We consider a one-dimensional model consisting of an assembly of two-velocity particles moving freely between collisions. When two particles meet, they instantaneously annihilate each other and disappear from the system. Moreover each moving particle can spontaneously generate an o spring having the same velocity as its mother with probability 1 $\,$ q. This model is solved analytically in mean-eld approximation and studied by numerical simulations. It is found that for q = 1=2 the system exhibits a dynamical phase transition. For q < 1=2, the slow dynamics of the system is governed by the coarsening of clusters of particles having the same velocities, while for q > 1=2 the system relaxes rapidly towards its stationary state characterized by a distribution of sm all cluster sizes.

I. IN TRODUCTION

B allistically-controlled reactions provide sim ple exam ples of non-equilibrium systems with complex kinetics and have recently attracted a lot of interest [1{9]. They consist of an assembly of particles moving freely between collisions with given velocities. When two particles meet, they instantaneously annihilate each other and disappear from the system.

Depending on the initial velocity distribution, two classes of asym ptotic states have been observed in one dim ensional system s. In general, for continuous initial velocity distribution [3,10], as well as for some special case of discrete velocity distribution (symmetric two-velocity distribution [1,2,5], or symmetric trimodal velocity distribution with a su ciently small fraction of immobile particles [6,7]), the steady-state turns out to be empty and it is approached algebraically in time. The dynam ical exponent characterizing the time decay depends on the initial velocity distribution and it is still not com pletely clear how to characterize the universality classes for this problem [10]. On the contrary, for some discrete velocity distribution, the stationary state m ay not be empty, but may contain particles moving all with the sam evelocity (for exam ple non-sym m etric bim odal velocity distribution [1,5] or a trim odal velocity distribution with more than 25% of particles initially at rest [6,7]). This non-interacting state is generally approached with an exponentially fast decay.

A richer behavior can be expected in a system with, in opposition to the ballistic annihilation case, an interacting steady-state. This can be achieved by constantly bringing new particles in the system by some suitable mechanism. A possibility is to allow branching processes: ballistically moving particles can spontaneously generate, with a given branching rate, some o springs. A coordingly, one speaks of ballistic branching-annihilation.

The problem of branching-annihilation has been recently studied in the fram ework of a di usive dynam ics [11,12]. The simplest example of such a system would be one with a single species of particle A, undergoing diffusive behavior, single { particle annihilation A ! ; , and branching A ! 2A. There is always a trivial absorbing state, with no particles. For su ciently low branching rate, this is the only stationary state, but for larger values of this rate, another non-trivial active' stationary state appears. This stationary state phase transition belongs to the directed percolation universality class [13]. A slightly more complicated class of model are reactiondi usion system s with the underlying reaction processes 2A ! ; and A ! (m + 1)A, with m even. It turns out that for these models the critical exponents are not the ones of directed percolation but belong to a new universality class [11,12] characterized by branching and annihilating walks with an even number of o springs. The constraint of local 'parity' conservation is the reason for the existence of this new universality class.

Our aim here is to study the problem of ballistic branching-annihilation (BBA) in one dimension forwhich interesting new properties can be foreseen. The paper is organized as follows. In section II, the BBA model is de ned. The exact dynamical equations of motion are derived for the one dimensional case. In section III, the dynamics of the model is studied within a mean-

eld like approximation. In particular, the phase diagram of the steady-state is established in terms of the di erent parameters of our model. In this approximation, the steady-state is always approached exponentially fast. Section IV is devoted to num erical simulations of the one dimensional model. It is shown that uctuations plays a crucial role. Indeed, as in the mean-eld approxim ation, a phase transition occurs when the probability that the o spring takes the velocity of its mother is q = 1=2; how ever, for q < 1=2 the dynam ics is be governed by the coarsening of clusters of particles having the sam e velocity, and the system approaches a completely lled stationary state with a power law decay. For q > 1=2, there is no coarsening and the system relaxes rapidly towards a non-lled stationary state. Finally, the results are discussed in section V.

