Abstract

In this note we apply some theoretical predictions that arise in the mean field framework for a large class of infinite range models to structural glasses and we present a first comparison of these predictions with numerical results.

1 Introduction

In recent years some theoretical progresses in our understanding of glasses have been achieved by comparing the results obtained for soluble models of generalized spin glasses [1, 2] with structural glasses properties under the assumption that the phase space of the two systems is similar. These progresses are also due to the use of the replica method and of related concepts as replica symmetry breaking, coupled replicas, dynamic transitions ...

In the nutshell many of the ideas of this replica approach are already present in the original papers of Gibbs and DiMarzio [4]. However, the use of the whole panoply of tools developed in the study of spin glass models allow us to put these ideas in a much sharper form and to test them in numerical (and possibly real) experiments. Moreover the comparison of structural glasses and generalized spin glasses, introduced in ref.[5], has proven extremely useful and the conjecture that the two models have similar energy landscapes has been a fruitful starting point.

In this note we will not discuss the theoretical basis under which this scenario has been derived but we will concentrate the attention on the physical picture and on the consequences of these predictions on the statistical properties of relative small samples.

The basic assumption is that, at sufficiently low temperatures but still in the liquid phase, the system is almost always trapped for a long time in one of the exponentially large number of local minima of the free energy. The number (N) of these local minima is related to the configurational entropy or complexity by

$$N = \exp(N \phi(T)); \quad (1)$$

N being the number of particles and the previous formula being asymptotic for large N . The total entropy density S is the sum of two contributions: the entropy density of each minimum and the complexity. This description is valid for $T_K < T < T_D$. The complexity [6] (which starts from a non zero value at T_D) is supposed to vanish linearly at a lower temperature, (i.e. at the temperature T_K) where the height of the typical barriers becomes infinite. The correlation time diverges at T_K , and one can argue in favour of a Vogel-Fulcher law (e.g. $\tau \sim \exp(A/(T - T_K))$), where $A > 1$).

This scenario is implemented in a large class of infinite range models [5], where a more detailed picture of the phase space of the system is obtained. Indeed these infinite range models are soluble because the appropriate mean field theory is exact. The study of the mean field theory for these models is not a trivial task: the phase space structure of the configurations with low energy is quite complex and this is shown up in a rather interesting behaviour of the system both at equilibrium and in its approach to equilibrium. The existence of these complex structures implies the need of using modern tools (like the replica formalism) to study the properties of these systems.

The aim of this note is to spell out some of the theoretical predictions that are obtained in the mean field framework for these infinite range models, to apply them (with the appropriate modifications) to the case of structural glasses and to present a first comparison of these predictions with numerical simulations.

2 A mini theoretical review

The main hypothesis of the Gibbs-DiMarzio's approach is that at low temperatures the system quite always stays close to a minimum of the free energy and that the long time dynamics is

dominated by the time needed to escape from one valley to another.

As noticed in ref. [5] this scenario is implemented in long range models in which detailed computations can be done and a more precise picture can be obtained [7, 8].

Let us consider for definiteness a spin model where the local variables are spins (i) , $i = 1 :: N$. They could be either Ising spins $(i) = \pm 1$ or spherical spins, i.e. real variables which satisfy the constraint

$$\frac{\sum_{i=1}^N (i)^2}{N} = 1: \quad (2)$$

The Hamiltonian $H(\cdot)$ has a form that we do not need to specify here. There are many different models with quite different Hamiltonians which share the properties that we are going to describe. In the following we will consider a finite large system and only at the end we will send the value of N to ∞ .

We suppose that the phase space can be broken into many valleys separated by high mountains. In other words, the free energy (or the energy at low temperature) has many minima and the free energy barrier which we have to cross for going from one state to another is quite large. In the infinite range approximation it will be proportional to N . We can consider all the local minima of the energy as functions of the configuration and we can associate a valley to each of them at zero temperature. At higher temperature we have to consider the minima of the free energy and when increasing the temperature the valleys will disappear.

We could also define the valleys in a dynamical way as regions of configuration space in which the system remains trapped for a large time. This definition is similar to the previous one if we assume that the large time behaviour of the dynamics at low temperature is dominated by activated processes which correspond to the crossing of high free energy barriers.

Each valley (which we label by α) may be characterized by a magnetization

$$m_\alpha(i) = h_\alpha(i); \quad (3)$$

where $h_\alpha(i)$ is the statistical expectation value restricted to the α -valley. One can define a free energy $F[m]$, which is a function of all the local magnetizations, whose functional form depends on the system. The valleys are local minima of this free energy.

2.1 Equilibrium properties

One finds in a very large class of models the following behaviour for the equilibrium properties depending on the temperature [6]–[10]:

For temperatures higher than T^* there is only one minimum of the free energy $F[m]$ at $m(i) = 0 \forall i$. In this case the total free energy of the system F is given by $F = F[0]$.

