# Lim it cycles of a perceptron 

M . Schroder and W . K inzel<br>Institut fur Theoretische Physik, Universitat W urzburg, Am Hubland, D-97074 W urzburg

#### Abstract

A n arti cialneural netw ork can be used to generate a series of num bers. A boolean perceptron generates bit sequences with a periodic structure. The corresponding spectrum of cycle lengths is investigated analytically and num erically; it has sim ilarities $w$ ith properties of rational num bers.

In the last fteen years $m$ odels and $m$ ethods of statistical physics have successfully been used to understand em ergent com putation of neural netw orks. Several properties of in nitely large attractor and multilayer networks could be calculated analytically. Such system s of sim ple units interacting by synaptic weights can be used as associative $m$ em ory and classi ers; they are trained by a set of exam ples, detect unknown rules and structures in high \{dim ensional data, and store pattems in a distributed and content addressable way (H ertz et al 1991, W atkin et al 1993, O pper and K inzel 1996).

A nother im portant application of neural netw orks is tim e series analysis (W eigand 1993). But only recently statistical physics has been used to model training and prediction ofbit sequences by a perceptron (E isenstein et al 1995, Schroder et al 1996). A neural network is trained by a sequence of num bers; after the training phase the netw ork $m$ akes predictions on the rest of the sequence. In analogy to generalization the training and test data are generated by a neural netw ork, as well. It tums out that the generation of sequences of num bers by a perceptron or m ultilayer netw ork is already an interesting problem which should be understood before prediction is investigated (E isenstein et al 1995, K anter et al 1995).

This problem is a special case of the neuronic equations of C aianiello (1961). These equations, which were suggested to $m$ odela neuron inchuding tim e dependency, can only be solved in special cases. M ost work was done for one input and a $m$ em ory badk into tim ew ith couplings that decrease exponentially $w_{i}=a^{i}(a<1)$. Several analytic results for the transients and the lim it cycles of the resulting dynam ics have been achieved for this case (for exam ple C aianiello and Luca 1965 or C osnard et al 1988). O nly few work has been done for other weights (for exam ple Cosnard et al 1988b and 1992). Our $m$ otivation for studying this recursion equation is to exam ine the generalization ability
and in a rst step the ability of a perceptron to generate tim e series. H ence we have no restrictions on the weight vector a priori.

N um erical analysis of a perceptron with random weights generating sequences of num bers show $s$ that the sequences are related to the Fourierm odes of the w eight vector. Therefore it is usefiul to study weight vectors $w$ ith a single $m$ ode only. In this case an analytic solution of a stationary sequence could be derived for large frequencies ( $K$ anter et al 1995).

This solution holds for continuous odd transfer functions, for exam ple tanh ( $x$ ). A s a function of the slope a phase transition to a nonzero sequence occurs. The phase of the weight vector results in a frequency shiff of the attractor. In this letter we want to extend this solution to in nite slope and general frequencies, that is we derive an analytic solution for the bit generator. W e nd a much richer structure of the bit sequences generated by a boolean perceptron com pared to sequences of continuous ones.

A bit generator ( gure 1) is de ned by the equation

$$
\begin{equation*}
S=\operatorname{sign}{ }_{j=1}^{x^{N}} w_{j} S \quad(2 f N ; N+1 ; N+2 ;::: g) \tag{1}
\end{equation*}
$$

where the $S 2 \mathrm{f}+1$; 1 g is a bit of the sequence ( $\mathrm{S}_{0} ; \mathrm{S}_{1} ; \mathrm{S}_{2} ; \mathrm{S}_{3} ;::$ :) and $\mathrm{w} 2 \mathrm{R}^{\mathrm{N}}$ is the weight vector of the perceptron of size $N$. A sm entioned, it is useful to restrict the weights to one single $m$ ode.

$$
\begin{equation*}
w_{j}=\cos \left(2 q \frac{j}{N}+\quad\right) \tag{2}
\end{equation*}
$$

where $q 2 \mathrm{~N}$ is the frequency and $2[0 ; 1[$ is the phase of the weights. $G$ iven an initial state ( $\mathrm{S}_{0} ;::: ; \mathrm{S}_{\mathrm{N}}{ }_{1}$ ) equation (1) de nes a sequence ( $\mathrm{S}_{\mathrm{N}} ; \mathrm{S}_{\mathrm{N}+1} ;:::$ ) which has to run into a periodic cycle of length $L$ 2.$W$ etry to nd an analytic solution of the periodic attractor.

