A bstract

All systems in therm al equilibrium exhibit a spatially variable energy landscape due to therm all uctuations. Thus at any instant there is naturally a therm odynam ically driven localization of energy in parts of the system relative to other parts of the system. The speci c characteristics of the spatial landscape such as, for example, the energy variance, depend on the therm odynam ic properties of the system and vary from one system to another. The tem poral persistence of a given energy landscape, that is,

the way in which energy uctuations (high or low) decay toward the thermal mean, depends on the dynam ical features of the system . We discuss the spatial and tem poral characteristics of spontaneous energy localization in 1D anharm onic chains in therm al equilibrium.

1 Introduction

The pioneering work of Ferm i, Pasta and U lam¹ demonstrated that a periodic lattice of coupled nonlinear oscillators is not ergodic, and that energy in such a lattice may never be distributed uniform ly. A great deal of work has followed that classic paper trying to understand how energy is distributed in discrete nonlinear system s.²⁽⁷⁾ Speci cally, the possibility of spontaneous energy localization in perfect anharm onic lattices has been a subject of intense interest.⁷⁽¹³⁾ The existence of solitons and m ore generally of breathers and other energy-focusing mechanism s, and the stationarity or periodic recurrence or even slow relaxation of such spatially localized excitations, are viewed as nonlinear phenom ena with in portant consequences in m any physical system s.^{10,14,15}

The interest in the distribution and motion of energy in perfect arrays arises in part because localized energy in these systems may be mobile, in contrast with systems where energy localization occurs through disorder. The interest also arises because such arrays may them selves serve as models for a heat bath for other systems connected to them $.^{16}$ A locit in di erent contexts, \perfect" arrays serving as energy storage and transfer assemblies for chem ical or photochem ical processes are not uncom m on $.^{17,18}$

The study of anham onic chains and of higher-dimensional discrete arrays has been less than system atic, certainly an inevitable consequence of the breadth and m athem atical di culty of the subject. Some studies (including the work of Ferm i, Pasta, and U lam) deal with m icrocanonical arrays. Here one observes the way in which a given constant am ount of energy distributes itself am ong the elements of the array. The notion of \tem perature" usually does not enter in these discussions, although such an association could be m ade if the energy is random ly distributed. O ther studies of anham onic chains (farm ore limited in number) deal with systems subject to external noise and other external forces. The questions of interest here involve the ways in which noise can enhance (as in noise-enhanced signal propagation¹⁵) or even totally modify (as in noise-induced phase transitions¹⁹) the properties of the nonlinear array. Even m ore limited has been the study of systems that are in them al contact with one or more external heat baths maintained at a constant temperature.^{10,12} Here the questions usually revolve around the robustness against therm al uctuations of stationary or quasi-stationary solutions of the microcanonical problem. In both microcanonical and canonical systems, some work concentrates on stationary states or long-time behavior or equilibrium properties of the array, while other work deals with transport properties or with the approach to equilibrium. Furtherm ore, there is variation in the portion of the potential where the nonlinearity resides. Thus, in some cases the elements of the array are them selves nonlinear while in others it is the coupling between elements that is nonlinear (and, on occasion, both are nonlinear).

W ithin this broad setting, our interest in this paper focuses on one-dimensional arrays of classical oscillators in them al equilibrium 12 An understanding of them al equilibrium properties and the e ects of nonlinearities on these properties is a prerequisite to the perhaps more interesting analysis of the nonequilibrium behavior of anharm onic lattices in the presence of them all uctuations and the approach to equilibrium in such systems. In particular, here we deal with the case of \diagonal anharm onicity," that is, the nonlinearity in our model is inherent within each oscillator in the array (representing, for example, intram olecular interactions), while the connections between oscillators (representing, for example, interm olecular interactions) are ordinary linear springs. The anharm onicity m ay be soft or hard. We explore the conditions that lead to spontaneous energy localization in one or a few of the oscillators in the array, and the tim e it takes for a given energy landscape to change to a di erent landscape. O ne could undertake a parallel study in system s with anharm onic interactions between oscillators (\o -diagonal" anharm onicity). We address such system s in subsequent work.²⁰

The energy landscape is determ ined by the local potential of each oscillator, and by the channels of energy exchange in and out of each of the oscillators. The couplings between oscillators provide one such exchange channel, and the coupling of the array with the heat bath provides the other. We shall see that di erent arrays (soft, hard) behave very di erently in response to these channels. We broadly anticipate our conclusions by revealing that 1) persistent energy localization occurs in arrays of weakly coupled soft oscillators even when strongly coupled to a heat bath (while such localization is absent in the hard chain); 2) persistent localization occurs in strongly coupled hard arrays provided they are weakly coupled to a heat bath (while such localization is absent in the soft chain); 3) quasi-dispersionless m obility of localized energy requires o -diagonal anharm onicity.

These remarks point to the fact that our analysis of anham onic chains in them al equilibrium could start from two \opposite" view points. On the one hand, we m ight start by analyzing uncoupled oscillators in them al equilibrium and then proceed to investigate what happens if we couple these oscillators to one another. This approach focuses on the entropic localization m echanism ¹² and the way in which the coupling between the oscillators eventually degrades it. On the other hand, we m ight start with a coupled isolated chain, focus on energetic localization m echanism s in such a chain,⁷ and then proceed to investigate the ways in which therm all uctuations and dissipation a ect such local structures. Since we are explicitly interested in localization in the presence of therm all uctuations, and since entropic e ects have received far less attention than energetic ones, we choose to follow the form er approach.

Nom atter the sequence of our queries, since here our interest lies mainly in understanding energy localization in a nonlinear discrete array in thermal equilibrium and the way in which thermal ects depend on system parameters, we pose our questions as follows:

How is the energy distributed in an equilibrium nonlinear chain at any given instant of time, and how does this distribution depend on the anharm onicity? In other words, can one talk about spontaneous energy localization in therm all equilibrium, and, if so, what are the mechanisms that lead to it?

How do local energy uctuations in such an equilibrium array relax in a given oscillator? A re there circum stances in the equilibrium system wherein a given oscillator remains at a high level of excitation for a long time?