At temperatures lower than T^* there is an exponentially large number of minima. The contribution of these minima to the partition function can be estimated by

$$Z_m = \int df \exp(-Nf + N(f; \beta)) \approx \exp(-Nf + N(f^*; \beta)); \quad (4)$$

where f is the free energy density ($Nf = F$), $\exp(N(f; \beta))$ is the number of minima of the free energy density f and f^* is the value of f which maximizes the exponent, that is a function of β .

Below T_m we can distinguish three regions:

For $T > T_K$ the contribution to the partition function of the non trivial minimum can be neglected and the free energy is still given by $F[0]$.

For $T_K > T > T_D$ the contribution to the partition function of the non trivial minimum is dominant. The number of minima which dominate the partition function is exponentially large and the total entropy of the system is given by

$$S = S_m + N \langle f(\epsilon) \rangle; \quad (5)$$

where S_m is the contribution to the total entropy of one minimum and $\langle f(\epsilon) \rangle > 0$.

The magnetization averaged over all the minima is given by $m(i) = \langle h(i) \rangle = \frac{1}{P} \sum_i w_i h(i)$, where $w_i / \exp(-\beta F_i)$ is proportional to the contribution of the i -th minimum to the partition function ($\sum_i w_i = 1$).

In this region the magnetization averaged over all the minima is zero and the total free energy which is dominated by the contribution of all the non trivial minima is still given by $F[0]$. The free energy and all the other static equilibrium properties (quantities?) are fully regular at T_D .

For $T < T_K$, $\langle f(\epsilon) \rangle = 0$. For T slightly larger than T_K one finds $\langle f(\epsilon) \rangle / (T - T_K)$, so that the complexity (and consequently the entropy) has a discontinuity in the temperature derivative at $T = T_K$, which is the transition point from a thermodynamic point of view. Here the entropy becomes equal to the contribution of a single minimum and this temperature may be identified with the Kauzmann temperature.

The region $T < T_K$ can be characterized by a peculiar behaviour. The partition function is dominated by those states which have the minimum free energy and there are some minima for which quantities w_i remain of order 1.

In the previous description we have neglected the possibility of crystallization, i.e. the formation of a highly ordered state which leads to a first order transition. If we consider this possibility we have to distinguish two cases, systems with quenched disorder in the Hamiltonian and systems without disorder (often with a translation invariant Hamiltonian).

There are systems whose Hamiltonian contains quenched disorder. A typical example would be:

$$H = \sum_{i,j,k,l} J(i,j;k,l) \sigma_i \sigma_j \sigma_k \sigma_l; \quad (6)$$

where the variables J are random (e.g. Gaussian).

Another example (in which the mean field approximation is non exact) would be a system in which the particles interact not only with themselves but also with an external, fixed, random potential. It is clear that if the external potential is strong enough the free energy of the crystal phase may become quite large, while that of the glassy phase may be much less affected.

Other systems may not contain quenched variables in the Hamiltonian. A typical example [12] is:

$$H = \frac{1}{N} \sum_{i,j,k=1}^N \sin \frac{2\pi ijk}{N} (\sigma_i - \sigma_j)^2 \quad \text{with} \quad \sigma_i = \pm 1; \quad (7)$$

Another example would be a system in which the particles interact only with themselves with a given potential.

The two categories of models seem rather different one from another; however it has been noticed that in the mean field approximation systems belonging to the two categories behave in a quite similar way, with the only difference that systems without quenched disorder may crystallize.

While this kind of results can be proved in the long range models, their validity for short range models (like structural glasses) remains an open question. In this note we would like to present numerical evidence for the correctness of these ideas also for structural glasses. Before doing so we will examine in detail the predictions of the mean field approach.

2.2 Equilibrium properties at low temperature

For simplicity let us consider the predictions that would follow from the application of the replica approach to a system of N particles interacting with a given Hamiltonian in a box.

We will consider for simplicity a system without any type of symmetry (the box is not symmetric and the particles interact with the walls, periodic boundary conditions are not used so that there is no translational invariance). We suppose that for a given value of N the Hamiltonian has many minima which we label by α .

The partition function can thus be written as

$$Z(\beta; N) = \sum_{\alpha} \exp(-\beta F_{\alpha}(\beta; N))$$

$$F_{\alpha}(\beta; N) = E_{\alpha} - TS(\beta; N); \quad (8)$$

where for simplicity we label the configurations in increasing free energy order. For small temperatures the entropic contribution to the free energy will be as usual negligible. It is quite evident that for a finite system the partition function is dominated by the lowest energy configurations in the limit of zero temperature, and we will suppose that this property persists in the infinite volume limit.

For different values of N we will have quite different values of the free energies. The lowest free energy states will have free energy differences of order 1, so that by adding a single particle (i.e. going from N to $N + 1$) we can strongly change the values of the $F_{\alpha}(\beta; N)$. If we label by F_0 the lowest free energy we expect that the quantities $F_{\alpha}(\beta; N) - F_0(\beta; N)$ remain of order 1 when N goes to infinity, but they do not go to any limit (they have no $N \rightarrow \infty$ limit?) because they change with N . In this case it is natural to introduce a probability distribution for the differences in free energies, which tell us the probability of finding a given value of $F_{\alpha}(\beta; N) - F_0(\beta; N)$ if we chose randomly (albeit large) the value of N . In other words if the value of the free energy changes strongly with N it is convenient to introduce the probability distribution of their values.