II.THE MODEL

We shall rst de ne precisely the BBA model studied and secondly derive the corresponding equations of motion.

A.De nition of the model

We consider a one-dimensional system composed of particles of size initially uniform ly random ly distributed in space. Moreover, at t = 0, the velocities of the particles are random independent variables distributed with the symmetric bin odal distribution:

$$P(v) = \frac{1}{2} (v c) + (v + c)$$
(1)

The dynam ics consists of two mechanisms:

The ballistic annihilation: Two particles making contact (with opposite velocities) disappear instantaneously.

The branching: during the time interval [t;t+ dt], the follow ing branching processes take place:

 A particle with coordinates (position and velocity) (x; c) produces with probability p(1 q)dt a pair of particles with coordinates (x ; c) and (x; c).

- 2. A particle with coordinates (x; c) produces with probability podt a pair of particles with coordinates (x; c) and (x; c).
- 3. A particle with coordinates (x; c) produces with probability p(1 q)dt a pair of particles with coordinates (x; c) and (x + ; c).
- 4. A particle with coordinates (x; c) produces
 with probability pqdt a pair of particles with coordinates (x; c) and (x + ; c).

(the particular choice of the position of the new ly created particle has been m ade in order that, independently of its velocity, a child cannot collide with its m other at birth.) Thus the parameter 0 p 1 characterizes the overall branching rate, while the parameter 0 q 1 characterizes the probability that the o spring has a velocity opposed to the one of its m other. The particular case p = 0 corresponds to the pure ballistic annihilation problem previously studied [1,2,5,6].

B.Exact equations of m otion

W e can now derive the equations of motion describing the dynam ics of the system . In the particular case p = 0, a kinetic equation for the two-particle conditional distribution of nearest neighbors was derived as a rigorous consequence of the dynam ics of ballistic annihilation [5,6]. This equation completely described the evolution of the system when initially higher order conditional distributions factorized into products of two-particle ones. It was then possible to extract exactly and analytically the long time behavior of the particle density for several velocity distributions. Unfortunately, this property is no longer valid in the case with branching. Having not been able to nd an observable in which one is able to reproduce this exact closure, one has to face the usual problem of dealing with a complete hierarchy of coupled equations [14]. It seems thus hopeless to nd an exact analytical solution to these equations. A coordingly we shall only write the equation for the one-particle density distribution $_1(x;v;t)$. In section III, this equation will be solved using a mean-eld approximation.

A careful bookkeeping of the possible dynamical processes leads to the following equations:

and

h X
$$Z$$
 i
+ p(1 q) 1 (x ; c;t) dy 2 (x ; c;x + y;v;t) (3)
 $v = c^{0}$

where $_{2}(x_{1};v_{1};x_{2};v_{2};t)$ is the joint two-particle density to nd a particle in the state $(x_{1};v_{1}) \sin u$ taneously with another in the state $(x_{2};v_{2})$ at time t.

The right-hand side of equation (2) can be interpreted in the following way: the st term describes the annihilation of a particle (x;c) with a particle of opposite velocity. It is given by the product of the density of a collision con guration $[_2(x;c;x + ; c;t)]$ with the frequency of such an encounter (2c=). The second term describes the branching of a particle of velocity c, at position x , giving birth to a particle of velocity + c at position x. This is only possible if no other particles are present in the interval [x;x+] (otherwise there will be an overlap between two particles) and it happens with the rate pq. F inally, the third term describes the creation with rate p(1 q) of a particle whose mother have the same velocity. The same restriction as in the previous case applies.

O ne can in principle write the equation of motion for $_2$ along the same lines. However, we shall not give here this cum bersom e equation, as we are not going to use it.

