E cient Parallel Simulations of A synchronous Cellular A mays

Boris D. Lubachevsky bdl@bell-labs.com Bell Laboratories 600 Mountain Avenue Murray Hill, New Jersey

A bstract

A de nition for a class of asynchronous cellular arrays is proposed. An example of such asynchrony would be independent Poisson arrivals of cell iterations. The Ising m odel in the continuous time form ulation of G lauber falls into this class. A lso proposed are e cient parallel algorithms for simulating these asynchronous cellular arrays. In the algorithm s, one or several cells are assigned to a processing element (PE), local times for di erent PEs can be di erent. A lthough the standard serial algorithm by M etropolis, R osenbluth, R osenbluth, Teller, and Teller can simulate such arrays, it is usually believed to be without an e cient parallel counterpart. How ever, the proposed parallel algorithm s contradict this belief proving to be both e cient and able to perform the same task as the standard algorithm. The results of experiments with the new algorithm s are encouraging: the speed-up is greater than 16 using 25 PEs on a shared m em ory M IM D bus com puter, and greater than 1900 using 2¹⁴ PEs on a SIM D com puter. The algorithm by Bortz, K alos, and Lebow itz can be incorporated in the proposed parallel algorithm s, further contributing to speed-up.

1. Introduction

Simulation is inevitable in studying the evolution of complex cellular systems. Large cellular array simulations m ight require long runs on a serial computer. Parallel processing, wherein each cell or a group of cells is hosted by a separate processing element (PE), is a feasible m ethod to speed up the runs. The strategy of a parallel simulation should depend on whether the simulated system is synchronous or asynchronous.

A synchronous system evolves in discrete time t = 0;1;2; ... The state of a cell at t + 1 is determined by the state of the cell and its neighbors at t and m ay explicitly depend on t and the result of a random experiment.

An obvious and correct way to simulate the system synchrony using a parallel processor is simply to m in ic it by the executional synchrony. The simulation is arranged in rounds with one round corresponding to one time step and with no PE processing state changes of its cells for time t + 1 before all PEs have processed state changes of their cells for time t.

An asynchronous system evolves in continuous time. State changes at dierent cells occur asynchronously at unpredictable random times. Here two questions should be answered: (A) How to specify the asynchrony precisely? and (B) How to carry out the parallel simulations for the specied asynchrony?

Unlike the synchronous case, sim plem in icry does not work well in the asynchronous case. W hen G em an and G em an [1], for exam ple, em ploy executional physical asynchrony (introduced by di erent speeds of di erent PEs) to m in ic the model asynchrony, the simulation becom es irreproducible with its results depending on executional tim ing. Such dependence m ay be tolerable in tasks other than simulation ([1] describes one such task, another exam ple is given in [2]). In the task of simulation, how ever, it is a serious shortcom ing as seen in the follow ing exam ple.

Suppose a simulationist, after observing the results of a program run, wishes to look closer at a certain phenom enon and inserts an additional print' statement into the code. As a result of the insertion, the executional timing changes and the phenom enon under investigation vanishes.

Ingerson and Buvel [3] and Hofmann [4] propose various reproducible computational procedures to simulate asynchronies in cellular arrays. However no uniform principle has been proposed, and no special attention to developing parallel algorithms has been paid. It has been observed that the resulting cellular patterns may depend on the computational procedure [3].

Twom ain results of this paper are: (I) a de nition of a natural class of asynchronies that can be associated with cellular arrays and (II) e cient parallel algorithms to simulate systems in this class. The following properties specify the Poisson asynchrony, a most common member in the introduced class:

A rrivals for a particular cell form a Poisson point process.

A rrivals processes for di erent cells are independent.

The arrival rate is the same, say , for each cell.

W hen there is an arrival, the state of the cell instantaneously changes; the new state is computed based on the states of the cell and its neighbors just before the change (in the same manner as in the synchronous model). The new state may be equal to the old one.

The time of arrival and a random experiment may be involved in the computation.

A familiar example of a cellular system with the Poisson asynchrony is the Ising model [5] in the continuous time formulation of G lauber [6]. In this model a cell conguration is dened by the spin variables s(c) = 1 specified at the cells c of a two or three dimensional array. When there is an arrival at a cell c, the spin s(c) is changed to s(c) with probability p. W ith probability 1 p, the spin s(c) remains unchanged. The probability p is determined using the values of s(c) and neighbors $s(c^0)$ just before the update time.