The precise construction is the following: for any large value of N we introduce a reference free energy $F_R(\beta; N)$ such as that, in the whole region $F_{\alpha}(\beta; N) < F_R(\beta; N)$, the probability of finding a minimum of free energy F is given by

$$P(F) = \exp(-x(F - F_R(\beta; N))); \quad (9)$$

where the quantity $x(\cdot)$ parameterizes the probability distribution.

The condition that the free energy is approximately given by F_R implies that the integral

$$\int_{F_R(\mu N)}^{\infty} P(F) \exp(-\beta(F - F_R(\mu N))) dF \approx 1 \quad (10)$$

is convergent and therefore $x(\mu) \approx 1$.

The probability of finding a configuration in the minimum labeled by μ is

$$w_\mu = \exp(-\beta F_\mu) / Z \quad (11)$$

where the normalization condition

$$\sum_\mu w_\mu = 1 \quad (12)$$

is satisfied.

In many models x becomes equal to 1 at the temperature T_K . At low temperatures x is proportional to the temperature (it would be exactly proportional to the temperature if we neglect the entropic contribution).

An important property of the model is how different the various minima are. The simplest hypothesis is that they are as different as possible, i.e. the correlations among the particles in one minimum and in another minimum (among those of lowest energy) are zero. For example the probability of finding two particles in two different minima at a given distance r does not depend on the distance:

$$P_{\mu, \nu}(r) = \sum_{i,j} x_i(\mu) x_j(\nu) \delta(r - |x_i - x_j|) = x^2 \quad (13)$$

This hypothesis is usually called one step replica symmetry breaking. More complicated distributions of the distances are discussed in the literature.

If there are symmetries the situation becomes slightly more complex. For example in a translational invariant system if $x(i)$ are the coordinates of a minimum, $x(i) + a$ are the coordinates of another minimum. It is therefore useful to consider all the minima which are related by a symmetry transformation as a single minimum.

2.3 The probability distribution of the distance

The properties of the system may be sharpened by introducing an appropriately defined distance between configurations of particles and looking at the corresponding equilibrium probability distribution:

$$P_N(d) = \sum_i w_i w_j \delta(d - d_{ij}) \quad (14)$$

In the limit of large N we have that

$$P_N(d) = a_N \delta(d - d_0) + b_N \delta(d - d_1); \quad (15)$$

where $a_N + b_N = 1$. Of course for a finite system the delta function will be smoothed.

The function a_N represents the probability of finding two different configurations in the same minimum and it is given by

$$a_N = \sum_i w_i^2 \quad (16)$$

In the one step replica symmetry breaking hypothesis two configurations that are not in the same minimum are expected to be orthogonal, i.e. at the maximum possible distance d_1 . This happens with the probability:

$$b_N = \frac{1}{N} \sum_{i,j} w_{ij} w_{ji} : \quad (17)$$

The functions a_N and b_N are naturally depending on the temperature. In the mean field framework one finds that the weight of the δ -function in d_1, b_N , that is zero for $T > T_K$, increases continuously when lowering the temperature below the transition point.

The probability distribution $P_N(d)$ should therefore be an appropriate observable for looking at the transition from the high- T region (where $P_N(d)$ is Gaussian-like for a finite system) to the glassy phase in which it is expected to show a non trivial behaviour, strongly depending on N .

2.4 The approach to equilibrium

For simplicity we will point the attention on the relaxation of the energy density when the system is quenched abruptly (at the time $t = 0$) from a random initial configuration (i.e. in finite cooling rate) to the final temperature.

In the mean field picture [13] one finds two different relaxation behaviours, depending on the final temperature value:

At high temperatures the energy reaches exponentially its equilibrium value, i.e. $e(t) = e_{eq} + c \exp(-t/\tau)$. The relaxation time increases when lowering the temperature and it diverges for $T \rightarrow T_D$.

Below the dynamical transition point T_D the energy behaves linearly as a function of t [14], i.e. $e(t) = e_0 + ct$, the exponent being weakly depending on T . Here the system is evolving towards some metastable states (with infinite life time) and correspondingly the asymptotic energy value e_0 is higher than that of the equilibrium.

The infinite life time of metastable states is just an artefact of the mean field approximation. In a real system we expect the approach to the equilibrium for $T < T_D$ consisting of two steps:

The convergence to some metastable states with a mean field like behaviour.

The slow decay of metastable states due to activated processes. In this second step the system reaches the true equilibrium state that will be still the replica-symmetric one for $T > T_K$.