Can local high-energy uctuations move in some nondispersive fashion along the array? In other words, can an array in therm al equilibrium transmit long-lived highenergy uctuations (if indeed they exist) from one region of the array to another without too much energy loss to dispersion?

The answers to these questions have not been found analytically, and are for that reason most clearly presented in comparative fashion. Starting with an ensemble of uncoupled oscillators at therm all equilibrium, one knows exactly the behavior of a single harm onic oscillator and can say a great deal about the behavior of a single anharm onic oscillator from general therm odynam ic considerations. Thus, for instance, the mean energy of a single harm onic oscillator in them al equilibrium at tem perature T is $E = k_B T$ ($k_B = B$ oltzm ann's constant). This energy is on average divided equally between kinetic and potential (a partition that enters in portantly in questions concerning landscape persistence). A simple virial analysis in mediately shows that a soft anharm onic oscillator in therm al equilibrium has energy greater than $k_B T$ while a hard anharm onic oscillator has energy smaller than $k_B T$. Both share the property of the harm onic oscillator that the average kinetic energy is $k_B T=2$, but their average potential energies di er. One also knows exactly the energy uctuations in a harm onic oscillator: the energy variance ² is equal to $k_B^2 T^2$, and the ratio of to E is therefore independent of tem perature. The energy uctuations are easily determ ined to be greater in a soft oscillator and sm aller in a hard oscillator. From these facts one can arrive at rather de nitive qualitative conclusions regarding the distribution and persistence of energy in ensembles of single oscillators and the e ects of the anharm onicities on these factures.¹²

The situation becomes more complicated when such oscillators are connected to one another. Not only can the oscillators now exchange energy with the heat bath, but there are also coupling channels whereby oscillators can exchange energy with one another. The interplay of these various energy exchange channels and the elects of anharm onicity on this interplay are some of the issues to be addressed in this work.

This paper is organized as follows. In Section 2 we introduce our model and notation. We x some of the parameter values and brie y discuss the numerical methods used in our simulations. Here we introduce the hard, harm onic, and soft local potentials to be compared. In Section 3 we review and illustrate previous results for uncoupled oscillators in therm al equilibrium so as to establish the background for the coupled systems. The phenomenon of \entropic localization," whereby ensembles of single therm alized soft oscillators localize and retain energy more electively than harm onic or hard oscillators, is recalled. In Section 4 we explore the consequences of coupling our oscillators. In Section 5 we brie y address the mobility of energy uctuations in our systems. Finally, Section 6 sum marizes our indiges and anticipates further studies.

2 The M odel and N um erical M ethods

Our system is a one-dimensional chain of N identical unit-m ass oscillators labeled i = 1;2; ;N with harmonic nearest-neighbor interactions and on-site potentials V_i)(that may be hard, harmonic or soft. Here x_i is the displacement of oscillator i from its equilibrium position, with associated momentum p_i . We assume periodic boundary conditions. The Hamiltonian of the system is

$$H = \sum_{i=1}^{N} \frac{p_i^2}{2m} + \frac{1}{2}k(x_i - x_{i+1})^2 + V(x_i) ; \qquad (1)$$

where k is the interm olecular force constant. Figure 1 is a schem atic of the m odel.

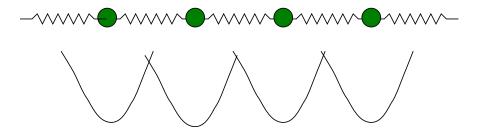

Figure 1: Illustration of the 1D chain considered in this work. Each oscillator in the chain experiences an on-site potential and is harm onically bound to its nearest neighbors.

To represent the therm alization of our chain the model is further expanded to include the Langevin prescription for coupling a system to a heat bath at tem perature T via uctuating and dissipative terms. The stochastic equations of motion for the chain are then given by the Langevin equations

$$x_{i} = k (2x_{i} \quad x_{i+1} \quad x_{i1}) \quad x_{i} \quad \frac{dV(x_{i})}{dx_{i}} + i(t)$$
 (2)

where a dot represents a derivative with respect to time. The $_{i}$ (t) are mutually uncorrelated zero-centered G aussian -correlated uctuations that satisfy the uctuation-dissipation relation:

$$h_{i}(t)i = 0;$$
 $h_{i}(t)_{j}(t^{0})i = 2 k_{B} T_{ij}(t t^{0}):$ (3)

Since we are interested in assessing the elects of anharm on icities on energy localization,

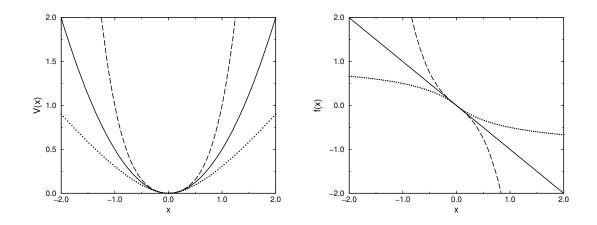

Figure 2: Left panel: the on-site potentials de ned in Eq.(4). R ight panel: the associated forces. Solid lines: harm onic potential, $V_0(x)$. D otted lines: soft anharm onic potential, $V_s(x)$. D ashed lines: hard anharm onic potential, $V_h(x)$.

we start by specifying the on-site potentials to be used in our analysis:

$$V_{0}(\mathbf{x}) = \frac{1}{2}\mathbf{x}^{2}$$

$$V_{s}(\mathbf{x}) = \mathbf{j}\mathbf{x}\mathbf{j} \quad \ln(1 + \mathbf{j}\mathbf{x}\mathbf{j}) \quad (4)$$

$$V_{h}(\mathbf{x}) = \frac{1}{2}\mathbf{x}^{2} + \frac{1}{2}\mathbf{x}^{4}:$$

The subscript 0 stands for the harm onic case, s for the soft and h for the hard. At sm all amplitudes the three potentials are harm onic with a unit natural frequency. Fig. 2 shows the potentials and associated forces.