It is instructive to review the computational procedures for Ising simulations. First,

the Ising simulationists realized that the standard procedure by M etropolis, Rosenbluth, Rosenbluth, Teller, and Teller [7] could be applied. In this procedure, the evolution of the conguration is simulated as a sequence of one-spin updates: G iven a conguration, de ne the next conguration by choosing a cell cuniform by at random and changing or not changing the spin s(c) to s(c) as required. In the original standard procedure time is discrete. Time continuity could have been simply introduced by letting the consecutive arrivals form the Poisson process with rate N, where N is the total number of spins (cells) in the system.

The problem of long simulation runs became immediately apparent. Bortz, Kalos, and Lebow itz [8] developed a serial algorithm (the BKL algorithm) which avoids processing unsuccessful state change attempts, and reported up to a 10-fold speed-up over the straightforward implementation of the standard model. Ogielski [9] built special purpose hardware for speeding up the processing.

The BKL algorithm is serial. Attempts were made to speed up the Ising simulation by parallel computations (Friedberg and Cameron [10], Creutz [11]). However, in these computations the original Markov chain of the continuous time Ising model was modiled to satisfy the computational procedure. The modil cations do not a lect the equilibrium behavior of the chain, and as such are acceptable if one studies only the equilibrium. In the cellular models how ever, the transient behavior is also of interest, and no model revision should be done.

This paper presents e cient m ethods for parallel simulation of the continuous time asynchronous cellular arrays without changing the model or type of asynchrony in favor of the computational procedure. The m ethods promise unlimited speed-up when the array and the parallel computer are su ciently large. For the Poisson asynchrony case, it is also shown how the BKL algorithm can be incorporated, further contributing to speed-up.

For the Ising model, presented algorithm s can be viewed as exact parallel counterparts to the standard algorithm by M etropolis et al. The latter has been known and believed to be inherently serial since 1953. Yet, the presented algorithm s are parallel, e cient, and fairly simple. The \conceptual level" codes are rather short (see F igures 3.1, 3.2, 3.4, 3.6, and 3.7,). An implementation in a real programming language given in the Appendix is longer, of course, but still rather simple.

This paper is organized as follows: Section 2 presents a class of asynchronies and a comparison with other published proposals. Then Section 3 describes the new algorithms on the conceptual level. While the presented algorithms are simple, there is no simple theory which predicts speed-up of these algorithms for cellular arrays and parallel processors of large sizes. Section 4 contains a simpli ed computational procedure which predicts speed-ups faster than it takes to run an actual parallel program. The predictions made by this procedure are compared with actual runs and appear to be rather accurate. The procedure predicts speed-up of more than 8000 for the simulation of 10^5 10⁵ Poisson asynchronous cellular array in parallel by 10^4 PEs. A ctual speed-ups obtained thus far were: more than 16 on 25 PEs of the Balance (TM) computer and more than 1900 on 2^{14} PEs of the Connection M achine (R).

⁰ Connection M achine is a registered tradem ark of Thinking M achines Corporation B alance is a tradem ark of Sequent C om puter System s, Inc.

2. M odel

T in e t is continuous. Each cell c has a state s = s(c). At random times, a cell is granted a chance to change the state. The changes, if they occur, are instantaneous events. R andom attempts to change the state of a cell are independent of similar attempts for other cells.

The general model consists of two functions: time_of_next_arrival () and next_state (). They are de ned as follows: given the old state of the cell and the states of the neighbors just before time t, s_t_0 (neighbors (c)), the next_state s (c) = s_t (c) is

$$s_{t}(c) = \text{next_state } (c; s_{t_{0}}(\text{neighbors}(c)); !; t);$$
(1)

where the possibility $s_t(c) = s_{t_0}(c)$ is not excluded; and the time next_t of the next arrival is

next t = tim e.of_next_arrival (c;
$$s_{t=0}$$
 (neighbors (c)); !; t); (2)

where always next t > t.

In (1) and (2), ! denotes the result of a random experiment, e.g., coin tossing, s (neighbors (c)) denotes the indexed set of states of all the neighbors of c including c itself. Thus, if neighbors (c) = fc;c_1;c_2;c_3;c_4g, then s (neighbors (c)) = (s(c);s(c_1);s(c_2);s(c_3);s(c_4)). Subscript t 0 expresses the idea of 'just before t', e.g., $a_{t=0}() = \lim_{t \to t} |t_{t}| < t a()$. A coording to (1), the value of s(c) instantaneously changes at time t from $s_{t=0}(c)$ to $s_t(c)$. At time t, the value of s(c) is already new. The 'just before' feature resolves a possible am biguity if two neighbors attempt to change their states at the same simulated time.