This means that by looking at $e(t)$ it is in principle possible to find numerical evidence for the reminiscence in real glasses of the mean field dynamical transition. Here T_D is expected to mark the onset of the two steps relaxation.

3 The model

We study a binary mixture of soft spheres, half of the particles being of type A with radius r_A and half of type B with radius r_B . The Hamiltonian is:

$$H_{pbc} = \sum_{i < k = 1}^N \frac{(i) + (k)}{r_i r_k} : \quad (18)$$

This model has been carefully studied in the past [20]–[28]. It is known that the choice $\rho_B = \rho_A = 1.2$ strongly inhibits crystallization. We also follow the convention of considering particles with average diameter 1 by setting:

$$\rho_A^3 + 2(\rho_A + \rho_B)^3 + \rho_B^3 = \frac{1}{2}; \quad (19)$$

Thermodynamic quantities only depend on $\rho = T^{-1/4}$, where $T = 1/\rho$ is the temperature and we have taken density $\rho = 1$ ($T = 1$). The N particles move in a 3d cube of size $L = N^{1/3}$. The glass transition is known [21] to happen around $\rho_c = 1.45$.

In order to obtain numerical results on the equilibrium properties comparable with the mean field theoretical picture we attempt to measure the equilibrium probability distribution $P(d)$ of the distance d between states. Following the usual strategy in spin glass simulations we introduce two evolving contemporaneously and independently replicas of the system. $P(d)$ is then given by:

$$P(d) = \frac{1}{N} \sum_i h(d, D_i); \quad (20)$$

D being the appropriately defined distance between the configurations of the two replicas.

Labeling by $\mathbf{r}_i, \mathbf{s}_i$ the positions of the N particles in the two replicas, a natural definition of D is the Euclidean one, minimized over permutations, rotations and reflections R and, when using periodic boundary conditions, translations T :

$$D^2 = \frac{1}{N} \min_{R, T} \sum_{i \in \text{type A}}^N (\mathbf{r}_i - \mathbf{s}_{(i)})^2 + \sum_{i \in \text{type B}}^N (\mathbf{r}_i - \mathbf{s}_{(i)})^2; \quad (21)$$

An analogous definition of distance between configurations of particles has been considered in [15] and in [16], in studies of potential energy minima for Lennard-Jones systems.

We minimize over permutations by an approximate procedure. For each particle i of one configuration we take (i) being the nearest one of the other. We expect this to be a reasonable approximation in the considered temperature range (from $\rho = 1$ to $\rho = 2$) since the probability for two particles of the same system of being at a distance lower than $2^{-1/4} \approx 0.71$ is very close to zero at not too high temperatures (the radial density-density correlation function in a simple liquid shows the well known behaviour $g(r) \approx 0$ for $r < 2$).

Minimization over rotations and reflections is easily performed since in the case of a 3d cube R results a discrete group that includes 48 symmetry operations, corresponding to the 2^3 reflections and to the $3!$ permutations of axes. On the other hand, minimization over the continuous group of translations is a hard task and we prefer to avoid it by not using periodic boundary conditions.

To measure $P(d)$ we have considered a slightly modified model in which particles are definitely confined in the cubic box of size L by a soft walls-repulsive potential term:

$$H_{sw} = H_{pbc} + c_1 \sum_{i=1}^N \frac{1}{(c_2 + r_i)^{10}} + \frac{1}{(L + c_2 - r_i)^{10}}; \quad (22)$$

We have chosen the values $c_1 = 5$ and $c_2 = 0.6$ that give a behaviour of the energy as a function of ρ quite near to that of the periodic boundary conditions case.

4 Numerical results on the dynamics

4.1 Algorithms

Both for finding the best numerical approach to the simulations of structural glasses at the equilibrium and for studying the dynamical properties of the model we have implemented different algorithms, considering stochastic and deterministic dynamics:

Monte Carlo (MC). We start from a random configuration and we quench abruptly the system by putting it at the final temperature (i.e. in finite cooling rate). During one step each particle is suggested to move of a random quantity and the maximum shift permitted is chosen in order to obtain an acceptance ratio near 0.5.

Molecular Dynamics (MD). When using MD to start with a completely random spatial configuration may cause difficulties. Here the initial spatial configuration is obtained from a random one by 60 Monte Carlo steps at the final temperature. At the beginning and again each 100 steps we extract momenta \mathbf{p}_i according to the Boltzmann distribution (we have taken the masses of particles $m_A = m_B = 1$) and we impose the condition $\sum_{i=1}^N \mathbf{p}_i^2 = (3N - f_{MD})T$, where f_{MD} is the number of frozen degrees of freedom. $f_{MD} = 3$ when using periodic boundary conditions since the three components of the total linear momentum \mathbf{P} are conserved (we have taken $\mathbf{P} = 0$), otherwise $f_{MD} = 0$. We use the velocity-Verlet algorithm [17] with $\tau = 1/250$ (a value that we have checked to be reasonable in our case, e.g. the total energy results perfectly constant).