We end this section with a brief description of the numerical methods used in our simulations throughout this paper. The numerical integration of the stochastic equations for all our simulations is performed using the second order Heun's method (which is equivalent to a second order Runge Kutta integration).^{21,22} We use a time step t = 0.005. The number of oscillators in our simulations ranges between 100 and 1000 and is indicated in each gure as appropriate. In each simulation the system is initially allowed to relax for enough iterations to insure therm al equilibrium, after which we take our \measurements." In all of our subsequent energy landscape representations we have used the same sequence of random numbers to generate the therm all uctuations.

3 Properties of Uncoupled Oscillators: Entropic Localization

In order to understand the equilibrium properties of a chain of oscillators it is useful to rst review the behavior of single (uncoupled) oscillators described by the potentials in Eq. (4).

Suppose rst that our oscillator is isolated. The salient features of anham onic oscillators are that 1) they oscillate with di erent frequencies at di erent energies, and 2) the density of states changes with changing energy. In particular, hard potentials are associated with increasing frequencies of oscillation and sparser densities of states with increasing am plitude (energy); on the other hand, in soft potentials the oscillation frequency decreases and the density of states increases with increasing am plitude.

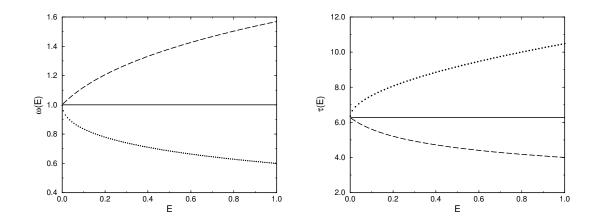

Figure 3: O scillation characteristics of single isolated oscillators. Left panel: frequency as a function of the oscillator energy for the potentials in Eq. (4). Right panel: oscillation periods for single oscillators. Solid lines: harm onic oscillator. D otted lines: soft anharm onic oscillator. D ashed lines: hard anharm onic oscillator.

To get a sense, useful for later analysis, of these and associated oscillator characteristics, we present several gures that show various distinct features of our three types of oscillators. Figure 3 shows the frequencies ! (E) of isolated single oscillators as a function of increasing energy E (which in turn corresponds to increasing am plitude). This frequency is evaluated directly by solving the equation of motion $dx=dt = \frac{p}{2 E} V(x)$ over one period of oscillation at energy E :

$$! (E) = \frac{\sum_{x_{max}} \frac{1}{p \cdot \frac{dx}{2E \cdot V(x)}}}{x_{max}} : (5)$$

The amplitude of oscillation $x_{m ax}$ at a given energy can be found by solving for the positive root of V (x) = E. The harmonic oscillator has a single frequency at unity. The soft and hard oscillators oscillate at unit frequency at low amplitudes (energies) because we have chosen all the oscillators to coincide there, but with increasing amplitude the hard oscillator frequencies increase and those of the soft oscillator decrease. In Fig. 3 we also show the period of oscillations (E) = 2 =! (E). The period increases with increasing energy for the soft oscillator, remains constant for the harmonic oscillator, and decreases with energy for a hard oscillator. This behavior will gure prominently in our subsequent analysis of energy localization.

Next we consider these same single oscillators, but now each connected to a heat bath at temperature T via Langevin term s. The left panel of F ig. 4 shows the norm alized energy distribution P(E) vs E for the three cases. This distribution is given by

$$P(E) = \frac{e^{E = k_{B}T}(E)}{\int_{0}^{1} dE e^{E = k_{B}T}(E)}$$
(6)

where the density of states is just the period of oscillations. The gure supports our introductory comments: rstly, that the average energy of the soft oscillators is greater than that of the harm onic oscillators, whose average energy is in turn greater than that of the hard oscillators; secondly, that the energy uctuations are smallest in the hard oscillator and largest in the soft oscillator. Thus in equilibrium we nd at any instant that there is a greater variability of energy in an ensemble of single soft oscillators than in one of harm onic or hard oscillators. The right panel of Fig. 4 shows the average period of oscillation ($k_B T$) for a therm alized distribution:

$$(k_{\rm B} T)$$
 dE (E)P(E): (7)

Consonant with the energy dependence of (E), the average period of the soft oscillator increases with tem perature, that of the harm onic oscillator is independent of tem perature, and that of the hard oscillator decreases with tem perature.

The features just discussed are also visible in the energy landscape rendition shown in Fig. 5. A long the horizontal direction in each panel lies an ensemble of 100 independent therm alized oscillators and the vertical upward progression shows how these oscillators evolve with time in the equilibrium system. Here and in all our energy landscape gures

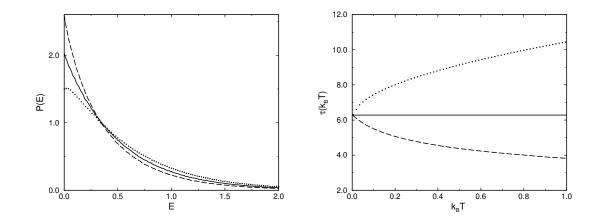

Figure 4: Left panel: energy distribution in single them alized oscillators for the three potentials at $k_B T = 0.5$. Right panel: average oscillation period for the three oscillators as a function of temperature. Solid lines: harm onic potential, $V_0(x)$. Dotted lines: soft anharm onic potential, $V_s(x)$. D ashed lines: hard anharm onic potential, $V_h(x)$.

the y axis covers 120 time units, the same units shown on time axes throughout the paper. Each oscillator is connected to a heat bath. The grey scale represents the energy { an oscillator of higher energy is darker in this portrayal.

The rst thing to note is that along any horizontal line (i.e. at any given time) the soft landscape is darker and grainier than the harm onic, and the lightest and least grainy is the hard oscillator landscape. This rejects the fact that the soft oscillators have the highest energies and the greatest energy uctuations. This observation provides a basis to be used in answer to the rst question posed in the introduction. In an ensemble of independent oscillators in them al equilibrium there is of course a greater energy in some oscillators than in others simply because there are energy uctuations in a system in them al equilibrium. These uctuations are greater in soft anharm onic oscillators than in harm onic or hard anharm onic oscillators.