Compare now the class of asynchronies de ned by (2) with the ones proposed in the literature:

(A) M odel 1 in [3] reads: $\$...the cells iterate random ly, one at a time." Let p_c be the probability that cell c is chosen. Then the following choice of law (2) yields this model

$$tim e_{of_next_arrival}(c; !; t) = t \qquad \frac{1}{p_c} \ln r(c; t; !);$$

where r(c;t;!) is a random number uniform by distributed on (0,1), and ln is the natural logarithm, $\ln(x) = \log_e(x)$. For $p_{c_1} = p_{c_2} = \dots =$, the asynchrony was called the Poisson asynchrony in Section 1; it coincides with the one de ned by the standard model [7], and by G lauber's model [6] for the Ising spin simulations.

(B) M odel 2 in [3] assigns \each cell a period according to a G aussian distribution... The cells iterate one at a time each having its own de nite period." W hile it is not quite clear from [3] what is meant by a \de nite period" (is it xed for a cell over a simulation run?), the following choice of law (2) yields this model in a liberal interpretation:

tim e_of_next_arrival (c; !; t) = t +
$$P_c^{\perp}$$
 (r(!));

where $P^{-1}(y) = x$ if P(x) = y, and $P_c(x)$ is the cumulative function for the Gaussian probability distribution with mean $m_c > 0$ and variance c^2 . The probability of next t < t is small when << m and is ignored in [3] if this interpretation is meant. In a less liberal

interpretation, $_{\rm c}$ 0 for all c, and m $_{\rm c}$ is itself random and distributed according to the G aussian law. This case is even easier to represent in term s of model (2) than the previous one: tim e_of_next_arrival⁽c; !; t) = t + m $_{\rm c}$ (!).

(3) M odel (2) trivially extends to a synchronous simulation, where the initial state changes arrive at time 0 and then always next.t t is identical to 1. The rst m odel in [4] is \to choose a number of cells at random and change only their values before continuing." This is a variant of synchronous simulation; it is substantially di erent from both m odels (A) and (B) above. In (A) and (B), the probability is 1 that no two neighbors attempt to change their states at the same time. In contrast, in this m odel m any neighboring cells are simultaneously changing their values. How the cells are chosen for update is not precisely specified in [4]. One way to choose the cells is to assign a probability weight p for cell c, c = 1;2;:::;N, and to attempt to update cell c at each iteration, with probability p_c , independent of any other decision. Such a method conforms with the law (2) because the method is local: a cell does not need to know what is happening at distant cells. The second m odel in [4] changes states of a xed number A of random ly chosen cells at each iteration. If A > 1, this method is not local and does not conform with the law (2).

3. A lgorithm s

E lim ination of !. Determ inistic computers represent random ness by using pseudorandom number generators. Thus, equations (1) and (2) are substituted in the computation by equations

$$s_{t}(c) = next_state (c; s_{t 0} (neighbors (c)); t);$$
(3)

and

next t = tim e_of_next_arrival (c;
$$s_t \circ (neighbors (c)); t$$
); (4)

respectively, which do not contain the parameter of random ness !.

This elim ination of ! symbolizes an obvious but important di erence between the simulated system and the simulator: In the simulated system, the observer, being a part of the system, does not know in advance the time of the next arrival. In contrast, the simulation ist who is, of course, not a part of the simulated system, can know the time of the next arrival before the next arrival is processed.

For example, it is not known in advance when the next event from a Poisson stream arrives. However, in the simulation, the time next t of the next arrival is obtained in a determ inistic manner, given the time t of the previous arrival:

$$next = t - log_e (r(n(t)));$$
 (5)

where is the rate, r(n) is the n-th pseudo-random number in the sequence uniform ly distributed on (0;1), and n(t) is the invocation counter. Thus, after the previous arrival is processed, the time of the next arrival is already known. If needed, the entire sequence of arrivals can be precomputed and stored in a table for later use in the simulation, so that all while t(c) < end_time

 wait_untilt(c) m in_{c⁰ 2 neighbors(c)} t(c⁰);
 s(c) next_state (c; s(neighbors(c)); t(c));
 t(c) tim e_of_next_arrival (c; s(neighbors(c)); t(c));
 g

Figure 3.1: A synchronous one-cell-per-one-PE algorithm

future arrival times would be known in advance.