Isothermal Molecular Dynamics (IMD). The system evolves according to the Gaussian isokinetic equations of motion [17]:

$$\dot{\mathbf{r}}_i = \mathbf{p}_i \quad \dot{\mathbf{p}}_i = \mathbf{F}_i \quad \mathbf{p}_i = \frac{\sum_{i=1}^N \mathbf{F}_i \cdot \mathbf{p}_i}{\sum_{i=1}^N \mathbf{p}_i^2} \mathbf{p}_i \quad (23)$$

At the beginning we extract momenta and we fix the constraint $\sum_{i=1}^N \mathbf{p}_i^2 = (3N - f_{IMD})T$, where $f_{IMD} = f_{MD} + 1$. Also in this case we start from a spatial configuration obtained from a random one by 60 Monte Carlo steps at the final temperature. We implement the algorithm by using a variant of the leap-frog scheme [17] again with $\tau = 1/250$.

Parallel Tempering (PT). Algorithms in which temperature is allowed to become a dynamical variable [18] are very effective for thermalizing systems with a complex free energy landscape. In this recently introduced [19] method a set of n different values $T_1 < T_2 < \dots < T_n$ is chosen a priori and n replicas of the system evolve contemporaneously. The extended Hamiltonian $H_{PT} = \sum_{a=1}^n (T_a) H[T_a]$ is defined and exchanges of temperatures between replicas

$$(T_1) \leftrightarrow (T_2) \dots (T_{n-1}) \leftrightarrow (T_n)$$

are allowed with probability $p = \min[1, \exp(-\beta_{PT})]$. The whole process is itself a Markov chain and, when equilibrium has been reached, each replica moves between different temperatures of the set remaining at the equilibrium. We start by extracting independently the n random initial configurations and we quench each replica at a different one of the chosen temperatures. In a PT step, sequentially for $a = 1 :: n$:

- { Replica a makes one M C step at its temperature $\beta(a) = \beta_k$.
- { A random number $j = 1$ with equal probability is extracted.
- { For $1 \leq k + j \leq n$ the exchange of temperatures between replica a and replica b , where $\beta(b) = \beta_{k+j}$, is suggested and possibly accepted.

The set of β values should be chosen carefully. We find that for the numbers of particles considered (up to $N = 36$) P T works well down to $\beta = 2$ with $n = 13$ different temperatures ($\beta = 1, 1.05 \dots 1.2, 1.3 :: 2$).

We have implemented and tested a combined technique of Parallel Tempering and Isothermal Molecular Dynamics (IM D P T). The n initial spatial configurations are obtained from random ones by 60 M C steps at $\beta = 1$. After extracting momenta we impose the constraints $\sum_{i=1}^N (p_i^a)^2 = (3N - f_{IM D}) T_a$ $a = 1 :: n$ (we have taken the same set of temperatures that in P T). Replicas evolve accordingly to IM D and each 10 IM D steps the exchanges of temperatures happen with probability $p = \min[1; \exp(-H_{PT})]$, where in H_{PT} only potential energies appear. Here to change temperature $T_{old} \rightarrow T_{new}$ means to transform momenta as $p_i \rightarrow (T_{new}/T_{old})^{1/2} p_i$; $i = 1 :: N$.

Finally we have performed M C simulations of large systems (2000 and 8000 particles) in the periodic boundary conditions case, by putting a cut-off on the soft spheres' potential:

$$V_{ik} = \begin{cases} \sum_{j=1}^8 \frac{(i)+(k)}{r_{ij} r_{kj}}^{12} & \text{for } r_{ij} \leq r_{kj} < R \\ \frac{(i)+(k)}{R}^{12} = V_{ik}^0 & \text{otherwise} \end{cases} \quad (24)$$

The algorithm is then implemented in such a way that for each particle the map of the ones which are at distance lower than $R + 2$ is recorded and updated during the run (β being the maximum shift permitted to a particle in one M C step). We have chosen $R = 1.7$ that means a practically negligible $V_{ik}^0 \approx 0 (10^3)$ ($V_{ik} = 1$ for $r_{ij} \leq r_{kj} < 2$).

4.2 On the energy relaxation behaviour

We look at the (potential) energy density relaxation when the system is quenched abruptly from a random initial configuration to the final (low) temperature. We compare results obtained by different numerical methods for $N = 34$ particles and we extend the analysis to large systems ($N = 2000$ and $N = 8000$) in the M C case. Here periodic boundary conditions are used.

In [Figs. 1-3] we present data obtained by M C, M D and IM D, respectively. Our results show no evident difference between stochastic and deterministic dynamics. Not only in the M C case, as already observed in previous simulations on the same model [26], but also when using Molecular Dynamics techniques the energy density relaxation is well compatible on a large time window with a linear behaviour in function of t . We get a non small exponent 0.3 , weakly β -dependent in the considered range (the dependence seems slightly more pronounced in the IM D case).