Equation (1) m ay be expressed in term s of the local elds $h=\frac{1}{N}^{P}{ }_{j=1}^{N} W_{j} S \quad j$ :

$$
h=\frac{1}{N}_{j=1}^{\mathrm{N}^{N}} \cos 2 q \frac{j}{N}+\quad \operatorname{sign}\left(\begin{array}{ll} 
& j \tag{3}
\end{array}\right):
$$

W e have to solve this self-consistent equation for the function $h$. Since sim ulations show that lim it cycles are dom inated by one frequency, we assume sign (h) is a periodically altemating step function $w$ ith frequency $k+$ (w th $k 2 \mathrm{~N}$; $2[0 ; 1 \mathrm{D}$, where the frequency is de ned for the variable $=\mathrm{N}$ :

$$
\begin{equation*}
\operatorname{sign}(h)=\operatorname{sign}\left(\sin \left(2 \frac{(k+\quad)}{N}\right)\right): \tag{4}
\end{equation*}
$$

In the case that $N$ is a multiple of $2(k+\quad)$, i.e. for integer wavelengths, we found an analytic solution of equation (1).W ith this ansatz the right hand side of equation (了)
is a periodic function $w$ ith a period of length $N=(k+\quad)$ and $h=h_{+N=(2(k+))}$ for 2 f0; :: : : $\frac{\mathrm{N}}{2(\mathrm{k}+)} \quad 1 \mathrm{~g}$. O urm ain result is

$$
\begin{align*}
& h=\frac{1}{N \sin \left(\frac{q}{N}\right)} \frac{\sin \left(\frac{1}{2}(T+1)\left(\frac{q}{k+}+\right)\right)}{\cos \left(\frac{q}{2(k+)}\right)} \sin \left(2 \frac{q}{N}+\quad+\frac{T}{2}\left(\frac{q}{k+}+\right)+\frac{q}{N}\right) \\
& \geqslant 0  \tag{5}\\
& \text { for } T \text { odd } \\
& \geqslant+\frac{2}{N} \cos (\quad)+\frac{\sin \left(\frac{q}{N}\right)}{N \sin \left(\frac{q}{N}\right)} \\
& \text { for } T \text { even }:
\end{align*}
$$

where we have abbreviated $T=[(k+)(2 \quad 2=N)]$ using the $G$ aussian bracket $\mathbb{x}]$ that denotes the closest integer less than x . For $==0$ and $\mathrm{k}=\mathrm{q}$ this results in

$$
\begin{equation*}
h=\frac{2 k}{N \sin \left(\frac{k}{N}\right)} \sin \left(\frac{2 k}{N}+\frac{k}{N}\right) \tag{6}
\end{equation*}
$$

A sample function isplotted in gure 2. N ote that it consists of tw o parts w the the sam e frequency $q$. In the lim it N ! 1 these parts are connected continuously. Equation ( gives the condition

$$
\begin{equation*}
h \quad 0 \quad 2 \text { f0;:::: } \frac{N}{2(k+)} \quad \lg \tag{7}
\end{equation*}
$$

Figure 3 shows the possible frequencies that satisfy condition $\left(\bar{T}_{1}\right)$ within our ansatz. Only values of $\mathrm{k}+=\mathrm{N}=(2 i) \mathrm{w}$ ith integers $i$ are possible w th our ansatz.

For N! 1 a necessary condition for equation ( $\bar{i}_{1}$ ) is $h_{0}=0$. Fork $q$ this is su cient so the nontrivial ( $\left.\begin{array}{lll}\mathrm{l} & 6 & 0\end{array}\right)$ solutions are given by the values of $; k$ that fulll the equation $\sin (+(2 k+1)(q=(2(k+))+=2))=0$ which is equivalent to $q(2 k+1)=(k+)\left(\begin{array}{lll}2 z & 2 & 1) \\ w\end{array}\right.$ th an integer $z$. The frequencies $k+$ that are allowed from this condition are shown in gure 3, too.

We see that the analytic solution of the sequence generator with a continuous transfer function ( $K$ anter et al 1995) cannot just be extrapolated to the case of the bit generator. The continuous generator, close to the transition point and for k 1, hask $=q$ and $=$,whereaswe nd a spectrum ofsolutionswith $k \quad q$ and ( $q$; ;k), as shown in gure 3 .

