(April 15, 2024)

We study the spin-1 chain with nearest neighbor couplings that are rotationally invariant, but include both Heisenberg and biquadratic exchange, with random strengths. We demonstrate, using perturbative renorm alization group m ethods as well as exact diagonalization of clusters, that the system generates ferrom agnetic couplings under certain circum stances even when all the bare couplings are antiferrom agnetic. This disorder induced instability leads to form ation of large m agnetic m oments at low temperatures, and is a purely quantum m echanicale ect that does not have a classical counterpart. The physical origin of this instability, as well as its consequences, are discussed.

Pacs: 75.10 J, 75.30 H, 75.50 E

Classical spin models have been studied extensively over the past half century. The inclusion of quantum mechanical nature of the spin variables result usually in quantitative e ects such as renorm alization of transition tem peratures, order param eter in the ordered phase, spin wave velocity, etc. How ever, it began to be realized about two decades back that quantum uctuations could result in qualitative changes such as the nature of the phase itself. M a et al. [1] showed that in a spin-1/2 chain with nearest neighbor antiferrom agnetic Heisenberg interactions of random strength, quantum uctuations lead to a divergent density of excitations at low energy scales even in the absence of such divergence in the distribution of bare couplings. A round the same time, Bhatt and Lee [2] independently showed that this occurs for highly disordered spin-1/2 antiferrom agnets with short range interactions in higher dimensions as well, and that this phenom enon is a purely quantum mechanical e ect [3]. A few years later, Haldane [4] showed that the uniform integer spin chains with antiferrom agnetic H eisenberg interactions exhibited a gap, and concom itant short-range spin-spin correlations in the ground state, in contrast with the half integer as well as classical spin chains. The Haldane gap, which scales as exp (S) with the spin S, is also a purely quantum mechanicale ect, unobtainable from the classical (S ! 1) lim it, where it appears as an essential singularity. In the past few years, studies of the quantum Ising model in a transverse eld in one, two and three dimensions [5,6] as well as Heisenberg spin chains [7{9] with random ness, have dem onstrated that the ground state (T = 0) phase diagram includes a G rifths phase with divergent response functions due to rare

uctuations. Thus, electronic systems in the quantum regime display a richer variety of phenomena resulting from the interplay between correlation and disorder, than is usual for classical systems.

In this paper, we describe another phenom enon occurring in spin-chains as a purely quantum mechanicale ect - namely, the generation of ferrom agnetic (F) couplings, and consequently large m om ents leading to a Curie susceptibility at low tem peratures, in a spin-1 chain with isotropic but random antiferrom agnetic (AF) couplings. Though the generated m om ents becom e arbitrarily large in the low tem perature limit, the phenom enon of the generation of ferrom agnetic couplings relies on a purely quantum m echanical e ect, and has no classical analog.

For the random spin-1/2 chain with near neighbor AF interactions, F isher [10] show ed that the real space renormalization group (RG) scheme [1,2] becomes asymptotically exact, and leads to a \random singlet" phase, where distant pairs of spins form singlets in a hierarchical manner dependent on the realization of the random bonds, and dom inate the low energy physics. In the presence of random ly placed ferrom agnetic couplings of arbitrary concentration, how ever, W esterberg et al. [11] show ed that the random singlet phase is destroyed in one-dimension due to the form ation of large moments by active, ferrom agnetically coupled spins, and the magnetic susceptibility at asymptotically low temperature assumes a pure Curie (1=T) form, right upto the ferrom agnetic bonds.

For a spin-1/2 system, spin rotational symmetry uniquely constrains the coupling between spins to be the Heisenberg form [12], JS_i §. For spins with S > 1=2, how ever, them ost general form of isotropic coupling between spins i and j with spin rotational invariance may be written in powers of the Heisenberg form : $H_{ij} = \int_{n=1}^{2S} J^{(n)}(S_i) S^n$: For the random spin-1 chain with nearest neighbor couplings, this in plies a Ham iltonian written m ost generally as:

$$H = \begin{bmatrix} X & [J_{i}S_{i} & S_{1} + D_{i}(S_{i} & S_{1})^{2}] \\ X & \stackrel{i}{q} \\ J_{i}^{2} + D_{i}^{2} [\cos_{i}S_{i} & S_{1} + \sin_{i}(S_{i} & S_{1})^{2}]; (1) \end{bmatrix}$$

where the J's and D's are uncorrelated random variables.

W ith purely Heisenberg couplings, it was showed [8] that as long as there are no F bonds in the bare Ham il-

tonian, the system cannot be in the pure C urie param agnetic phase. In this paper we show that this is no longer the case when biguadratic couplings are present [13].