Moreover, the energy values at a fixed temperature that one can estimate by asymptotically extrapolating the linear behaviours obtained by different methods, are near to be the same. On the other hand we are going to show that these asymptotic values (apart from the case of $\beta = 1.4$) are not the real equilibrium energy values of the system.

Figure 1: M C data on e as a function of $y = t^{(0.8)}$ at $\alpha = 1.4$ (+), 1.6 (x), 1.8 (*) and 2.0 (□). Here 150 different initial conditions are considered.

Figure 2: M D data on e as a function of $y = t^{(0.8)}$ at $\alpha = 1.4$ (+), 1.6 (x), 1.8 (*) and 2.0 (□). Here 100 different initial conditions are considered. When using Molecular Dynamics techniques the need of a non completely random initial configuration (i. e. the first 60 steps are M C steps) induces some short time effects and the linear behaviour takes place at a slightly larger time than in the M C case.

Figure 3: IM D data on e as a function of $y = t^{(0.8)}$ at $\alpha = 1.4$ (+), 1.6 (x), 1.8 (*) and 2.0 (□). Here 100 different initial conditions are considered. The dependence of e on y seems slightly more pronounced in this case, our best estimates ranging from 0.8 at $\alpha = 1.4$ to 1.1 at $\alpha = 2.0$.

We present in [Figs. 4-5] P T and IM D P T data. There is a reminiscence of the linear behaviour but here the system moves between the high and the low temperatures of the set, this preventing it from being trapped. At the end of the (quite large) time window, equilibrium is near to be reached and the energy values are definitely smaller than the ones estimable by extrapolating simple Monte Carlo or Molecular Dynamics data. The difference is already detectable at $\beta = 1.6$ and it becomes more pronounced at lower temperatures. To further outline this result we plot in [Fig. 6] data obtained by various methods at $\beta = 2.0$.

Figure 4: P T data on e as a function of $y = t^{(0.8)}$ at $\beta = 1.4$ (+), 1.6 (), 1.8 () and 2.0 (). Here 24 different initial conditions are considered. Note that both in this case and in the IM D P T one the obtained behaviour depends on the entire set of temperatures.

Figure 5: IM D P T data on e as a function of $t^{(0.8)}$ at $\beta = 1.4$ (+), 1.6 (), 1.8 () and 2.0 (). Here 24 different initial conditions are considered. Data are near to be compatible within the errors with the P T ones.

We have found numerical evidence for the energy relaxation at low temperatures consisting of two processes that happen on remarkably well separated time scales. Both in the M C and in the Molecular Dynamics data the first step is clearly observable, corresponding to the convergence to some metastable states with a mean field like behaviour (note that β is weakly

Figure 6: Data on e as a function of $t^{(0.8)}$ at $\beta = 2.0$ obtained by MC (+), MD (•), IMD (◻), PT (2) and IMPD (◊).

depending on the temperature on a large range). The fact that the extrapolated energy values are not the real equilibrium values gives evidence for the presence of a second step, the slow decay of metastable states dominated by activated processes.

These results are inadequate for understanding whether the curvature of low temperature data on $e(y)$ at very large times (small $y = t^{-0.8}$) is related to the quite small N value we are considering or it actually represents the beginning of the second step (possibly with an intermediate plateau). In order to clarify this point we consider definitely larger systems.

We plot in [Fig. 7] $e(y)$ as obtained by MC simulations for $N = 8000$ at $\beta = 1.4, 1.5, 1.8$ and 3.0 . At $\beta = 1.8$ we present data also for $N = 2000$ that result almost indistinguishable from the $N = 8000$ ones and remarkably similar to MC data for the well smaller $N = 34$ system. This means that we are actually looking both at the first relaxation step and at the beginning of the second one.

The different behaviours observed when varying the temperature agree well with the previously discussed theoretical picture:

At $\beta = 1.4$ no two steps behaviour is observable and the energy reaches the equilibrium value in the considered time window. The system appears to be still above T_D but quite near to it (the relaxation time seems to be very large, the expected exponential decay being not distinguishable from a linear behaviour in function of y).

For $\beta = 1.5$ the system is definitely below T_D . The energy relaxes linearly as a function of y to a value e_0 higher than that of equilibrium, the slow decay of metastable states happening on a well larger time scale.

The beginning of the second step is clearly observable at $\beta = 1.5$ and still quite evident at $\beta = 1.8$ but it disappears at $\beta = 3.0$. Here data behave linearly on the entire time window. This seems reasonable since the time scale that control the second step (i.e. the onset of activated processes) is expected to increase when lowering the temperature.

Figure 7: M C data on e as a function of $t^{(0.8)}$ respectively for $N = 8000$ (one initial condition) at $\alpha = 1.4$ (+), 1.5 (x), 1.8 (o) and 3.0 (2) and for $N = 2000$ (two different initial conditions) at $\alpha = 1.8$ (□).

Figure 8: M C data on e as a function of $t^{(0.8)}$ for $N = 8000$ at $\alpha = 1.5$ (+) and 1.8 (x). The lines are the corresponding best fits to $e(t) = at^{(0.8)} + bt + c$ obtained by the plotted points.