Up to now we have considered only integer wavelengths. N ow we want to discuss the general case of arbitrary values of $q$ and . W ewant to address the tw o questions:
(i) D o additional solutions consisting of one frequency exist?
(ii) W hat are the properties of the bit sequences?
$W$ e assum e that there are solutions of the form ( $(\underset{i}{4})$ ) w ith general frequencies $k+$ for a given system size N. A s a function ofq+ we num erically scan the output frequency
$k+$ and determ ine the frequency of the lim it cycle when the system was started w ith a sequence of frequency $k+$. Som e of these initial states stay at stable states $w$ ith alm ost the same frequency. Other ones run to the lowest branch ( $k=q$ ). Random initial states lead to the lowest branch w ith a very hight probability. Figure 3 show $s$ that the results of this sim ulation are in agreem ent with the extension of our equations $(\underline{\underline{G}})$ and ( $\overline{(1}_{1}$ ) to general $k+$ which leads to allowed regions for for $q+$ as a function of $k+$. For the lowest branch $k=q$ the phase of the weights results in a frequency shift of the bit sequence, with for $q 1$ sim ilar to the continuous case.
$T$ he next problem is to understand the length $L$ of the stationary cycle generated by the nite bit generator $w$ ith one frequency in the couplings and a random initial vector. W e consider the case $\mathrm{q}=\mathrm{k}$, only. Figure 5 show $s$ the results of a num erical calculation of Equation (1) for $\mathrm{N}=1024$. Obviously L has a ridh structure as the function of the phase of the weights. For $0 \quad \frac{1}{2}$ each cycle has only one $m$ axim um in the Fourier spectrum w th frequency $q+$ ( ). The num erical results show that in this case $L$ is lim ited to the value 2 N . Each value of L belongs to a whole interval in the \{axis, but only to a single value of . Hence, the function ( ) has a step like structure; is locked at rational num bers as shown in $F$ igure 6 . The size of the steps decreases with increasing $N$ and $r$.

C an this structure ofL ( ) be understood from the extension of the analytic solution Equation ( $(-)$ ). ? For arbitrary values of the sequence $S_{1}$ is quasi-periodic, in generalw ith an in nite period L. H ow ever, if $k+\quad$ is rational, $k+\quad=r=s w$ ith integers $r$ and $s$ which are relatively prim $e$, then the period $L$ is given by the num erator of $\mathrm{N} s=r$. This m eans, that $L$ is the $s m$ allest $m$ ultiple of the w avelength $N=(k+\quad)$ that is an integer. In fact, in F igure 5 we have plotted allofthese values ofL forq+ $=r=s$ and $L<2 \mathrm{~N}$. For $\mathrm{L}<\mathrm{N}$ allof these L values correspond to a cycle of the bit generator. ForN < L < 2N the bit generator produces only even values of $L$ whereas the analytic argum ent gives all integers L .

For $\frac{1}{2} \ll 1$ the bit-generator essentially produces the sam e structure of L values as for $0 \ll \frac{1}{2}$. However, there are alw ays a few solutions which are mixtures of severalm odes $\mathrm{k}_{1}+1$ and $\mathrm{k}_{2}+\quad$, and which yield periodswith $\mathrm{L}>2 \mathrm{~N}$. For $0 \ll \frac{1}{2}$ we never observed such $m$ ixtures ofm odes.

A sa side rem ark we notige that the structure ofL ( $q+\quad$ ) is essentially determ ined by properties of rational num bers, which $m$ ight be discussed in high schoolm athem atics. If the num erator $p$ is $p l o t t e d$ for each rational num ber $x=p=r$ in the unit interval, we obtain Figure 7 ( $r<800$ ). H enœ, above eadh rational num ber $p=r$ a roof opens below which no other values of pappear. Each roof has the form $1=j \quad r x j$. Low values of $r$ have a wide roof. These results, which detem ine the structure of the cycle lengths of the bit generator, $m$ ay be well know $n$ in num ber theory and nonlinear dynam ics (circle m ap, winding num ber), but they have skipped our attention so far.

