] is NP-hard.

In fact, it is easy to design surfaces that result in efficient relaxation to the global minimum, despite very large configurational spaces [4,6]. Such surfaces are characterized by a single deep funnel [7] leading to the global minimum, and this feature may underlie the ability of a protein to fold to the native state [8,9].

Hence, global optimization methods should find surfaces with a single funnel relatively easy to tackle. The problem is significantly harder if there is more than one funnel, since there are then competing relaxation pathways. The extreme case would be when a funnel that does not lead to the global minimum is thermodynamically favoured down to low temperatures. On cooling the system would probably be trapped in the secondary funnel. This explains why naive simulated annealing will often fail. A number of atomic clusters bound by the Lennard-Jones (LJ) potential exhibit surfaces with just such a topography. In this paper we examine in detail one such case, an LJ cluster with 38 atoms, to show how a recently-developed global optimization method is able to overcome trapping. Our results indicate some necessary conditions the algorithm must satisfy if it is to succeed when applied to PES's with multiple funnels.

Most small LJ clusters have global minimum based upon Mackay icosahedra [10]. However, for 38 atoms the global minimum is a face-centred cubic (fcc) truncated octahedron (Figure), and for 75, 77 and 102 the global minimum are based on Marks' decahedra [11]. These minima were initially discovered by construction [12,13], and until our recent application of a 'basin-hopping' algorithm [14] only the LJ_{38} global minimum had been found by an unbiased global optimization method.

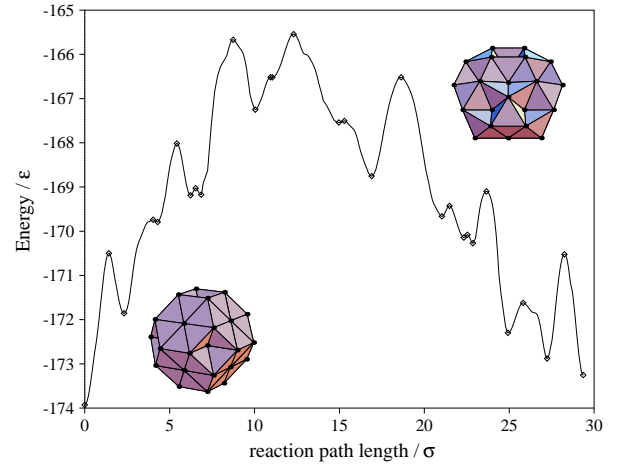

FIG. 1. Energy profile of a pathway between the two lowest energy minima of LJ_{38} , namely the fcc truncated octahedron (bottom left) and a structure based on the Marks' decahedron with C_{5v} point group symmetry (top right). $2^{1/6}$ is the equilibrium pair separation of the LJ potential. The method by which this pathway was obtained is described in Ref. [15].

The multiple-funnel character of the LJ_{38} PES is revealed in the energy profile of a pathway between the fcc global minimum and the lowest energy icosahedral minimum (Figure) [15]. Maxima on this pathway correspond to true transition states (stationary points with a single negative Hessian eigenvalue), and the segments linking maxima and minima are approximate steepest descent

paths. The two lowest energy minima are well separated in conformation space, and to cross the barrier between them the cluster must pass through high energy minima associated with the liquid-like state of the cluster. Transitions between the fcc and icosahedral regions of conformation space can only occur if the high energy 'liquid-like' minima have a significant probability of being occupied. At low temperatures the Boltzmann weights for these intermediate states are small leading to a large free energy barrier between the two regions.

FIG. 2. Equilibrium thermodynamic properties of the untransformed LJ_{38} PES. (a) The probability of the cluster being in the fcc, icosahedral and 'liquid-like' regions of bound conformation space. (b) The heat capacity, C_v . These results were obtained by summing the anharmonic partition functions for a sample of minima appropriately weighted to compensate for the incompleteness of the sample [16]. The liquid-like region of conformation space is defined as those minima with $E > -171.6$.

Some of the equilibrium thermodynamic properties of LJ_{38} are shown in Figure . There is only a small energy difference between the global minimum and the lowest energy icosahedral minimum. However, the entropy associated with the icosahedral structures is larger and icosahedra become favoured at low temperature. The centre of this transition is at a temperature of $0.12 k^{-1}$ (ϵ is the pair well depth of the LJ potential and k is the Boltzmann constant); it gives rise to the small peak in

the heat capacity (Figure b). The finite-size analogue of the bulk melting transition occurs at $0.18 k^{-1}$, producing them a peak in the heat capacity. These transitions are also reflected in the occupation probabilities for the different 'phases' (Figure a).

