Abstract: Some problems with the recent stimulating proposal of a “Gauge Theory of Finance” are outlined. First, the derivation of the log-normal distribution is shown equivalent both in information and mathematical content to the simpler and well-known derivation, dating back from Bachelier and Samuelson. Similarly, the re-derivation of Black-Scholes equation is shown equivalent to the standard one because the limit of no uncertainty is equivalent to the standard risk-free replication argument. Both re-derivations of the log-normality and Black-Scholes result do not provide a test of the theory because it is degenerate in the limits where these results apply. Third, the choice of the exponential form a la Boltzmann, of the weight of a given market configuration, is a key postulate that requires justification. In addition, the “Gauge Theory of Finance” seems to lead to “virtual” arbitrage opportunities for pure Markov random walk market when there should be none. These remarks are offered in the hope to improve the formulation of the “Gauge Theory of Finance” into a coherent and useful framework.

Ilinski and collaborators [1, 2] have recently proposed an intriguing analogy between quantum electrodynamics (QED), gauge field theory and financial markets (see also [3] for a simplified introduction). Their main idea starts from the recognition that the quest for arbitrage¹ opportunities by market players is one of the possible reasonable underlying explanation for anomalous behaviors such as deviations from log-normality of price variations. They then proceed to develop a geometrical theory in which an arbitrage opportunity is equivalent to a local curvature of the plaquettes corresponding to the different financial instruments. This is also very intuitive since a parameter-free definition of a (non-zero) curvature involves the non-closure of a parallel transport along a closed path, which is quite similar to an investment from its inception to closure. In other words, it is nothing but the standard discounted procedure. They then construct a set of axioms and then claim to provide an “intuitive” explanation for the log-normal distribution reference of price variations and to have the potential for a systematic analysis of deviations from the Black-Scholes option equation.

Here, I first show that their derivation of the log-normal distribution is in fact equivalent both in information and mathematical content to a simpler and well-known derivation, essentially dating

¹Arbitrage, also known as the Law of One Price, states that two assets with identical attributes should sell for the same price and so should the same asset trading in two different markets. If the prices differ, a profitable opportunity arises to sell the asset where it is overpriced and to buy it where it is underpriced.

back from Bachelier [4]. This is perhaps somewhat hidden behind the gauge field formulation (at least for non-physicists) and thus worth stressing. Similarly, their re-derivation of Black-Scholes equation is equivalent to the standard one because the limit of no uncertainty is equivalent to the standard risk-free replication argument [5]. My message is that both re-derivations of the log-normality and Black-Scholes result do not provide a test of the theory because it is degenerate in the limits where these results apply. In particular, the key postulate of Ilinski and collaborators [1, 2], namely the exponential form a la Boltzmann of the weight of a given market configuration, is in no way justified a priori. It is convenient for calculations but its validity must be tested thoroughly. Physical analogies are useful but must often be adapted to the market constraints and their specificities. For physical systems, the Boltzmann weight form has a strong mathematical basis derived from equally strong physical constraints for physical systems. Why should the same considerations work for the market? Samuelson, when referring to the use of entropy in economics, said “... I have come over the years to have some impatience and boredom with those who try to find an analogue of the entropy of Clausius or Boltzmann or Shannon to put into economic theory” [6]. A further argument is that the Boltzmann statistics was generalized in the last ten years into the Tsallis statistics [7], suggesting that not all phenomena in nature have to be described by Boltzmann statistics. Furthermore, the gauge theory of arbitrage is by construction such that the presence of noise introduces “virtual arbitrage” opportunities [1, 2]. However, take a pure Markov random walk market: by construction, there are no arbitrage opportunities but a lot of noise.