For simplicity, we shall only consider spatially hom ogeneous system. We can thus write $_1(x;v;t) = _1(v;t)$ and $_2(x_1;v_1;x_2;v_2;t) = _2(x_1 x_2;v_1;0;v_2;t)$. Introducing then the observable (t) $_1(c;t) _1(c;t)$, one easily shows that it is an exactly conserved quantity when q = 1=2. This feature re ects the particular choice of rule, which are precisely symmetric when q = 1=2. A s a consequence, one expects our model to exhibit a particular behavior at this point.

III.M EAN FIELD ANALYSIS

A rst attempt to obtain information about ourmodel is to apply a mean-eld approximation on equations (2) and (3). One then assumes the following factorization:

$${}_{2}(x_{1};v_{1};x_{2};v_{2};t) = {}_{1}(x_{1};v_{1};t) {}_{1}(x_{2};v_{2};t)$$

$${}_{1}(v_{1};t) {}_{1}(v_{2};t);$$

$${}_{2}(4)$$

(the last equality holds for a spatially hom ogeneous system).

It is then suitable to introduce in addition to the variable the second variable:

(t)
$$_{1}$$
 (c;t) + $_{1}$ (c;t); (5)

Equations (2) and (3) lead to

$$\frac{d}{dt} = p(1) c(2^{2});$$
 (6)

and

$$\frac{d}{dt} = p(1 \quad 2q)(1 \quad)$$
 : (7)

The form al solution of this last equation is

A s before, one sees that the value q = 1=2 plays a special role. Indeed, two regimes have to be distinguished:

1.For 0 q < 1=2: the exponential term diverges
unless (1) ! 0 as t ! 1 . Thus a possible
stationary solution is</pre>

$$_{s} = \frac{1}{;}$$
 $_{s}^{2} = \frac{1}{_{2}};$ (9)

In the particular case q = 0, the time dependent solution can be obtained explicitly as shown in Appendix. For t ! 1, one recovers the above stationary solution.

2. For 1=2 < q 1: in this case, a possible stationary solution is

$$_{s} = 0; \quad _{s} = \frac{1}{2} (1 + c = p)^{1}; \quad (10)$$

Is is straightforward to verify that the above stationary solutions are stable and are approached exponentially in time.

M oreover, when q = 1=2 the complete time dependent solution can be obtained. From equation (7), one indeed nds (t) = const = $_0$, and thus equation (6), becomes

$$\frac{d}{dt} = p \qquad (c+p)^2 + c^2_{0}; \qquad (11)$$

whose solution reads

$$(t) = \frac{p}{2(c+p)} + \frac{A \cosh(At) + A (c+p) \sinh(At)}{A \cosh(At) + (c+p) \sinh(At)};$$
(12)

with A =
$$p^2=4+c(c+p) {}_{0}^{2}$$
 and = (0) p=[2(c+p)].
The stationary state is then given by $s = {}_{0}^{0}$ and
 $q = {}_{s}(q = 1=2) = p + {}_{p^2}^{2} + 4c(c+p) {}_{0}^{2}$ (c+p):
(13)

Here again, one sees from equation (12) that the steady state is approached in an exponential way. As already noted, (t) is an exactly conserved quantity for q = 1=2. The mean-eld stationary phase diagram is shown in Fig.1. The stationary value $_{\rm s}$ is plotted against q for

a xed value of $p \in 0$. The interesting feature is the presence of a gap (p) for q = 1=2 given by

$$(p) = \frac{1}{-1} \frac{1}{1+c=p}$$
: (14)

(p) decreases as p increases. W hen q < 1=2, $_s = 1=$ for all values of p (completely led state), while for q > 1=2, $_s$ increases m onotonically with p. The dependence is linear for small p, but $_s ! 1=$ when p ! 1.

FIG.1. M ean-eld phase diagram : the stationary value of the averaged density $_{\rm s}$ is plotted against q for a xed value of p.

IV . NUMERICAL SIMULATIONS

In view of the situation when p = 0 [1,2,5], one can anticipate that the uctuations will also play an important role in the case with branching. One way to deal with the complete problem, including uctuations, is to perform num erical simulations.