At low temperatures one observes the cluster trapped in either the fcc or icosahedral funnels, because of the large free energy barrier between them. On cooling from the liquid-like state, there is a thermodynamic driving force for entering the icosahedral region of conformation space. This effect is exacerbated by the topography of the PES. The structure of simple atomic liquids has significant polytetrahedral character [17,18], and relaxation into the icosahedral funnel is more likely because icosahedra have more polytetrahedral character than the fcc structures. Hence, the icosahedral funnel is directly connected to the low energy liquid-like states, whereas the fcc funnel is only connected to the high energy liquid-like states. Therefore, it is extremely probable that the system will enter the icosahedral funnel on cooling and there become trapped.

To observe the truncated octahedron we must simulate the cluster in the small temperature window where both the high energy liquid-like minima and the fcc structures have small, but significant, probabilities of being occupied. Indeed, we did observe the truncated octahedron in this temperature range, but only once in regular quenches from a 0.25 s simulation for Ar. The situation for the larger clusters with non-icosahedral global minima is even worse. The decahedral to icosahedral transition is sharper and lies even further below the melting transition than for LJ_{38} (e.g. for LJ_{75} it occurs at $T = 0.09 k^{-1}$).

The global optimization method that we analyze here belongs to the family of hypersurface deformation methods [19]. In this approach the energy function is transformed, usually to a smoother surface with fewer minima. The lowest minimum of this new surface is then mapped back to the original surface, but there is no guarantee that the global minimum on the two surfaces are related and often there are good reasons to think that they are not [12]. In contrast, the transformation that we apply is guaranteed to preserve the global minimum. The transformed energy E' is defined by:

$$E'(X) = \min_f E(X)g; \quad (1)$$

where X represents the vector of nuclear coordinates and \min_f signifies that an energy minimization is performed starting from X .

The above approach is very similar to Li and Scheraga's Monte Carlo (MC) minimization [20]. In our recent application to LJ clusters it has outperformed all other methods in the literature, finding all the known lowest energy LJ clusters up to 110 atoms, including those with non-icosahedral global minima [14]. The method we use

to explore the E^* surface is simply a canonical MC simulation at constant temperature, in this case 0.8 k^{-1} . Interestingly, the other methods that have been most successful for LJ clusters are genetic algorithms [21,22] which use minimization to refine the new coordinates generated at each step, thus in effect performing a search on the same transformed surface, E^* .

FIG. 3. Equilibrium thermodynamic properties of the transformed LJ_{38} PES. (a) The probability of the cluster being in the fcc, icosahedral and ‘liquid-like’ regions of bound conformation space. (b) The configurational component of the heat capacity.

The topography of the transformed surface is that of a multidimensional staircase with each step corresponding to the basin of attraction surrounding a minimum. The transformation has a significant effect on the dynamics. Not only are transitions to a lower energy minimum barrierless, but they can also occur at any point along the boundary between basins of attraction, whereas on the untransformed surface transitions can occur only when the system passes along the transition state valley. As a result intrawell vibrational motion is removed and the system can hop directly between minima at each step.

However, the increase in interbasin transitions will not necessarily aid the location of the global minimum on a multiple-funnel PES unless the transformation also changes the thermodynamics. For LJ_{38} the probability of

the system occupying the intermediate states between the funnels must be non-negligible under conditions where the icosahedral and fcc structures also have significant occupation probabilities. This is indeed what is observed for the E^* surface (Figure 3). The transitions have been smeared out and there is now only one broad peak in the heat capacity. Most significantly, the probability that the system is in the basin of attraction of the global minimum decays much more slowly, and the temperature range for which both the high energy liquid-like minima and the global minimum have significant probabilities is large. MC simulations anywhere in this temperature range easily locate the global minimum from a random starting point. Furthermore, the E^* transformation opens up new paths between the two lowest energy minima because atoms are now able to pass through one another. Such paths would obviously not be feasible on the untransformed PES. Consequently, even at $T = 0.2 \text{ k}^{-1}$ the cluster can escape from the icosahedral region of the transformed surface.