To fit the two steps behaviour is a hard task. In [Fig. 8] we show our best results at $\beta = 1.5$ and 1.8 ($N = 8000$), obtained by $\chi^2_{\text{min}} = 0.8$ and considering $e(t) = at^{(0.8)} + bt + c$. It is interesting to note that in both cases we get a positive value of the same order, $\approx +0.1$. It seems reasonable that the second step corresponds to a stretched exponential decay, i.e. $e(t) = a_1(t-t_1)^{\alpha} + a_2 \exp(-C(t-t_2)^{\beta}) + e_{\text{eq}}$, at $t^{(0.8)} \gg t_2^{\beta} + e_{\text{plateau}}$ for $t \gg t_2$. However we stress that this is a purely indicative result since quite different values (possibly of the opposite sign) are obtainable by slightly varying β or the time window.

To conclude this section, we note that IM-DPT works well but seems to be not more effective than usual PT. We have done some dynamical simulations with different methods also in the case of Hamiltonian (22). We do not show the results that are qualitatively similar to those obtained by using periodic boundary conditions, the only difference being that here the onset of the second step becomes evident at shorter times.

5 Numerical results on the statics

5.1 Simulations at the equilibrium

In order to get the equilibrium behaviour of $P(d)$ we use Parallel Tempering, simulating contemporaneously two independent sets of replicas. Thermalization is a hard task and we limit our analysis to quite small numbers of particles ranging from $N = 28$ to $N = 36$. For each N value we perform an extensive simulation of $2^{22} \approx 2^{24}$ PT steps (i.e. up to more than 16 millions of MC steps for each one of the 26 replicas). We measure all the quantities we are interested in during the last 3/4 of the run.

Thermalization is checked in different ways:

We divide the last part of the run, in which statistics is collected, into 16 equal intervals and we look for possible shifts of the corresponding mean values (particularly we do not find evident changes in the behaviour of $P(d)$).

We check that each replica moves more than once from an extrema of the temperature range to the other and back in the last part of the run.

We evaluate the specific heat c both using $c = \partial \langle e \rangle / \partial T$ and using $T^2 c = \langle e^2 \rangle - \langle e \rangle^2$, checking compatibility of results.

Errors are estimated from the mean values obtained in each one of the 16 intervals.

Despite our efforts it is not possible to exclude the presence of lower minima in the free energy landscape that are not accessible to the system on the considered time scale. To clarify this point it is interesting to look at the particular value $N = 32 = 4^3 = 2$. Here particles are allowed to fill all the sites of a fcc structure. Once this crystalline equilibrium state has been reached (in about $2^{24} \approx 2^{25}$ PT steps) the system rests definitely trapped in it, the crystalline conformation corresponding to a "golf-hole" shaped minimum in the free energy landscape. The energy density results a discontinuous function of β as expected for a first order (liquid-crystal) transition.

It seems unlikely to us but particles could be able to arrange themselves in some sort of crystalline conformation that we have not detected, also for $N \neq 32$. On the other hand we would like to look at the glass equilibrium states, apart from the possible presence of lower crystalline minima. We find therefore reasonable to assume that on the time scale studied the system extensively explores the entire phase-space region we are interested in.

5.2 On the behaviour of $P(d)$

Data on the energy density $e(\beta)$ for different N values are plotted in [Fig. 9]. We note that the equilibrium energy density is a not regular function of the number of particles since it is definitely smaller for $N = 34$ than for $N = 36$. The non trivial N -dependence of the model at low temperatures is outlined when looking at the specific heat $c(\beta)$ [Fig. 10].

Figure 9: Data on the energy density e as a function of β for $N = 28$ (+), 30 (\circ), 34 (\square) and 36 ($*$). Lines are only to join neighbouring points.

It should be stressed that for each given N value the energy appears a continuous function of β and correspondingly the behaviour of $c(\beta)$ looks quite smooth, this giving evidence for the physics phenomenon we are studying being not a crystallization process. Moreover, we never observed the system definitely trapped in a configuration as it happens in the previously discussed $N = 32$ case.

We plot in [Fig. 11] data on $P(d)$ for different N values at the highest temperature considered ($\beta = 1$). The shape is the Gaussian-like one characteristic of the liquid phase and it changes very little when varying the number of particles.

Finally we present in [Figs. 12-15] the low temperature data on $P(d)$ for $N = 28, 30, 34$ and 36 , respectively. The qualitative features are the same for different number of particles. The behaviour changes in a remarkably short range around $\beta = 1.2$, and $P(d)$ looks highly non trivial at higher β values. The physical meaning of the peaks shown by the equilibrium probability distribution of distance between states in the low temperature region comes from the mean field theoretical picture. In this region the data are well consistent with the scenario that in the glassy phase a small number of valleys in the free energy landscape give the dominant contribution to the partition function.