A synchronous one-cell-per-one-PE algorithm. The algorithm in Figure 3.1 is the shortest of those presented in this paper.

To understand this code, imagine a parallel computer which consists of a number of PEs running concurrently. One PE is assigned to simulate one cell. The PE which is assigned to simulate cell c_0 , PE c_0 , executes the code in Figure 3.1 with $c = c_0$. The PEs are interconnected by the network which matches the topology of the cellular array. A PE can receive information from its neighbors. PEc maintains state s(c) and local simulated time t(c). Variables t(c) and s(c) are visible (accessible for reading only) by the neighbors of c. Time t(c) has no connection with the physical time in which the parallel computer runs the program except that t(c) may not decrease when the physical time increases. At a given physical instance of simulation, di erent cells cm ay have di erent values of t(c). Value end time is a constant which is known to all PEs.

The algorithm in Figure 3.1 is very asynchronous: di erent PEs can execute di erent steps concurrently and can run at di erent speeds. A statem ent wait until condition', like the one at Step 2 in Figure 3.1, does not im ply that the condition must be detected im mediately after it occurs. To detect the condition at Step 2 involving local times of neighbors a PE can poll its neighbors one at a time, in any order, with arbitrary delays, and without any respect to what these PEs are doing meanwhile.

Despite being seem ingly almost chaotic, the algorithm in Figure 3.1 is free from deadlock. Moreover, it produces a unique simulated trajectory which is independent of executional tim ing, provided that:

(i) for the same cell, the pseudo-random sequence is always the same,

(ii) no two neighboring arrival times are equal.

Freedom from deadlock follows from the fact that the cell, whose local time is minim al over the entire array, is always able to make progress. (This guaranteed worst case perform ance, is substantially exceeded in an average case. See Section 4.)

The uniqueness of the trajectory can be seen as follows. By (ii), a cell c passes the test

at Step 2 only if its local time t(c) is smaller than the local time $t(c^0)$ of any its neighbor c^0 . If this is the case, then no neighbor c^0 is able to pass the test at Step 2 before c changes its time at Step 4. This means that processing of the update by c is safe: no neighbor changes its state or time before c completes the processing. By (i), functions next_state() and time_of_next_arrival() are independent of the run. Therefore, in each program run, no matter what the neighbors of c are doing or trying to do, the next arrival time and state for c are always the same.

It is now clear why assumption (ii) is needed. If (ii) is violated by two cells c and c^0 which are neighbors, then the algorithm in Figure 3.1 does not exclude concurrent updating by c and c^0 . Such concurrent updating introduces an indeterm inism and inconsistency. A scenario of the inconsistency can be as follows: at Step 3 the old value of s(c^0) is used to update state s(c), but immediately following Step 4 uses the new value of s(c^0) to update time t(c).

In practice, the algorithm in Figure 3.1 is safe, when next_t(c) t(c) for di erent c are independent random samples from a distribution with a continuous density, like an exponential distribution. In this case, (ii) holds with probability 1. U nless the pseudo-random num ber generators are faulty, one m ay imagine only one reason for violating (ii): nite precision of com puter representation of real num bers.

Synchronous one-cell-per-one-PE algorithm. If (ii) can be violated with a positive probability (if t takes on only integer values, for example), then the errors m ight not be tolerable. In this case the synchronous algorithm in Figure 3.2 should be used.

Observe that while the algorithm in Figure 32 is synchronous, it is able to simulate correctly both synchronous and asynchronous systems. Two main additions in the algorithm in Figure 32 are: private variables new_s and new_t for tem poral storage of updated s and t, and synchronization barriers 'synchronize'. When a PE hits a 'synchronize' statement it must wait until all the other PEs hit a 'synchronize' statement; then it may resume. Two dum my synchronizations at Steps 9 and 10 are executed by idling PEs in order to match synchronizations at Steps 5 and 8 executed by non-idling PEs.