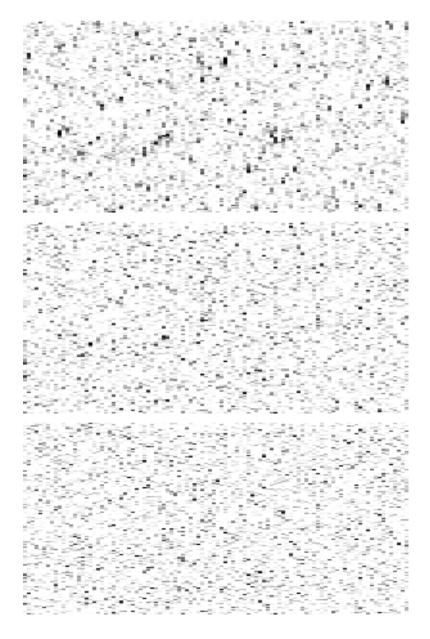

Figure 5: Energy (in grey scales) for ensembles of 100 therm alized independent oscillators as a function of time. The oscillators are lined up (but not connected) along the x-axis and time advances along the y-axis. The temperature is $k_B T = 0.5$ and the dissipation parameter is = 1. Top panel: soft oscillators; middle panel: harm onic oscillators; low er panel: hard oscillators.

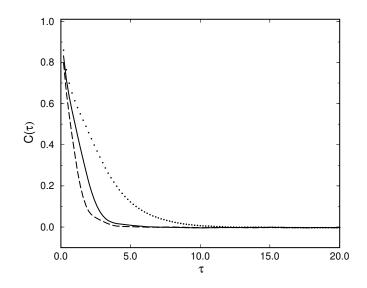

Figure 6: Energy correlation function vs time for independent oscillators with $k_B T = 0.5$ and = 1. Note that the energy changes most slow ly in the soft potential ensemble. Solid line: harm onic potential. Dotted line: soft anharm onic potential. D ashed line: hard anharm onic potential.

The second noteworthy feature of the landscape illustrates the answer to the second question posed in the introduction, namely, how long it takes in an equilibrium ensemble for the uctuations to relax and the energy landscape to change. The trend for our independent oscillators is clear: the soft oscillators retain a given energy for a longer time than do the hard oscillators. This is particularly evident for those oscillators that acquire a high energy through a uctuation: in the soft oscillator landscape the dark streaks are clearly visible. The reason for this behavior becomes clear if we write the equation of motion for the energy $E = p^2=2 + V(x)$ for each oscillator. Setting p = x and using Eq. (2) one not sthat for any type of oscillator

$$E_{-}=p^{2}+p$$
 (t): (8)

Thus, the energy exchange with the surroundings involves only the momentum variable (i.e., the kinetic energy). Consider an oscillator that has acquired a given high-energy uctuation E, and consider how this energy is distributed between the oscillator displacement and momentum. In a harmonic oscillator the energy during one cycle of oscillation is equally partitioned between kinetic and potential. In a soft oscillator, how ever, the energy spends

relatively more time in potential than in kinetic form (and the opposite is true for the hard oscillator). Thus, during the major portion of the cycle the momentum of a soft oscillator is relatively low (while its displacement is large); the energy in the soft oscillator can therefore not enter from and leave to the thermal surroundings as easily as in the other oscillators. The energy relaxation process is therefore slower, and a soft anharm onic oscillator retains a high energy it might have gained via a uctuation for a longer time.¹²

The energy relaxation process visible in Fig. 5 is shown more quantitatively in Fig. 6. Here we have plotted the norm alized energy correlation function

$$C() = \frac{\text{he}(t)\text{E}(t+)\text{i} \text{he}(t)\text{i}\text{he}(t+)\text{i}}{\text{he}^{2}(t)\text{i} \text{he}(t)\text{i}^{2}} :$$
(9)

The innerbrackets indicate an average over timet (200,000 iterations) and the outer brackets an average over an ensemble of 1000 oscillators. The correlation function is normalized so that all energies, high and low, contribute \equally." It is thus a measure of the full exchange of energy with the heat bath, both through the dissipative term and also via the uctuations. We note that the trend in Fig. 6 (slower decay as the oscillators soften) is consistent with the corresponding slowing trend for each temperature in the right panel of Fig. 4. A lso note that on average the energy of an oscillator changes on the time scale of half a period of oscillation, i.e. on the time scale it takes the oscillator to move from one side of the potential well to the other.

We have thus sum marized and illustrated our earlier ndings,¹² namely, that in an array of independent oscillators in them al equilibrium at a given temperature there are larger energy uctuations and longer retention of energy the softer the oscillators. This is an entropy-driven localization, arising from the fact that the density of states in soft oscillators increases with increasing energy. It minimizes the free energy because it is entropically favorable for oscillators to populate phase space regions where the density of states is higher, which in an ensemble of soft oscillators leads to a greater spatial variability than in harm onic or hard oscillators. The tem poral persistence of this greater variability is a consequence of the fact that coupling to a heat bath occurs only via the kinetic energy. In the soft ensemble the energy is in potential form a greater fraction of time than in kinetic form, which is not the case for the other ensembles.

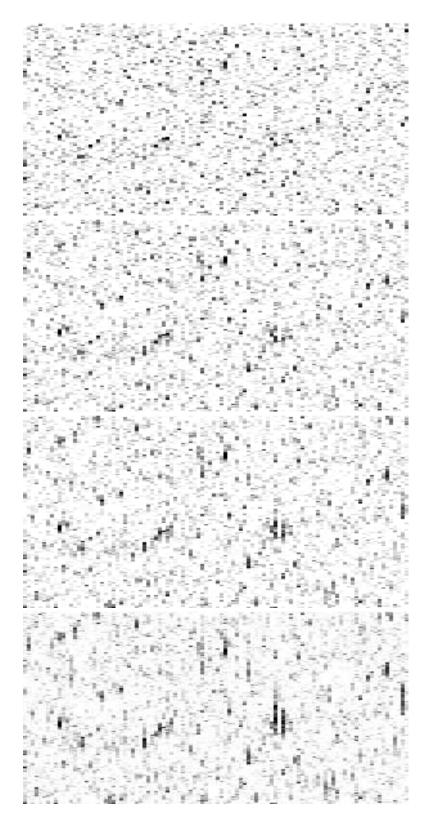

Figure 7: Energy landscapes for therm alized independent soft oscillators as a function of time for di erent temperatures. The dissipation parameter is = 1. Temperatures from top to bottom: $k_B T = 0.1$; 0.5; 1.0 and 2.0.