The simulations were performed for a one-dimensional periodic lattice with typically 2^{17} sites. The velocity of each particle was drawn from a symmetric bimodal distribution. However, on computational grounds, the particle velocities were chosen to be $(0;c^0)$ (with $c^0 > 0$). The results for our model de ned in section II can be recovered by performing a simple Galilean transform ation and putting $c = c^0=2$. The particle size is the lattice spacing, and the discretized time step is given by $= = e^{2}$.

The algorithm used to simulate the dynamics is the following. During one time step $\,$, the three following processes occur sequentially:

- 1. Ballistic motion: independently of the occupation state of the sites, the particles with velocity $c^0 m$ ove one site to the right.
- 2. Annihilation: two particles located on the sam e site disappear.

3. Branching: for each remaining particle, one draws two random numbers, r_p and r_q , uniform ly distributed in the interval [0;1]. One o spring particle is added to the left (right) nearest neighbor of a particle with velocity c^0 (0) if the site is en pty and if r_p is the less than a given value p. Hence, p is the probability of branching. This new particle takes the velocity of its mother with a certain probability 1 q, i.e. if $r_q > q$ (and the other velocity of the same site (thus born from two di erent mothers), they annihilate instantaneously.

For each of the above di erent steps, the sites were updated simultaneously. The simulations were run on a Connection M achine CM -200 and the data averaged over 10 independent realizations. Them ean initial density for all the simulations was 0.5, with, in average, the same densities of both kinds of particles. We have also shown that our results obtained for lattice of 2^{17} sites were free of nite size e ects.

Note that when a particle branches, it can create at most one particle during a time step \therefore As a consequence, this lim it the value of p that can be explored through the simulations. Indeed, the branching rate p is related to p via

$$p = p$$
 : (15)

Thus using the denition of and c_r one nds

$$\frac{p}{c} = 2p:$$
(16)

p being a probability, the adim ensional branching rate p = c can only take values between 0 and 2.

We can now discuss the numerical data obtained using the above algorithm. Two kinds of quantities have been investigated: rst, the time dependent density with particular emphasis on the stationary states and the way these stationary states are approached; second, a more m icroscopic quantity, namely the time dependent cluster size distribution P (`;t) in the system and some of its moments. These quantities are well suited to describe the coarsening process present in the system.

As in the mean- eld approach and as expected from the last remark of section II, the value q = 1=2 turns out to play a particular role and three regimes have to be distinguished.

1. For 0 q < 1=2: The time evolution of the particle density (t) is shown in Fig. 2 for several values of p. C learly, the system reaches a stationary state $_{s} = 1 =$ in agreement with the mean-eld prediction. However, as shown in Fig. 3, the stationary state is approached as $_{s}$ (t) t $^{1=2}$. This power law establishes after a crossover time roughly proportional to 1=p.

FIG.2. Time evolution of the particle density (t) as a function of time t for q = 0.1 and several values of p.

2. For 1=2 < q 1: The time evolution of the particle density (t) is shown in Fig. 4 for several values of p. As depicted on Fig. 5, the stationary value of the density depends both on p and q. For p < 0:1, it is well tted by</p>

$$_{s}(p;q) pexp(0:55=q);$$
 (17)

M oreover, for p large enough $_{\rm s}$ is not increasing m onotonically as a function of p, but $_{\rm s}$ exhibits a maximum and then slightly decreases as p increases. As shown in Fig. 6, the stationary state is approached in an exponential way according to $_{\rm s}$ (t) exp(Apt), where A may depend on q.

3. The limit case q = 1=2 is more di cult to investigate due to the slow decay towards the stationary state. In fact for p > 0.3, there are evidences that the stationary state is completely lled, i.e. s = 1=. For smaller values of p the simulations do not allow us to draw any conclusions, as shown in Fig. 7.