W hen (ii) is violated, the synchronous algorithm avoids the ambiguity and indeterm inism (which in this case are possible in the asynchronous algorithm) as follows: in processing concurrent updates of two neighbors c and c^0 for the same simulated time $t = t(c) = t(c^0)$, rst, c and c^0 read states $s_{t=0}$ and times t of each other and compute their private new_s's

and new_t (Steps 3 and 4 in F igure 3.2); then, after the synchronization barrier at Step 5, c and c^0 write their states and times at Steps 6 and 7, thus making sure that now rite interferes with a read.

A ggregation. In the two algorithms presented above, one PE hosts only one cell. Such an arrangement may be wasteful if the communication between PEs dominates the computation internal to a PE. A more e cient arrangement is to assign several cells to one PE. For concreteness, consider a two-dimensional n n array with periodic boundary conditions. Let n be a multiple of m and $(n=m)^2$ PEs be available. PEC carries m m subarray C, where $C = 1;2; ...; (n=m)^2$. (Capital C will be used without confusion to

Figure 32: Synchronous one-cell-per-one-PE algorithm

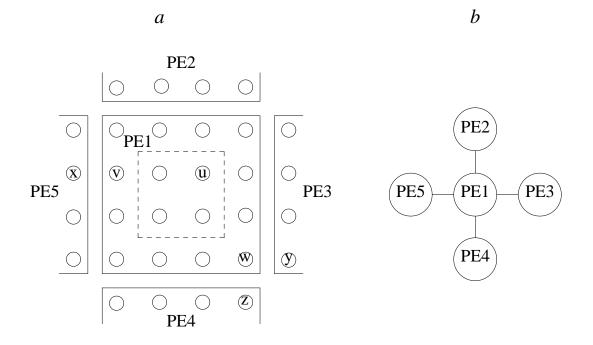

Figure 3.3: Aggregation: a) mapping of cells to PEs, b) the interconnection among the PEs which supports the neighborhood topology among the cells

represent both the subarray index and the set of cells c the subarray comprises, e.g. as in c 2 C) A fragment of a square cellular array in an example of such an aggregation is represented in Figure 3.3a, wherein m = 4.

The neighbors of a cell carried by PE1 are cells carried by PE2, PE3, PE4, or PE5. PE1 has direct connections with these four PEs (Figure 3.3b). G iven cell c in the subarray hosted by PE1, one can determ ine with which neighboring PEs communication is required in order to learn the states of the neighboring cells. Let W (c) be the set of these PEs. Examples in Figure 3.3a : W (u) is empty, W (v) = fPE5g, W (w) = fPE3, PE4g.

Figure 3.4 presents an aggregated variant of the algorithm in Figure 3.1. PEC, which hosts subarray C, maintains the local time register T (C). PEC₀ simulates the evolution of its subarray using the algorithm in Figure 3.4 with $C = C_0$. Each cell c 2 C is represented in the memory of PEC by its current state s(c) and its next arrival time t(c). Note that unlike the one-cell-per-one-PE algorithm, the t(c) does not represent the current local time for cell c. Instead, local times of all cells within subarray C are the same, T (C).