We gave this scenario the name stochastic localization in our earlier work,¹² but will refer to it as entropic localization, a term that more accurately rejects its physical causes. It is important to stress that entropic localization in soft oscillators is robust in the sense that it becomes more pronounced as temperature increases provided the potential continues to soften, and that it is achieved regardless of the initial condition of the system.

The remaining parameters that can be varied at this point are the dissipation parameter and the temperature. A change in the dissipation parameter does not a ect Fig. 4 since this is an equilibrium distribution. In Fig. 5 a higher dissipation parameter would cause a more rapid decay of energy uctuations (and, correspondingly, a lower dissipation parameter allows an energy uctuation to survive for a longer time). Thus, although high dissipation does not interfere with the appearance of greater energy uctuations in the soft oscillators, it works against the temporal retention of excess energy by any one oscillator. The energy correlation function decays more slow ly for the soft oscillator for any dissipation, and this decay is more rapid (for all the oscillators) as the dissipation increases. In any case, for a given dissipation parameter the softer potential retains energy for a longer time.

The tem perature a ects the quantitative outcome of Figs. 4 and 5. In Fig. 4 the distributions broaden with increasing tem perature, but the di erences between the di erent oscillators remain and, in particular, the fact that the distribution for the soft oscillator is the broadest continues to be true. In Fig. 5 higher tem peratures produce relatively greater graininess in the soft oscillator gure than in the other two. This is clearly observed in the sequence of Fig. 7, which shows the evolution of ensem bles of soft oscillators for di erent tem peratures. A tem perature increase leads to stronger entropic localization and this e ect also appears in the energy correlation functions, as shown in Fig. 8. This behavior is contrasted with that of harm onic and hard anharm onic oscillators, whose energy landscapes and energy correlation functions show essentially no tem perature dependence in this range. The energy uctuations in these latter cases dissipate very quickly. Note that the tem perature dependence of the correlation tim es in plicit in Fig. 8 is consistent with the tem perature dependence of an average period of oscillation of a soft oscillator as shown in the right panel in Fig. 4: with increasing tem perature the correlation tim e continues to be approxim ately half a period.

W ith this background, we are now ready to consider the behavior of chains of oscillators, where everything that we have found so far has to be reconsidered in the face of the

15

additional forces now present through the oscillator {oscillator coupling.

4 Coupled O scillators

In this section we explore the consequences of coupling the oscillators discussed in the previous section with harm onic springs. In this exploration we attempt to bring some order to seem ingly contradictory reports that the coupled oscillators must be hard in order for such an array to localize energy electively, or that the coupled oscillators must be soft in order to accomplish such localization. To anticipate our results: we will show that both claims are correct, but each in a dilerent parameter regime and for dilerent physical reasons. The variable parameters in this discussion are the temperature $k_B T$, the dissipation parameter , and the coupling strength k.

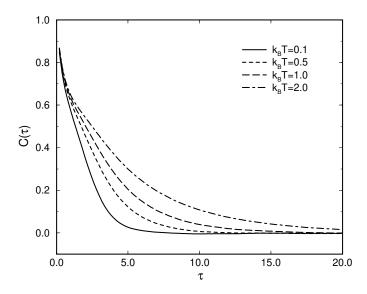

Figure 8: Energy correlation function vs time for independent soft oscillators with = 1 and di erent tem peratures (the same as in Fig. 7).

In order to determ ine the conditions that m ay lead to energy localization in a therm alized chain of oscillators it is useful to investigate the ways in which energy m ay escape from a given oscillator. It is apparent from the Langevin equation (2) that there are now two channels of escape. As in the last section, one is the friction term that dissipates the energy to the bath. The other is the coupling term that transfers energy to the nearest neighbors. The di erence between these two mechanisms is that the dissipation is determined entirely by the kinetic energy of the oscillator. Energy transfer along the chain, on the other hand, while still dependent on the kinetic energy, is primarily determined by the extension or contraction of the springs connecting neighboring oscillators, that is, by the potential energy through the relative oscillator displacements. To make these statements more quantitative, it is useful to generalize the concept of a local energy by de ning a local function whose sum over sites is the total energy of the chain. To include the contribution from the nearestneighbor restoring forces one writes

$$E_{i} = \frac{p_{i}^{2}}{2} + V(x_{i}) + \frac{k}{4} [(x_{i} - x_{i+1})^{2} + (x_{i} - x_{i+1})^{2}]; \qquad (10)$$

and the total energy of the system is then $E = \prod_{i=1}^{P} E_{i}$. The rate of change of the local energy is easily found to be

$$E_{i} = p_{i}^{2} + p_{i}(t) \frac{k}{2} (x_{i} - x_{i+1}) (p_{i} + p_{i+1}) \frac{k}{2} (x_{i} - x_{i-1}) (p_{i} + p_{i-1}):$$
(11)

Note that although this expression does not explicitly involve the potential, the rate of local energy loss of course does depend on the potential through the displacem ents and m om enta.

The dynamics of the local energy will thus depend on the interplay of the therm al (uctuations), dissipative, and intrachain forces. In order to highlight the main comparisons and contrasts, we frequently will juxtapose the behavior of chains for which one or the other of the energy exchange channels is clearly the dom inant one, and in each case assess the e ects of tem perature changes.