Nevertheless, for q < 1=2, one has $_s = 1=$, for all values of p while for q > 1=2, equation (17) shows that, at least for small p, $_s \notin 1=$. Thus for small p, $_s$ has a jump at q = 1=2, and we believe that such a jump will be present for all nite values of p.

FIG.3. s (t) versus t in a double logarithm ic scale, for q = 0.1 and several values of p. For comparison, the full line represents t ¹⁼². This decay establishes after a crossover time which behaves as =p.

FIG.4. Time evolution of the particle density (t) as a function of time t for q = 0.9 and several values of p. The stationary state is reached after a time of order 10 =p.

FIG.5. The stationary values of the averaged density $_{\rm s}$ is plotted against p, for several values of q > 1=2, obtained by num erical simulations.

FIG.6. Sem i-logarithm ic plot of (t) $_{\rm s}$ versus t for q = 0:9 and p = 0:01. The exponential approach towards the steady state establishes for t= ' 250.

FIG.7. Time evolution of the particle density (t) as a function of time t for q = 0.5 and several values of p. For sm all values of p (less than 0.3), we are unable to extract the steady-state density, for CPU reasons.

We can now consider the properties of the clusters present in the system at a given time. The qualitative situation is well illustrated by the two snapshots in Fig. 8. They represent the time evolution of a 512-site system during 1024 iterations. M oreover, a change of reference fram e has been perform ed such that the particle velocities appears to be c. Depending on q, one observes totally di erent pictures. In the case p = 0.7; q = 0.1(Fig. 8a), large clusters (of sim ilar particles) are present. They are separated by two types of interfaces: vertical ones (which are stable) and rough ones. The dynam ics of the system is totally governed by the random walks of the rough interfaces. During the time evolution, one rough interface may collide with a stable interface leading to the coalescence of two clusters into a large one. In the case p = 0.7; q = 0.9 (Fig. 8b), the sizes of the clusters are rather sm all and there is no stable interfaces. The dynamics is of a di erent type.

A more quantitative description is given by the investigation of the time dependent cluster size distribution P (';t). In the domain 0 q < 1=2, where coarsening is observed, one expects [15] that P (';t) will obey to a scaling form :

FIG.8. Time evolution (vertical axes) of the congurations for a chain of 512 sites (the initial density is approximately one half) and for 1024 time iterations. The white pixels indicate sites without particle, the grey ones, sites with a particle towards the right and the black ones, sites with a particle moving towards the left. Fig. a is for p = 0.7, q = 0.9 while Fig. b is for p = 0.7, q = 0.1.

In Fig. 9, we plot the scaling function obtained by the collapse of the data for p = 0.7; q = 0.1, with = 1 and = 0.5. Although the plot is very noisy, one still notes that the scaling function (z) has a very particular shape, with a sharp maximum at $z = z_{m ax}$. The value of $z_{m ax}$ increases slow ly with q, going from 0.4 for q = 0.1 to 1.2 for q = 0.4.

A better way to extract the exponents and is to consider the n-th order m om ents of the distribution dened as:

$$h^{n} i = \frac{\frac{R_{1}}{R_{1}} d^{\prime n} P(\prime;t)}{\frac{d^{\prime P}(\prime;t)}{d^{\prime P}(\prime;t)}}$$
(19)

which according to the scaling form given by equation (18), should behave as:

$$h^{n}i t^{n} = t^{n}; \qquad (20)$$

while

Ζ

Thus, the two above relations allow us to determ ine the exponents and . The values of $_n$ for n = 1;:::;6 are shown on Fig. 10 for p = 0.7, q = 0.1. A good t is obtained for = 0.48 0.02 and = 0.96 0.04, in very good agreement with our collapsed plot. By repeating our analysis for other values of q (nam ely, 0.2, 0.3 and 0.4), the same values for the exponents t reasonably well the data.