T (C) moves from one t(c) to another in the order of increasing value. Three successive iterations of this algorithm are shown in Figure 3.5, where the subarray C consists of four cells: C = f1;2;3;4g. C incles in Figure 3.5 represent arrival points in the simulated time. A crossed-out circle represents an arrival which has just been processed, i.e., Steps 3, 4, and 5 of Figure 3.4 have just been executed, so that T (C) has just taken on the value of the processed old arrival time t(c), while the t(c) has taken on a new larger value. This new value is pointed to by an arrow from T (C) in Figure 3.5. It is obvious that always t(c) \geq T (C)

```

Figure 3.4: A synchronous m any-cells-per-one-PE algorithm. General asynchrony

ifc 2 C.

Local times T (C) maintained by dierent PEC might be dierent. A wait at Step 3 cannot deadlock the execution since the PEC whose T (C) is the minimum over the entire cellular array is always able to make a progress.

A ssum ing property (ii) as above, the algorithm correctly simulates the history of updates. The following example may serve as an informal proof of this statement. Suppose PE1 is currently updating the state of cell v (see Figure 3.3a) and its local time is T_1 . Since W (v) = fPE 5g, this update is possible because the local time of PE5, T_5 , is currently larger than T_1 . At present, PE1 receives the state of x from PE5 in order to perform the update. This state is in time T_5 , i.e., in the future with respect to local time T_1 . However, the update is correct, since the state of x was the same at time T_1 , as it is at time T_5 .

Indeed, suppose the state of x were to be changed at simulated local time T, $T_1 < T < T_5$. At the moment when this change would have been processed by PE5, the local time of PE1 would have been larger than T, and T would have been the local time of PE5. A fler this processing has supposedly taken place, the local time of PE1 should not decrease. Yet at the present it is T_1 , which is smaller that T. This contradiction proves that the state of x cannot in fact change in the interval $(T_1;T_5)$.

In the example in Figure 3.5, only one t(c) supplies min $_{c^{0}2C}$ t(c^{0}). However, the algorithm in Figure 3.4 at Step 2 commands to select a cell not the cell. This covers the unlikely situation of several cells having the same minimum time. If next_t(c) t(c) for di erent c are independent random samples from a distribution with a continuous density, this case occurs with the probability zero. On the other hand, if several cells can, with positive probability, update simultaneously, a synchronous version of the aggregated algorithm should be used instead. To eliminate indeterminism and inconsistency, the latter would use synchronization and intermediate storage techniques. These techniques were demonstrated in the algorithm in Figure 3.2 and their discussion is not repeated here.

For an important special case of Poisson asynchrony in the aggregated algorithm, the algorithm of Figure 3.4 is rewritten in Figure 3.6. This specialization capitalizes on the additive property of Poisson streams, speci cally, on the fact that sum of k independent

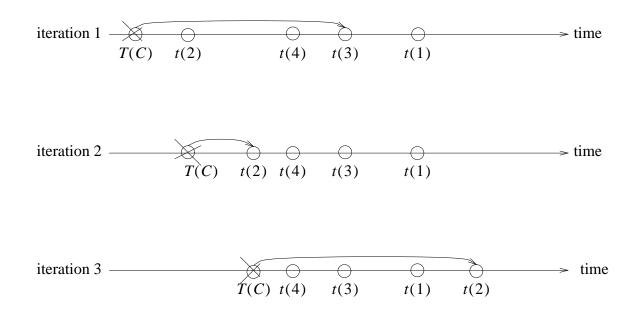

Figure 3.5: T (C) slides along a sequence of t(c)'s in successive iterations of the aggregated algorithm

Figure 3.6: A synchronous m any-cells-per-one-PE algorithm . Poisson asynchrony

Poisson streams with rate each is a Poisson stream with rate k. In the algorithm, $k = \text{num ber_of_cells_in_C}$; this k is equal to m² in the special case of partitioning into m m subarrays. Unlike the general algorithm of Figure 3.4, in the specialization in Figure 3.6 neither individual streams for di erent cells are maintained, nor future arrivals t(c) for cells are individually computed. Instead, a single cumulative stream is simulated and cells are delegated random by to meet these arrivals.

At Step 5 in Figure 3.6, r(C; n(T(C))) is an n(T(C))-th pseudo-random number in the sequence uniform by distributed in (0,1). It follows from the notation that each PE has its own sequence. If this sequence is independent of the run (which is condition (i) above) and if updates for neighboring cells never coincide in time (which is condition (ii) above), then this algorithm produces a unique reproducible trajectory. The same statement is also true for the algorithm in Figure 3.4. However, uniqueness provided by the algorithm in Figure 3.6 is weaker than the one provided by the algorithm in Figure 3.4. However, a trajectory produced by the algorithm in Figure 3.6 may change; how ever, a trajectory produced by the algorithm in Figure 3.4 is invariant for such changes given that each cell cuses its own xed pseudo-random sequence.

E ciency of aggregated algorithm s. Both many-cells per-one-PE algorithm s in Figure 3.4 and Figure 3.6 are more e cient than the one-cell-per-one-PE counterparts in Figure 3.1 and Figure 3.2. This additional e ciency can be explained in the example of the square array, as follows: In the algorithm s in Figure 3.1 and Figure 3.2, a PE m ay wait for its four neighbors. However, in the algorithm s in Figure 3.4 and Figure 3.6, a PE waits for at most two neighbors. For example, when the state of cell w in Figure 3.3 a is updated, PE1 m ight wait for PE3 and PE4. M oreover, for at least (m 2)² cells c out of m², PE1 does not wait at all, because W (c) = ;. The cells c such that W (c) = ; form the dashed square in Figure 3.3 a.

This additional e ciency becomes especially large if, instead of set neighbors (c) in the original formulation of the model, one uses sets

neighbors² (c)
$$\stackrel{\text{der}}{=}$$
 next_to_nearest_neighbors (c) (6)

or, more generally, q-th degree neighborhood, neighbors $^{\rm q}$ (c). The latter is dened for q >1 inductively

neighbors^q (c)
$$\stackrel{\text{def}}{=}$$
 neighbors (neighbors^{q 1} (c)) (7)

where neighbors (S) for a set S of cells is de ned as neighbors (S) $\stackrel{\text{def S}}{=} S_{c2S}$ neighbors (C).

It is easy to rewrite the algorithm s in Figure 3.1 and Figure 3.2 for the case q > 1. The obtained codes have low e ciency however. For example, in the square array case, one has jneighbors^q (c) j 1 = 2q(q+1). Thus, if q = 2, a cellm ight have to wait for 12 cells in order to update. In the same example, if one PE carries an m m subarray, and m > q, then the PE waits for at m ost three other PEs no m atter how large the q is. M oreover, if m > 2q then in (m $2q)^2$ cases out of m² the PE does not wait at all.