The e ect of interoscillator coupling on entropic localization is illustrated in Fig. 9. In this gure we show the system of soft oscillators that were uncoupled in Fig. 7 (speci cally, the case with $k_B T = 0.5$ and = 1), but now providing successively larger values for the coupling constant k. Entropic localization is still apparent for sm all values of k, but as coupling increases there is clear degradation of entropic localization. This is to be expected since energy exchange is sensitive to large oscillator amplitude di erences in soft oscillators.

The associated energy correlation functions

$$C() = \frac{H_{i}(t)E_{i}(t+)i}{H_{i}^{2}(t)i} + \frac{H_{i}(t)iH_{i}(t+)i}{H_{i}^{2}(t)i}$$
(12)

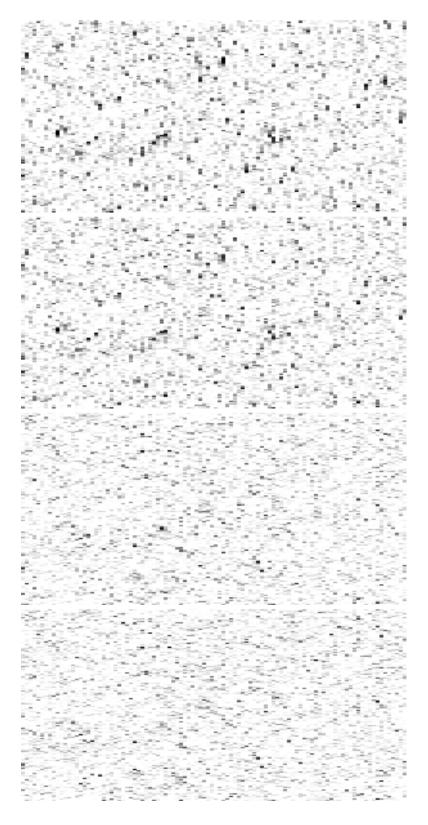

Figure 9: Energy landscapes for therm alized soft oscillators as a function of time. The dissipation parameter is = 1 and the temperature $k_B T = 0.5$. From top to bottom the coupling constants are k = 0; 0:05; 0:5 and 1:0.

for the cases in Fig. 9 are shown in Fig. 10. These curves con m the degradation of entropic localization with increasing k.

We thus turn to chains of coupled oscillators with low dissipation (= 0.05) and focus, in particular, on strongly coupled chains (if both k and are small we know pretty much what happens from the analysis in the previous section). In Fig. 11 we have drawn the energy landscape for the soft (top panel), harmonic (middle panel) and hard oscillators (low er panel) providing $k_B T = 0.5$, = 0.05, and k = 1.0. From this gure it is clearly evident that now the localization of energy at a given site is greater in the hard case than in the harmonic case, and this in turn, is greater than in the soft case. The con rm ing local energy correlation functions for these cases are plotted in Fig. 12. C learly, for a given tem perature the hard array retains energy at a given location for a longer time than do the other two arrays.

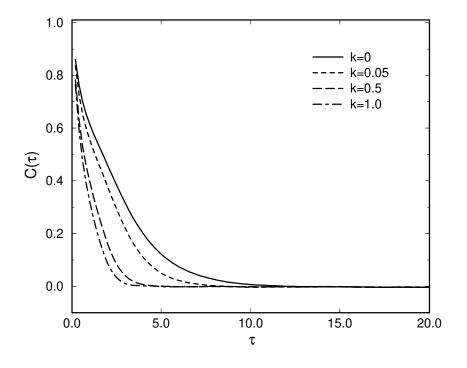

Figure 10: Local energy correlation function vs time for chains of soft oscillators with = 1, $k_B T = 0.5$ and dimension to the coupling constant (same as in Fig. 9).

In the low -, large k regime the elective energy exchange channel is sensitive to the oscillator amplitude rather than to its kinetic energy, so we expect entropic localization in

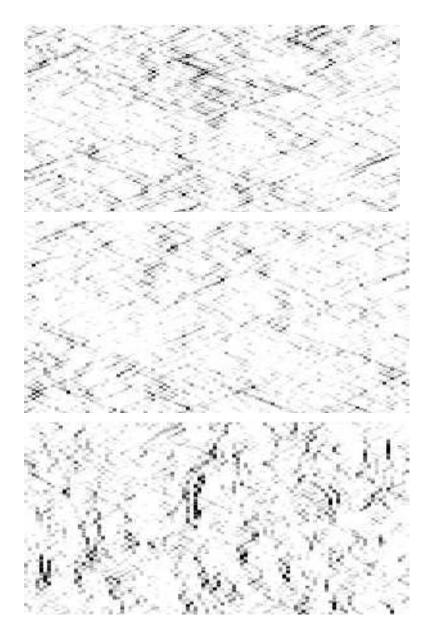

Figure 11: Energy landscapes for therm alized strongly coupled oscillators as a function of time. The dissipation parameter is = 0.05, the temperature $k_B T = 0.5$, and the coupling constant k = 1.0. Top panel: soft oscillators; middle panel: harm onic oscillators; lower panel: hard oscillators.

the soft array to be degraded since soft oscillators have large am plitudes. Furtherm ore, as the harm onic coupling increases it eventually overwhelms the local soft potential and the soft chain becomes an essentially harm onic chain at su ciently large k. On the other hand, hard oscillators exchange little energy via the coupling channel since they do not reach large am plitudes. This, and the fact that dissipation to the bath via kinetic energy (the other energy exchange channel) has been m in in ized (low), leads to persistent energy localization in the hard array. This is an energetic localization mechanism. The frequency m ism atch between an energetic hard oscillator and its less energetic neighbors, and the dearth of density of states at high energies, further contribute to this persistence.

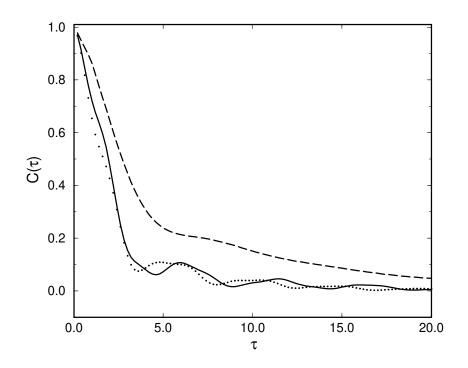

Figure 12: Energy correlation function vs time for coupled oscillators with = 0.05, $k_B T = 0.5$, and k = 1.0. Solid line: harm onic potential. Dotted line: soft anharm onic potential. D ashed line: hard anharm onic potential.