The upper bound of the cycle length $L$ of 2 N can be understood as follow s. The analytic solution ( sequences with in nite cycle lengths $L=1$ for irrational $k+$. However, each cycle length has to be lim ited by the number of input strings for the determ inistic bit generator, Equation ( $\underline{I}_{1}^{1}$ ), which gives $L<2^{N}$. The last argum ent opens a
 $\left(\mathrm{S}_{0} ; \mathrm{S}_{1} ;::: ; \mathrm{S}_{\mathrm{N}}{ }_{1}\right)$ given by the equation $(\underset{-1}{(5)})$, of the analytic solution. If a bit generator tries to follow this solution it can do so only if each input string ( $\mathrm{S}_{1} ; \mathrm{S}_{1+1} ;::: ; \mathrm{S}_{1+\mathrm{N}} \quad 1$ ) has not occurred before. H ence, the rst appearance of a previous sequence

$$
\begin{equation*}
\left(\mathrm{S}_{1} ; \mathrm{S}_{1+1} ;::: ; \mathrm{S}_{1+\mathrm{N}}\right)=\left(\mathrm{S}_{1+\mathrm{L}} ; \mathrm{S}_{1+\mathrm{L}+1} ;::: ; \mathrm{S}_{1+\mathrm{L}+\mathrm{N}} \quad 1\right) \tag{8}
\end{equation*}
$$

de nes a length $L$ of a cycle.
M ore insight can be achieved by exam ining the continued fraction expansion of $2(k+)=\mathrm{N}$ :

$$
\begin{equation*}
2 \frac{k+}{N}=\frac{1}{a_{1}+\frac{1}{a_{2}+\frac{1}{a_{3}+:!:}}} ; \quad a_{i} 2 \mathrm{~N} \tag{9}
\end{equation*}
$$

$W$ e de ne the expansion to order $i$ to be $s_{i}$ and $l_{i}$ to be the denom inators the $s_{i}$ :

$$
\begin{align*}
\mathrm{s}_{0} & =0 & l_{0} & =1 \\
\mathrm{~s}_{1} & =\frac{1}{a_{1}} & l_{1} & =a_{1} \\
\mathrm{~s}_{2} & =\frac{1}{a_{1}+\frac{1}{a_{2}}} & l_{2} & =a_{1} a_{2}+1 \\
\mathrm{~s}_{3} & =\frac{1}{a_{1}+\frac{1}{a_{2}+\frac{1}{a_{3}}}} & l_{3} & =\left(a_{1} a_{2}+1\right) a_{3}+a_{1}  \tag{10}\\
& \vdots & \vdots & \\
& & l_{i} & =a_{i} l_{i}+l_{i 2}
\end{align*}
$$

If $2(k+)=N$ is of the form $S_{1}=1=a_{1}$ the length $L$ of the cycles as a function of $N$ can be given easily:

$$
L=\begin{array}{ll}
<1 & \text { for } N<a_{1}  \tag{11}\\
: 2 a_{1} & \text { for } N
\end{array}
$$

Is is obviously lim ted by 2 N .
For general $2(\mathrm{k}+\quad)=\mathrm{N}$ the continued fraction expansion reveals a hierarchy of of \defects", each having a period of $l_{i}$, in the periodic structure of the resulting sequence. $T$ his leads to the the fact that for any length scale introduced by $N$, two identical subsequences of length N w th a distance less than 2 N can be found.

A s a consequence the perceptron locks, for a given frequency $k+$, in cycles that correspond to frequencies given by the continued fraction expansion of $2(\mathrm{k}+\quad)=\mathrm{N}$, truncated at a certain depth. This explains the steps in gure 6.

Finally we point out sim ilarities to the case of bit generators w ith exponentially decaying weights and additionalbias (C osnard et al 1988). In this case one nds cycles which are lim ited by $\mathrm{N}+1$. All of the cycles can be classi ed by rational num bers $\mathrm{r}=\mathrm{L}$ where $L$ is the length of the cycle, $L \quad N+1$ and $r$ is the num ber of positive bits in the cycle.

In sum m ary, we have obtained an analytic solution for the cycles of a bit-generator w ith periodic weight vectors. We found a whole spectrum of periodic attractors; the frequencies $k+$ depend in a com plex way on the frequency $q$ and phase of the weight vector of the perceptron.

Num erical sim ulations showed that the bit sequences relax into cycles with lengths L , which are sm aller than 2 N . The structure ofL as a function ofk+ hasbeen analyzed in term s of num ber theory. A $n$ analytic solution was given for certain frequencies; the extension to the $m$ easured frequencies results in a sim ilar structure of cycles.