The BKL algorithm [8] was originally proposed for Ising spin simulations. It was noticed that the probability p to ip s(c) takes on only a nite (and small) number d of values $p_1; \dots; p_d$, each corresponding to one or several combinations of old values of s(c) and neighboring spins $s(c^0)$. Thus the algorithm splits the cells into d pairwise disjoint classes $1, 2, \dots, d$. The rates p_k of changes (not just of the attempts to change) for all c 2 = k are the same. At each iteration, the BKL algorithm does the following:

(a) Selects $_{k_0}$ at random according to the weights $j_k \dot{p}_k$, k = 1;2;:::d, and selects a cell c 2 $_{k_0}$ uniform by at random.

(b) F lips the state of the selected cell, s(c) = s(c).

(c) Increases the time by $\log_e(r) = (\begin{pmatrix} p \\ 1 & k & d \end{pmatrix} j_k j_k)$, where r is a pseudo-random number uniform ly distributed in (0,1).

(d) Updates the membership in the classes.

If the asynchrony law is Poisson, the idea of the BKL algorithm can be applied also to a determ inistic update. Here the probability p of change takes on just two values:

 $p_1 = 0$ if next_s (c) = s(c), and $p_2 = 1$ if next_s(c) \in s(c).

A coordingly, there are two classes: $_{0}$, the cells which are not going to change and $_{1}$, the cells which are going to change. A swith the original BKL algorithm, a substantial overhead is required form aintaining an account of the mem bership in the classes (Step (d)). The BKL algorithm is justiled only if a large number of cells are not going to change their states. The latter is often the case. For example, in the C onways's synchronous G ame of Life (G ardner [12]) large regions of white cells (s (c) = 0) remain unchanged form any iterations with very few black cells (s (c) = 1). One would expect similar behavior for an asynchronous version of the G ame of Life.

The basic BKL algorithm is serial. To use it on a parallel computer, an obvious idea is to run a copy of the serial BKL algorithm in each subarray carried by a PE. Such a procedure, how ever, causes roll-backs, as seen in the following example:

Suppose PE1 is currently updating the state of cell v (Figure 3.3a) and its local time is T_1 , while the local time of PE5, T_5 , is larger than T_1 . Since x is a nearest neighbor to B, x's membership m ight change because of v's changed state. Suppose x's membership were to indeed change. A likely this change would have been in e lect since time T_1 , PE5, which is responsible for x, would learn about the change only at time $T_5 > T_1$. As the past of PE5 is not, therefore, what PE5 has believed it to be, interval $[T_1;T_5]$ m ust have been simulated by PE5 incorrectly, and must be played again. This original roll-back m ight cause a cascade of secondary roll-backs, third generation roll-backs etc.

A modi ed BKL algorithm applies the original BKL procedure only to a subset of the cells, whereas the procedure of the standard model is applied to the remaining cells. More speci cally: An additional separate class $_0$ is de ned. Unlike other $_k$, k > 0, class

 $_{\rm 0}$ always contains the same cells. Steps (a) – (d) are performed as above with the following modi cations:

1) The weight of $_0$ at step (a) is taken to be j $_0$ j.

2) If the selected c belongs to $_0$, then at step (b) the state of c m ay or m ay not change. The probability p of change is determ ined as in the standard m odel.

3) The time at step (c) should be increased by $\log_e(r) = ((j_0 j + \int_{1 k d} j_k j_k))$, where r = r(c; n(t)) is a pseudo-random number uniform by distributed in (0;1).

Now consider again the subarray carried by PE1 in Figure 3.3a. The subarray can be subdivided into the (m 2) (m 2) \kernel" square and the remaining boundary layer. If rst degree neighborhood, neighbors (c), is replaced with the q-th degree neighborhood, neighbors^q (c), then the kernel is the central (m 2q) (m 2q) square, and the boundary layer has width q. In Figure 3.3a, the cells in the dashed square constitute the kernel with q = 1. To apply the modil ed BKL procedure to the subarray carried by PE1, the boundary layer is declared to be the special xed class $_0$. Sim ilar identic cation is done in the other subarrays. As a result, the fast concurrent BKL procedures on the kernels are shielded from each other by slower procedures on the layers.

The roll-back is avoided, since state change of a cell in a subarray does not constitute state or membership change of a cell in another subarray. Unless the performance of PE1 is taken into account, the neighbors of PE1 can not even tell whether PE1 uses the standard or the BKL algorithm to update its kernel. As the size of the subarray increases, so does both the relative weight of the kernel and the fraction of the fast BKL processing.

G enerating the output. Consider the task of generating cellular patterns for speci ed simulated times. A method for performing this task in a serial simulation or a parallel simulation of a synchronous cellular array is obvious: as the global time reaches a speci ed value, the computer outputs the states of all cells. In an asynchronous simulation, the task becomes more complicated because there is no global time: dierent PEsmay have dierent local times at each physical instance of simulation.

Suppose for example, one wants to see the cellular patterns at regular time intervals K_0 t; (K_0+1) t; (K_0+2) t; :::on a screen of a monitor attached to the computer. W ithout getting too involved in the details of performing I/O operations and the architecture of the parallel computer, it would be enough to assume that a separate process or processes are associated with the output; these processes scan an output bu ermem ory space allocated in one or several PEs or in the shared memory; the bu er space consists of B frames, numbered 0,1,...,B 1, each capable of storing a complete in age of the cellular array for one time instance. The output processes draw the image for time K to nothe screen as soon as the frame number rem (K = B) (the rem inder of the integer division K by B) is full and the previous in ages have been shown. Then the frame is ashed for the next round when it will be led with the image for time (K + B) t and so on.

The algorithm must lithe appropriate fram e with the appropriate data as soon as both data and the fram e becom e available. The modi cations that enable the asynchronous al-