For q = 1=2, the di erent moments of the cluster size distribution are $_1 = 0.33$, $_2 = 0.96$, $_3 = 1.60$, $_4 = 2.22$, $_5 = 2.82$ and $_6 = 3.40$. These exponents

are of the form $_n = 0.26 + 0.61n$ which is not compatible with the relation (20). This probably shows that the simulations have not yet reached the true asymptotic regime. Moreover, as shown on Fig. 11, P (';t) is of the form :

FIG.9. Scaling form of the cluster sizes distribution for p = 0.7; q = 0.1. P (';t)t is plotted versus 't for = 1 and = 0.5.

FIG.10. Exponent $_n$ (open circles) of the n-th moment of the cluster distribution function for n = 0; :::; 6 and p = 0:7; q = 0:1. The line is the t $_n = 0:01 + 0:48n$.

P (';t) t
$$^{1=3}$$
 ' $^{4=3}$; (22)

over two decades in the variable '. Note that equation (22) cannot be valid for arbitrary large ', because the moments of P (';t) diverge with the upper limit of integration.

F inally, in the domain 1=2 < q 1, where no coarsening is observed, the system approaches very rapidly its stationary state and no dynam ical scaling has been found for the cluster distribution. However, in the stationary state, the cluster distribution takes the form :

$$P(') = C_1 \exp(C_2')$$
 (23)

where C_1 and C_2 are two constants.

V.INTERPRETATION OF THE RESULTS AND CONCLUSIONS

The st interesting point is the particular sole played by the value q = 1=2. As already mentioned in section II, for q = 1=2, one notes the presence of an extra conservation law in the system. The di erence between the average local density of particles with positive and negative velocities is strictly zero. It is well known that conservation laws has a great in uence on the dynam ics of non-equilibrium statistical system s. A coordingly, one m ay expect that the dynam ics in q = 1=2 is particular.

FIG.11. Scaling form of the cluster sizes distribution for p = 0.7; q = 0.5. P (';t)t¹⁼³ is plotted versus ' in a double logarithm ic scale. The full line represents ' $^{4=3}$.

In view of the scaling properties of the problem it may be useful to think about it in terms of dynamical renormalization group. Based on the results of both meaneld approximation and the numerical simulations, one is lead to conjecture the presence of three xed points in this system . An unstable \critical" xed point at q = 1=2and two attractive xed points at q = 0 and q = 1.

W hen q < 1=2, the branching processes favors the apparition of pair of consecutive particles with the same velocities and the dynam ics is governed by the attractive xed point at q = 0. Large particle clusters with opposite velocities are form ed during the tim e evolution and two kinds of interfaces are present into the system (see Fig. 8a). First, let us consider the interface between two clusters of colliding particles and call this type of interface I1. Such interface has a very long life. Indeed, the probability that a vacancy presents at one of the extrem ity of a cluster of size L traverses the cluster and perturbates the interface is of the order of $(1 p)^{L}$. Thus, an interface I_1 is very stable in the long time lim it where the system is made up of large clusters. The second type of interface, called I2, separates non-colliding clusters. Thus it has not necessarily a one site extension, but it can be wider. Hence, its behavior is more subtle. Three di erent regim es m ay be considered. The sim plest case to discuss is when p = c > 1. In this case, the interface I_2 is typically form ed by only one em pty lattice site, whose dynam ic is di usive. Indeed, one can show that both boundaries of an interface I_2 perform a Brownian motion. Moreover, when p = c > 1, this random walk is biased, so that both

boundaries tend to com e closer together. For su ciently long time, the initial gap separating two non-colliding clusters will shrink to one single site, which will perform a random walk. Eventually, this hole will encounter an I₁ interface, permitting the coalescence of two clusters into a larger one. The random walk aspect of this dynamics is responsible for the slow approach towards the stationary state (in t $^{1=2}$) observed in the simulations. W hen p = c = 1, the boundaries of an interface I_2 both perform an unbiased random walk. Accordingly, the initial gap between two non-colliding clusters will not, on average, vary. However, because of the BBA dynam ics, this gap will eventually shrink to a single site, either through a creation of cluster inside the gap when $q \in 0$, or through the coalescence of two interfaces. Thus the previous argum ent holds. Finally, when p = c < 1, the situation is sim ilar: although the boundaries of I₂ perform a biased random walk which tends to increase the separation between the two non-colliding clusters, the coalescence of two interfaces or a creation of a new cluster inside the gap (if q f 0) will llup this space in a more e cient way.