The energetic localization mechanism in strongly coupled hard oscillators is robust against temperature increases. Indeed, according to our explanation, the localization should become more pronounced and persistent as temperature increases provided the dissipation is su ciently weak. In Fig. 13 we have drawn the energy landscapes for a strongly coupled

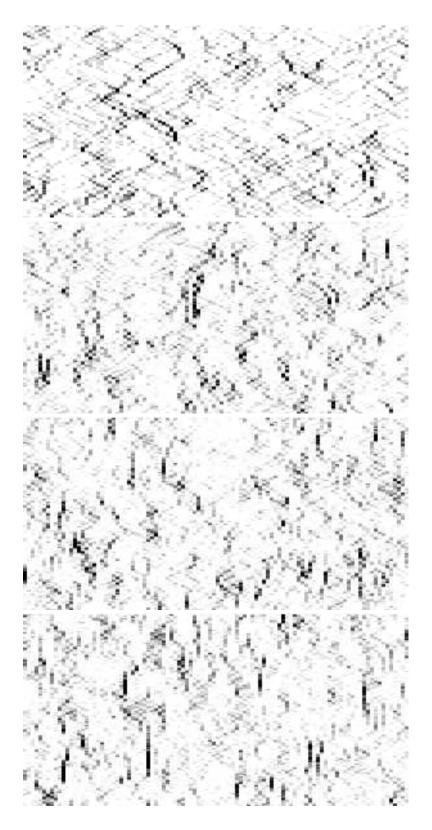

Figure 13: Energy landscapes for therm alized coupled hard oscillators as a function of time. We take = 0.05 and k = 1.0. Tem peratures from top to bottom : $k_B T = 0.1$; 0.5; 1.0 and 2.0.

(k = 1.0) array of hard oscillators, weakly coupled to the bath (= 0.05) at di erent tem peratures. The gure qualitatively con m s these expectations. The corresponding energy correlation functions are plotted in Fig. 14: C () for the hard chain does decay m ore slow ly with increasing tem perature. Thus, localization in this strongly coupled system of hard oscillators becom es m ore e ective with increasing tem perature and is not entirely fragile against dissipative forces. On the other hand, the soft and harm onic correlation functions (not shown here) are essentially independent of tem perature. Note that the trend in Figs. 12 and 14 is \opposite" to that of the uncoupled oscillators in the right hand panel ofFig. 4. In the strongly coupled chain harm onic and soft oscillators in fact lose their energy rather quickly on the time scale of one oscillation period of an isolated oscillator, but the hard oscillators retain energy correlations for longer than a period, indeed form any periods at the highest tem peratures shown. W ith increasing tem perature the hard oscillators retain energy m ore electively even while the average oscillation period decreases. In fact, the decay of the correlation functions appears to involve two tim elected sciences.

The tem poral irregularities (oscillations) visible in Figs. 12 and 14 are reproducibly there at all tem peratures; we do not know their source.

5 M obility of Localized Energy Fluctuations

The rst two energy landscapes in Fig. 11 show what m ight appear as fairly dispersionless energy transport. N arrow high-energy pulses move visibly along the chain before disappearing, while others appear (via therm all uctuations) to repeat the process elsewhere along the chain. However, this can not be claim ed to represent nonlinear behavior since the m iddle panel in Fig. 11 in fact represents com pletely harm onic system ! This serves as a cautionary note about the overinterpretation of such results.

We noted earlier that with increasing k the soft chain eventually becomes essentially harm onic because the interm olecular harm onic interactions overwhelm the local soft potential (the only way to prevent this is by considering soft interoscillator interactions, which we defer to another paper²⁰). The upper panel in Fig. 11 exhibits mostly this essentially harm onic behavior { it is quite similar to the middle panel { but not entirely so. The soft oscillator chain clearly shows higher-energy regions than the harm onic (darker patches,

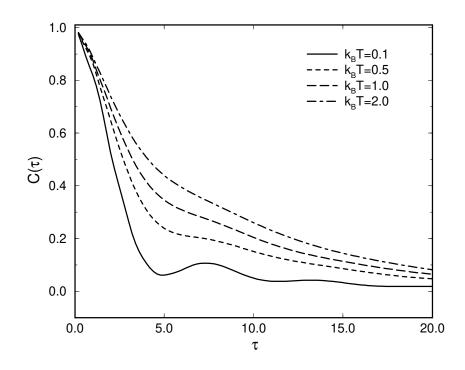

Figure 14: Energy correlation function vs time for strongly coupled hard oscillators with = 0.05, k = 1 and di erent tem peratures (sam e as in Fig. 13).

a not fully degraded rem nant of entropic localization) that move more rapidly (steeper streaks) over longer distances (longer streaks) than in the harm onic chain. Therefore, the soft anharm onicity is clearly still playing som e role, albeit a dim in ishing one with increasing coupling. To provide som e quanti cation, we introduce the dynam ical energy correlation function

$$C (j;) = \frac{hE_{i}(t)E_{i+j}(t+)i hE_{i}(t)ihE_{i+j}(t+)i}{hE_{i}^{2}(t)i hE_{i}(t)i^{2}}; \qquad (13)$$

This correlation function plotted as a function of j for various time dierences is shown in Fig. 15 for a soft chain and in Fig. 16 for a harm onic chain. For a given coupling constant k and delay time , the correlation function peaks at the site i+ j to which most of the energy originally at i has m igrated. The change of the peak position with k indicates the velocity of the m igration, and the height and width of the pulse reject the dispersive dynam ics.