We can understand the different thermodynamics for the two surfaces by writing the partition function as a sum over all the geometrically distinct minima on the PES. On the untransformed surface this gives for p_s , the probability that the cluster is in minimum s ,

$$p_s = \frac{n_s \exp(-E_s / kT)}{\sum_s n_s \exp(-E_s / kT)} \quad (2)$$

where $kT = 1/kT$, N is the number of atoms, $\bar{\omega}_s$ is the geometric mean vibrational frequency of minimum s (calculated by diagonalizing the Hessian matrix), n_s is the number of permutational isomers of minimum s and is given by $n_s = 2N! / h_s$, where h_s is the order of the point group of minimum s . This equation is only approximate since it assumes that each well is harmonic. However, it does give a qualitatively correct picture of the thermodynamics [23], and although anharmonic corrections can be found [16] they are rather cumbersome. For the transformed surface

$$p_s = \frac{n_s A_s \exp(-E_s / kT)}{\sum_s n_s A_s \exp(-E_s / kT)} \quad (3)$$

where A_s is the hyperarea on the PES for which minimization leads to minimum s . The A_s values depend upon the available nuclear conformation space, which must be bounded to prevent evaporation. We have considered both placing the cluster in a container and restricting the conformation space to hyperspheres around each local minimum by setting the coordinates to those of the relevant minimum in the Markov chain. Similar results are obtained for appropriate choices of container and hypersphere radii; the A_s values reported below and the results in reference [14] were obtained by resetting the coordinates.

Expressions (2) and (3) differ only in the vibrational frequency and A_s terms. The fcc to icosahedral and the

icosahedral to liquid transitions are caused by the greater number of minima associated with the higher temperature state, which leads to a larger entropy. On the untransformed surface this effect is reinforced by the decrease in the mean vibrational frequencies with increasing potential energy, $\overline{\omega}_{\text{fcc}} : \overline{\omega}_{\text{icos}} : \overline{\omega}_{\text{liquid}} = 1 : 0.968 : 0.864$. Although these differences may seem small, when raised to the power $3N \approx 6$ they increase the entropy of the higher energy states significantly, sharpening the transitions and lowering the temperature at which they occur. In contrast, A_s decreases rapidly with increasing potential energy, $A_{\text{fcc}} : A_{\text{icos}} : A_{\text{liquid}} = 1 : 0.0488 : 0.00122$. These values were obtained by inversion of the occupation probabilities obtained in MC runs of up to 10^6 steps. The decrease in A_s reduces the entropy of the higher energy states, causing the transitions to be broadened and the temperature at which they occur to increase.

We can now explain in detail why the basin-hopping method is successful. First, the staircase transformation removes the barriers between minima on the PES without changing the identity of the global minimum, accelerating the dynamics. Second, it changes the thermodynamics of the surface, broadening the transitions so that even for a multiple-funnel surface such as that of LJ_{38} , the global minimum has a significant probability of occupation at temperatures where the free energy barrier for passage between the funnels is sumountable.

It is this latter feature which is especially important in overcoming the difficulties associated with multiple funnels and represents a new criterion for designing successful global optimization methods.

The broadened transition that results from the transformation also differs markedly from the optimum conditions for protein folding, if we assume that proteins have evolved single-funnel surfaces in order to fold efficiently. A steep funnel provides a large thermodynamic driving force for relaxation to the global minimum [6,9], and also leads to a sharp thermodynamic transition. However, in global optimizations one cannot make assumptions about the topography of the PES and on a multiple-funnel surface such features can exacerbate the difficulties associated with trapping in secondary funnels [6].

Moreover, in protein folding there is the extra requirement that the folded protein must remain localized in the native state, and this necessitates a sharp transition. There is no need for a global optimization method to mimic this property. Indeed, when applied to a PES with multiple funnels the optimum temperature for the basin-hopping approach is above the transition, where the system only spends a minority of its time in the global minimum.

We have tested the basin-hopping method on a number of other systems, and its performance is equally impressive. For example, it succeeds in finding the global minimum for clusters bound by short range Morse potentials, which have much rougher energy landscapes than

LJ clusters [12]. We have also obtained results for water, metal and silicon clusters which are helping to interpret experimental results.