W ith no random ness (i.e. $J_i = J_i D_i = D$), the properties of the Hamiltonian of Eq. (2) is controlled by the angular variable satisfying $\tan = D = J$. There exist four di erent phases (see Fig. 1). For =2 < < 5 =4, each individual bond favors a total spin $S_{tot} = 2$ state for the pair it connects, and the ground state of the entire chain is the spin fully polarized ferrom agnetic state. For < =4 the system is in the Haldane gapped =4 < phase [4]. For 3 =4 < < =4 the chain is spontaneously dimerized [14], while an extended gapless phase < =2 [15]. has been predicted in the region =4 <Except for the ferrom agnetic phase, the other phases all have singlet ground states with unbroken spin-rotationalsym metry, and we therefore refer to bonds in this region as antiferrom agnetic.

In the presence of strong random ness, the system m ay be studied using a hierarchical real space RG approach. We search for the bond in the system with the largest gap separating its ground state and low est energy excited state, say the bond coupling spins 2 and 3, with coupling constants J_2 and D_2 (see Fig. 2a). If the ground state of this bond is a singlet ($3 = 4 < 2 < \arctan \frac{1}{3}$), then spins 2 and 3 form an inert singlet in the low-energy states of the system, and mediate elective couplings between their neighboring spins 1 and 4, which may be calculated using second order perturbation theory [16]:

$$J_{14}^{*} = \frac{(2J_{1} \quad D_{1})(2J_{3} \quad D_{3})}{3(J_{2} \quad 3D_{2})} \quad \frac{D_{1}D_{3}}{9(J_{2} \quad D_{2})}; \quad (2)$$

$$D'_{14} = \frac{2D_1 D_3}{9(J_2 \quad D_2)};$$
(3)

If the ground state of the bond is a triplet (arctan $\frac{1}{3} < 2 < =2$), spins 2 and 3 form an e ective spin 2' with $S_{2^0} = 1$, and its couplings to its neighbor spin 1 are

$$J_{12^0} = (J_1 \quad D_1) = 2;$$
 (4)

$$D_{12^0}^{\circ} = D_1 = 2:$$
 (5)

C ouplings to spin 4 have identical expressions. Should the ground state of the bond be a quintuplet, an elective spin with S = 2 form s, and the structure of the original spin-1 chain gets distorted.

Exam ination of Eqs. (2) and (3) shows that the generated bond m ay be ferrom agnetic, even if all the bonds involved are antiferrom agnetic and favor singlet ground states. For concreteness, we consider the case where bonds 2 and 3 are H eisenberg, i.e., $D_2 = D_3 = 0$. In this case the e ective bond between spins 1 and 4 are: $J_{14}^{-1} = 2J_3(2J_1 \quad D_1)=3J_2$ and $D_{14}^{-1} = 0$. Therefore the generated bond is H eisenberg and ferrom agnetic if

$$J_1 \quad D_1 = 2 < 0$$
: (6)

C learly, bond 1 can be AF and satisfy Eq. (6) if it lies in the shaded region of Fig. 1.

We have veried the above results of perturbation theory, that it is possible to get $S_{tot} = 2$ ground states when Eq. (6) is satistical, by performing exact diagonalization of four spin clusters. The results of one such calculation is shown in Fig. 3: as a function of J_2 , the ground state of the cluster changes from $S_{tot} = 0$ (which evolves from a product of singlets between spins $S_1 \& S_2$ and $S_3 \& S_4$ in the limit $J_2 = 0$) to $S_{tot} = 2$.

The perturbative RG described above is reliable when the random ness is strong and the distributions of the couplings are broad [1,10]. We now consider the opposite lim it of dilute random ness, namely a uniform AF spin-1 chain in the Haldane phase (=4 < < =4, see Fig. 1), with a nite Haldane gap and a small fraction of in purity bonds that are much weaker than (see Fig. 2b). Here one must identify the true low energy degrees of freedom [8]. If the impurity bonds were taken away, the original chain would have been chopped into decoupled segments; the low-energy degrees of freedom are the two spin-1/2 at the two edges of each segment with a coupling (that can be either F or AF) decreasing exponentially with the length of the segment. Putting back the impurity bonds, as long as they are weak compared to , does not alter the bulk structure of the segments; their primary e ect is to couple neighboring edge spins in di erent segments. Let us assum e bond 1 coupling spins 1 and 2 is such an impurity bond, with J_1 ; D_1 .To calculate the coupling between the two edge spin-1/2s, which we label 1' and 2', we project the original operators onto the subspace of states below the Haldane gap, i.e., states of the e ective edge spins [17]:

$$H_{1^{0}2^{0}} = P H_{12}P = J_{1}P S_{1} \quad \mathcal{D}P + D_{1}P (S_{1} \quad \mathcal{D})^{2}P;$$
 (7)

where P is the projection operator. Rotational symmetry as well as properties of spin-1/2 guarantee that $H_{1^{0}2^{0}} = J_{1^{0}2^{0}}S_{1^{0}}$ $S + C_{1^{0}2^{0}}$; where $C_{1^{0}2^{0}}$ is a constant. We also have PS_1 $SP = PS_1P$ PSP, because spins 1 and 2 live in decoupled Hilbert spaces if bond 1 were not there, and the W igner-Eckart theorem [18] guarantees $PS_iP = S_i^0$. The constant depends on bulk properties of the segments; for in nitely long segment with Heisenberg coupling, 1:0640 [19]. Sim ilarly P (S₁ $\mathfrak{S}^{2}P = a + bS_{1^{\circ}}$ $\mathfrak{S};$ and the important constant b m ay be determ ined by calculating certain m atrix elements of $(S_1 \ p)^2$ in the subspace: $b = 2 [h''_{1^0} ''_{2^0}]$ $(S)^2 j "_{1^0} "_{2^0} i h "_{1^0} #_{2^0} j (S_1 S)^2 j "_{1^0} #_{2^0} i]: U s$ j(S₁ ing the commutation relations of S and the fact [19] $h''_{1^{\circ}} j_{1^{\circ}}^{z} j''_{1^{\circ}} i = = 2 \text{ etc, we obtain } b =$ $^2=2.$ Therefore $J_{1^{\circ}2^{\circ}} = {}^{2}(J_{1} \quad D_{1}=2)$, and again we and $J_{1^{\circ}2^{\circ}}$ may be ferrom agnetic even when the original bond 1 was AF, with the same condition as before, namely Eq. (6). We have thus demonstrated the existence of such an instability to form ferrom agnetic couplings in both the high disorder and dilute disorder lim its.

W e now discuss the origin of this ferrom agnetic instability, and in particular, the signi cance of the special combination of J and D in Eq. (6). By introducing a new coupling constant $K = J \quad D = 2$; the RG equations (2) and (4) simplify signi cantly:

$$K_{14} = \frac{4K_1K_3}{3(K_2 \quad 5D_2=2)}; K_{12^0} = K_1=2:$$
(8)

C om bining these with equations (3) and (5), we nd K and D decouple except through energy denom inators, and one cannot generate K from D, or vice versa. This suggests that K and D represent couplings of operators with di erent sym m etry properties.

To proceed further, we note that products of di erent components of the spin operator (that appear in the H am iltonian) may be organized to form traceless irreducible spherical tensor operators [18]: Y_{lm} (S), which is de ned by replacing cos by S_z , sin cos by S_x and sin sin by S_y in the usual spherical harmonics Y_{lm} (;), and symmetrizing noncommuting components. Y_{lm} (S) = 0 for l> 2S. A general way to write down the coupling between two spins that respect rotational symmetry (equivalent to H ij = $\int_{n=1}^{2S} J^{(n)}$ (Si \mathfrak{H}^n) is

$$H_{ij} = \begin{array}{ccc} X^{S} & X^{1} \\ K & (1) \\ I = 0 & m = 1 \end{array} (1)^{m} Y_{Im} (S_{i})Y_{I; m} (S_{j}); \quad (9)$$

where K 1 is the coupling constant of rank 1 spherical tensors. It is easy to verify that

$$+ \frac{8}{15} \prod_{m=2}^{N} (1)^{m} Y_{2m} (S_{1})Y_{2; m} (S_{2}) + \frac{1}{3}S_{1}^{2}S_{2}^{2}: (11)$$

Therefore for the coupling of the form JS_1 $\pounds + D$ $(S_1 S_2)^2$, we have K $^{(1)} = \frac{2}{3} (2J D) / K$, and K $^{(2)} = \frac{8}{15}D$. Thus the K variable is proportional to the coupling between rank 1 tensors (vectors), nothing but the H eisenberg coupling (in this tensor representation); and Eq. (6) indicates the H eisenberg coupling is ferrom agnetic.