Both the value of β and the $P(d)$ shape in the glassy phase are strongly dependent on N . Differences are evident also when the number of particles is varied only of 2 (i.e. between $N = 28$ and 30 or $N = 34$ and 36). This is easily understandable since a little difference in N can change abruptly the kinds (and the number) of configurations that maximize and that are near to maximize relative distances between particles (minimizing the Hamiltonian). On the other hand, the observed non trivial dependence of the behaviour of the model on the number

Figure 10: Data on the specific heat c as a function of T for $N = 28(+)$, $30(-)$, $34(-)$ and $36(2)$. Lines are only to join neighbouring points.

Figure 11: Data on $P(d)$ at $\beta = 1$ for $N = 28(+)$, $30(-)$, $34(-)$ and $36(2)$.

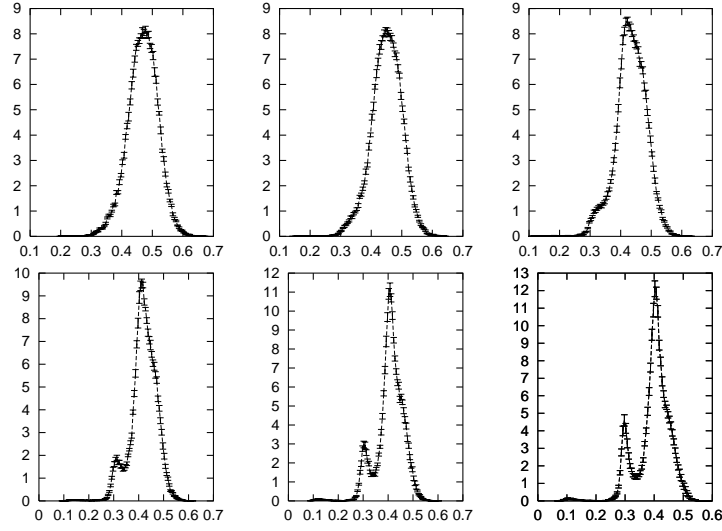

Figure 12: Data on $P(d)$ for $N = 28$. From left to right and top to bottom $\beta = 1.5, 1.6, 1.7, 1.8, 1.9$ and 2 . Plotted data have been measured during a 2^{24} P T steps run but we stress that they are perfectly compatible with those obtained by a previous 2^{22} step run.

Figure 13: Data on $P(d)$ for $N = 30$. From left to right and top to bottom $\beta = 1.5, 1.6, 1.7, 1.8, 1.9$ and 2 (i. e. the same value that in previous [Fig. 10]). Here data have been measured during a 2^{22} P T step run.

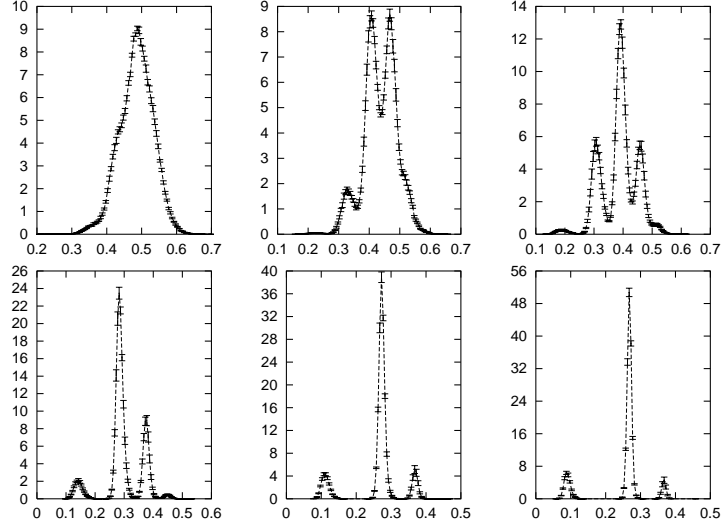

Figure 14: Data on $P(d)$ for $N = 34$. From left to right and top to bottom $\beta = 1.2, 1.3, 1.4, 1.6, 1.8$ and 2 . Here and in the next case of $N = 36$ data have been measured during a 2^{24} P T step run.

Figure 15: Data on $P(d)$ for $N = 36$. From left to right and top to bottom $\beta = 1.2, 1.3, 1.4, 1.6, 1.8$ and 2.0 (i. e. the same value that in previous Fig. 15).

of particles seems to agree with N playing in some way in structural glasses the same role that quenched random variables do in spin glasses.

As a last remark we note that when reaching values well higher than some peaks of $P(d)$ disappear and the height of the other ones (usually corresponding to smaller d values) goes up. This seems quite reasonable in a finite size system with continuous degrees of freedom since in spite of the absence of a perfectly crystalline ground state only a few configurations of the particles are expected to really minimize the Hamiltonian.

The natural next step in this analysis should consist in trying to get the behaviour of quantities averaged over different N values. We advance that from early new results [29] a slightly different definition of distance seems to be more suitable for mixtures and it could make easier this kind of study, permitting to gain a further insight into structural glass properties.