Eventually, the stationary state is completely lled, only one cluster remains and the annihilation process do not act anym ore. For values of q not too far from 1=2, this asymptotic behavior will show sup only for very long times. A coordingly, the results of the (nite time) numerical simulations may still be a exted by the properties of the critical xed point at q = 1=2, and the dynamics will exhibit some crossover behavior.

In the situation q > 1=2, a majority of pairs of particles with opposite velocities are created during branching. Due to the annihilation processes, those particles will prevent the formation of large clusters of particles. O nem ay anticipate that the long time dynam ics is governed by the other attractive xed point corresponding to q = 1. The dynam ics is no longer governed by coarsening mechanism but only by the dynam ics of small clusters, hence the fast (exponential like) relaxation occurs. D epending upon the value of p, there is a more or less im - portant fraction of empty sites (or holes) into the system. The presence of these two di erent dynam ical regimes explains the jump observed in the stationary density at q = 1=2.

This paper shows once again, that the mean- eld results generally do not hold for low dimensional systems. Whereas the mean- eld approximation predict the exact critical value for q (because the mean- eld equation for is exact when q = 1=2) and the right stationary value of the density when q < 1=2, it is unable to give satisfactory results for the density stationary value for q > 1=2, (see Figs 1 and 5). Unsurprisingly, the mean- eld approximation is also unable to predict the power law approach to the stationary state when q < 1=2, which is obviously governed by uctuations. More surprisingly, its prediction of an exponentially fast approach towards the steady state when q > 1=2 is (qualitatively) well veried. However, to better understand this problem, it would be usefulto be able to nd an exact analytical solution at least for the three xed point cases (q = 0;1=2 and 1 for arbitrary values of p) as a support to the above qualitative picture. Unfortunately, we were not able until now to nd such exact solutions.

In conclusion, one sees that this simple BBA problem with one o spring exhibit already a very rich behavior. The case with two orm ore o springs is a completely open question.

APPENDIX A:

In this Appendix, we give an explicit solution to the mean-eld equations (5) and (6) for the case q = 0. Equations (5) and (6) lead to

$$\frac{d}{dt} \qquad \frac{d}{dt} = c (2^{2}): \qquad (A1)$$

Multiplying eq. (A1) by 2 , and introducing (t) = (t), eq. (A1) becomes

$$\frac{d}{dt} = c (^{2} 1);$$
 (A2)

R

whose solution is

$$(t) = \frac{1 + (0) + [(0) \ 1] \exp c_{0}^{N_{t}} ()d}{1 + (0) \ [(0) \ 1] \exp c_{0}^{N_{t}} ()d} : (A3)$$

If (0) = 1, then (t) = 1 and one nds (t) = (t) for all times, where (t) obeys

$$\frac{d}{dt} = p(1) ; \qquad (A 4)$$

whose solution is

(t)
$$^{1} = + \exp(pt)[(0)^{1}]$$
: (A 5)

Note that in these particular cases, only particles with velocity + c (or c) are present in the system at all times. If (0) \oint 1, one nds

$$\frac{d}{dt} = p(1) \qquad) = p \qquad (A 6)$$

$$1 \quad \frac{1+ (0) + [(0) \ 1] \exp \ c_0^{0} \ ()d}{1+ (0) \ [(0) \ 1] \exp \ c_0^{0} \ ()d} \quad :$$

As j (t) j is a nondecreasing function of time, when $t \mid 1$, the square bracket in eq. (A 6) approaches 1

depending on the sign of (0). Thus, eq. (A 6) reduces to eq. (A 4).