The advantage of writing the Ham iltonian in terms of couplings of irreducible spherical tensors instead of powers of S_1 for the spherical tensors instead of tensors with dimensional tensors with dimensional tensors with the event ranks do not allow them to mix in 1st and 2nd order perturbation calculations, as we have already seen; while $(S_1 \quad j)^n$ in general includes tensor couplings with all ranks up to n. For example, we know Y_{1m} (S) acting on a singlet creates an eigenstate of S_{tot}^2 and S_{tot}^z with $S_{tot} = 1$ and $S_{tot}^z = m$, therefore in the second order perturbation a coupling of rank 1 between

spins 1 and 4 is mediate through the channel of excited states with $S_{tot} = 1$ of spins 2 and 3. M ore rem arkably, when projecting spin-1 couplings to couplings between spin-1/2 edge spins, the fact that spin-1/2 object does not support tensors with ranks higher than 1 guarantees that the coupling must be proportional to J D = 2 of the original coupling, and the original rank 2 tensor coupling sim ply gets elim inated.

The above discussion also gives us insights into the origin of the ferrom agnetic instability we dem onstrated. E ven though a single bond favors a singlet ground state, it m ay well contain ferrom agnetic couplings between tensors with certain rank (say, rank 1, or Heisenberg coupling). In the absence of random ness no ferrom agnetic instability is triggered by such couplings. In the presence of random ness, how ever, energy scales in the system gets separated, and low - and high - energy subspaces of the Hilbert space get perturbatively decoupled (which is the basis for perturbative RG). In projecting to low -energy subspaces, certain AF couplings may get suppressed for symmetry reasons (as we have seen), while the original subdom inant ferrom agnetic couplings may survive and becom e dom inant. In the exam ple we illustrated above, the AF rank 2 couplings are suppressed in the low energy subspace, while the ferrom agnetic rank 1 (Heisenberg) coupling survives. This is the origin of the ferrom agnetic instability, which is a purely quantum mechanical e ect, and absent without random ness.

W ith the generation of ferrom agnetic bonds between segm ents as well as within segments, the decimated chain is very di erent from that obtained with pure Heisenberg coupling by Hym an and Yang [8]. In fact, it becomes of the universality class of the spin-1/2 chain with random AF and F couplings studied by W esterberg et al. [11]. Using our formalism, their RG scheme may be easily generalized to include higher spins and non-Heisenberg couplings, as ows of couplings of di erent rank tensors tend to decouple. Our results show that at low energies high rank couplings are strongly suppressed com pared to Heisenberg couplings, if the original couplings are dominantly Heisenberg, which is a likely situation in nature [20]. Therefore the active degrees of freedom in our case will be weakly coupled large moments as in the case of W esterberget al, which lead to a pure Curie susceptibility in the low temperature limit, because of a perfect cancellation between growing moments and reducing num bers N in the expression for the susceptibility = N (T) (T)²=T as T is low ered.

In sum mary, we have demonstrated the possibility of generating ferrom agnetic couplings in quantum spin chains with random rotationally invariant couplings, starting from the antiferrom agnetic sector of the phase diagram of the pure chain. Though we have discussed S = 1 exclusively for concreteness, sim ilar elects would be expected for higher spins, though their phase diagram s even for the pure case are not fully known. For integer spins, our arguments are valid in both large disorder and dilute limits, and the former case applies to larger half-odd-integer spins as well. However, as our treatment shows, the e ects are purely quantum mechanical, and dependent on either the spin gap or the region of valid-ity of second order perturbation theory, both of which are known to become smaller with increasing S. Consequently, we expect the region of this anom alous behavior to decrease with increasing S, and disappear in the classical limit S ! 1.

FIG.1. Phase diagram of a pure spin-1 chain. Solid lines are phase boundaries. Shaded regions represent couplings in the antiferrom agnetic sector satisfying J D = 2 < 0, which, in the presence of random ness, could generate e ective ferrom agnetic bonds at low energies.

FIG.2. Illustration of spin decimation procedures. (a) Strong random ness case. W hen the strongest bond (between spins 2 and 3) has a singlet ground state, spins 2 and 3 are decimated and an e ective bond connecting 1 and 4 is generated; when the ground state is a triplet, 2 and 3 form an e ective spin-1 object $S_{2^{\circ}}$, which is coupled to its neighbors 1 and 4. (b) D ilute random ness case. W hen a uniform spin-1 chain in the H aldane phase is broken into nite segments coupled by weak in purity bonds (dotted lines), the low energy degrees of freedom are half spins living at the edges of each segments; there is weak coupling between neighboring half spins, both in the same segment (broken lines) and di erent segments (dotted lines).

FIG.3. Ground state level crossing in a four-spin cluster for $J_1 = 1.0$, $D_1 = 1.5$, $J_3 = 1.0$, $D_2 = D_3 = 0$. The plot shows energies of the low est energy quintuplet ($S_{tot} = 2$, solid line) and triplet ($S_{tot} = 1$, broken line) states, m easured from low est energy singlet state. For $J_2 > 3.46$, the ground state has total spin $S_{tot} = 2$, despite the fact that all three bonds favor singlet ground states.