The following results are evident:

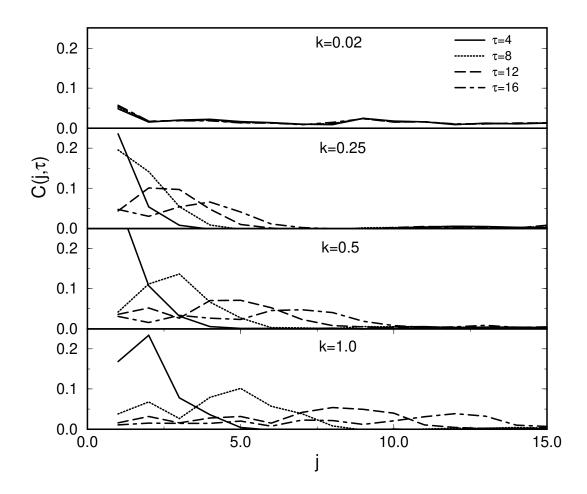

Figure 15: D ynam ical energy correlation function C (j;) for soft chains with ~= 0.05 and $k_{\rm B}\,T$ = 1.0.

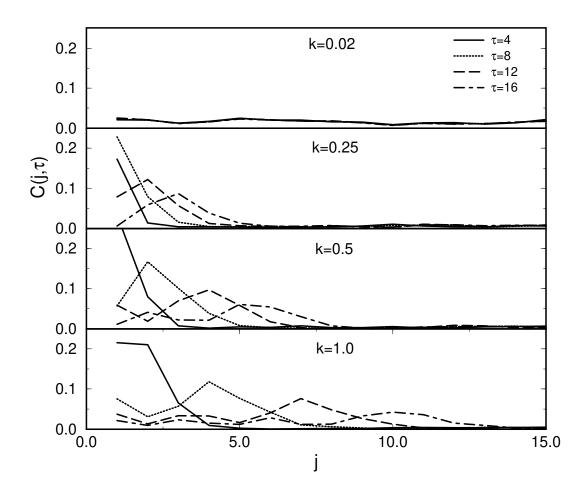

Figure 16: D ynam ical energy correlation function C (j;) for harm onic chains with ~=~0.05 and $k_B\,T$ = 1.0.

Increasing k in either soft or harm onic chains increases the velocity at which a uctuation propagates.

The velocity for a given set of parameters is greater in the soft chain.

D ispersion is slower in the soft chain.

However, as noted before, the di erences between soft and harm onic chains at large k are fairly marginal. More dramatic di erences in mobility features occur with anharm onic interm olecular potentials, a situation that will be presented elsewhere.²⁰

6 Conclusions

We have presented a fairly complete characterization of the therm alequilibrium behavior of oscillator chains with \diagonalanharm onicity," that is, chains with nonlinear on-site potentials and harm onic intersite potentials. Our particular interest lies in the characterization of possible spatial energy localization in such systems, and of the tem poral persistence of such localization.

The instantaneous localization of energy of a system in them al equilibrium is a manifestation of the them al uctuations: it is an equilibrium property unrelated to system dynamics. We argued that not only do soft anharm onic chains have a higher total energy at a given temperature than do harm onic or hard chains, but also that them al uctuations are more pronounced in the soft anharm onic chains. This is a consequence of the fact that free energy maximization favors the occupation of phase space regions with a high density of states. The density of states increases with energy in a softening potential, so it is entropically favorable for a few soft oscillators to have rather high energies. This in turn leads to greater spatial energy variability than in harm onic or hard chains, that is, soft chains have \hotter spots." The e ect becomes more pronounced with increasing temperature. This entroppic energy localization mechanism in soft chains is degraded as the harm onic intersite potential increases because the harm onic contributions become dom inant over the local soft anharm onicity e ects.

In addition to the capacity for instantaneous localization of energy (which is greatest in soft chains), one is interested in the temporal degradation of a high energy uctuation. That is, given a \local hot spot" (which is easier to nd in soft chains, but nevertheless

27

does occur in harmonic and hard chains due to thermal uctuations), how does such a uctuation evolve in time? Such a uctuation never grows spontaneously, nor does it persist inde nitely. Rather, it eventually degrades, either through dissipation into the bath or through dispersion along the chain.

The rate of dissipation into the bath depends on the value of the dissipation parameter and also on the kinetic energy of the oscillators. If the dissipation parameter is small, this channel is of course slow for any chain. However, even if the dissipation parameter is large, dissipation can still be slow if the energy is not primarily in kinetic form. This is the case for soft chains provided the interatom ic potential is weak (since otherwise the chain is essentially harm onic). In soft chains the energy is in potential form for a longer fraction of the time than in the other chains. A stem perature is increased, this e ect becomes more pronounced because ever softer portions of the potential become accessible, and the energy is stored as potential energy a greater fraction of the time.

Thus an increase in temperature in weakly coupled soft chains leads not only to greater energy uctuations but also to a slower decay of these uctuations.

Energy dispersion along the chain depends on the magnitude of the coupling constant and also on the relative oscillator displacements. If the coupling constant is small, this channel is slow for any chain. If it is large, then this channel can still be slow if relative displacements of neighboring oscillators are small. This is the case for the hard chain, where displacements are relatively small and don't change much with increasing energy. Furthermore, because in a hard oscillator the frequency increases with increasing energy, there is a frequency mismatch between a \hot" oscillator and its \colder" neighbors that further in pedes energy transfer. This leads to greater persistence of local high-energy uctuations with increasing temperature.

Thus an increase in temperature in weakly dissipative hard chains leads not only to greater energy uctuations but also to a slower decay of these uctuations.

The soft chain, on the other hand, increasingly loses its soft character as the interoscillator energy transfer channel strengthens, and therefore both the landscape and the dynam ical e ects of anham onicity quickly disappear as this coupling constant is increased.

Finally, we showed that in harmonically coupled nonlinear chains (that is, in chains with \diagonal anharmonicity") in thermal equilibrium, high-energy uctuation mobility does not occur beyond that which is observed in a harmonic chain. The situation might

28

be quite di erent if there is \nondiagonal anham onicity", that is, if the interoscillator interactions are anham onic. Our results on these systems will be presented elsewhere.²⁰

Further presentations will also deal with bistable im purities" connected to chains of the types that we have considered here.²³