Consider buying a security at price S_1 and selling it at price S_2 a time τ later. The return is $\frac{S_2}{S_1} - 1$. Suppose that instead you had sold at price S_1 and bought later (thus closing your position) at price S_2 a time τ . The return is now $\frac{S_1}{S_2} - 1$. Not knowing the direction of the security price, Ilinski and collaborators [1, 2] argue that it is natural to form a strategy where you buy and sell simultaneously. Then the return is $\frac{S_1}{S_2} + \frac{S_2}{S_1} - 2$. In the limit of small time increment, the return per unit time is ²

$$\frac{1}{\tau} \left[\frac{S_1}{S_2} + \frac{S_2}{S_1} - 2 \right] \approx \frac{\tau}{2} \left(\frac{\delta \ln S}{\delta \tau} \right)^2. \quad (1)$$

Plugging this expression in the postulated exponential probability for such an event to occur, we get the Wiener integral [8] whose solution is well-known to be the Gaussian distribution, hence the log-normal distribution for the log-price. In addition, the Wiener integral is the mathematical integral description of the random walk process. This is at the core of the Edwards’ model of polymers [9]. This is the essence of the “intuitive” derivation of Ilinski and collaborators [1]. Superficially, this seems to substantiate the choice of the exponential form of the probability, here in question. But this justification is based on the specific choice of the constructed portfolio. There are many different securities with complex non-linear dependence on underlying stocks and it is not clear at all what warrants this approach. One could argue that the Boltzmann weight assumption is not restrictive until one does specify the action. Basically, the question is about the action. Ilinski and collaborators [1, 2] follow standard arguments for small fluctuations and propose a quadratic action. The problem is that the quadratic form depends on the exponential Boltzmann weight assumption and on the choice of the portfolio. For instance, consider the choice of the magnetization M as the natural variable to describe a magnetic material. It leads to the Landau potential with a leading quadratic term. In contrast, suppose an alien was to choose $\log M$ as the natural variable. Then,

²This portfolio gives a certain return! But it is very small. With a typical daily price variation of about 1%, the return of this “long+sell” strategy is 0.005% per day or 1.25% per year.

the theory in terms of $\log M$ becomes highly involved with a multifractal structure.

Let us now examine the standard alternative derivation. Make an investment where you buy a security at price S_1 and sell it at price S_2 a time τ later. The corresponding return per unit time is $\frac{\delta \ln S}{\delta \tau}$. Now, following Bachelier, the absence of arbitrage opportunities corresponds to assume that $\frac{\delta \ln S}{\delta \tau}$ is random, with no memory :

$$\frac{\delta \ln S}{\delta \tau} = \eta(\tau) , \quad (2)$$

where η is a white noise with an arbitrary distribution. This is nothing but the equation of a random walk. By the central limit theorem, we retrieve the usual log-normal result. Expression (2) is the stochastic differential equation solution of the Wiener integral, thus showing the link between the two approaches. There is thus nothing particular in the derivation of Ilinski and collaborators [1]. A completely similar correspondence holds for their derivation [2] of the Black and Scholes option pricing equation. Their idea here is to construct the relevant portfolio and transaction steps, then take the continuous time limit and go to the limit of no uncertainty which amounts to take the stationary solution of the exponential weight. The limit of no uncertainty is nothing but the standard replication argument of Black and Scholes [10] for a complete market.

In conclusion, the idea of Ilinski and collaborators [1, 2] is potentially very interesting. However, the results on the log-normal distribution and the Black and Scholes equations are not proof of the correctness of the theory or even of its relevance. The same can be said for other general theories : general relativity is not correct because it reduces to Newton gravitation at small energies. This is only a requirement of correspondence (this point is indeed emphasized in Ref.[1, 2]). Other principles must apply to justify its construction. The concept of arbitrage is probably correctly advanced as a fundamental ingredient of the theory. The problem is that the theories that incorporate this ingredient are non unique. In fact, the finance litterature is all about arbitrage. Ross [11] wrote probably the first paper concerned with the essential role of the no-arbitrage condition in valuation. This led afterwards to the development of the general theory of asset pricing in terms of a valuation operator (the so-called stochastic discount factor) [12]. The problem, that any theory must face, is that for real (incomplete) markets, the valuation operator is not unique. The fundamental question is : which valuation operator should be used? How then does the gauge formulation of finance help shed light on this problem?

I acknowledge stimulating exchanges with K. Ilinsky, L. Martellini, D. Stauffer and B. Urošević.