```

Figure 3.7: Generating the output in the aggregated asynchronous algorithm

gorithm in Figure 3.4 to perform this task are presented in Figure 3.7. In this algorithm, variables new_T and K are private (i.e., local to PE) and t and K₀ are constants whose values are the same for all the PEs. Note that di erent PEs may lldi erent frames concurrently. If the slowest PE is presently lling an image for time K t, then the fastest PE is allowed to llthe image for time no later than (K + B = 1) t. An attempt by the fastest PE to llthe image for time (K + B) twill be blocked at Step 4, until the frame number rem (K = B) = rem ((K + B) = B) becomes available.

Thus, the niteness of the output bu er introduces a restriction which is not present in the original algorithm in Figure 3.4. A coording to this restriction, the lag between concurrently processed local times cannot exceed a certain constant. The exact value of the constant in each particular instance depends on the relative positions of the update times within the

t-slots. In any case, the constant is not smaller than (B 1) t and not larger than B t. However, even with a single output bu er segment, B = 1, the simulation does not become time-driven. In this case, the concurrently processed local times might be within a distance of up to t of each other, whereas t might be relatively large. No precision of update time representation is lost, although e ciency might degrade when both t and B become too small, see Section 4.

4. Perform ance assessment: experiments and simulations

M odeling and analysis of asynchronous algorithm s is a di cult theoretical problem. Strictly speaking, the following discussion is applicable only to synchronous algorithm s. However, one may argue inform ally that the performance of an asynchronous algorithm is not worse than that of its synchronous counterpart, since expensive synchronizations are eliminated.

First, consider the synchronous algorithm in Figure 3.2. Let N be the size of the array and N₀ be the number of cells which passed the test at Step 2, Figure 3.2. The ratio of useful work performed, to the total work expended at the iteration is N₀=N. This ratio yields the e ciency (or utilization) at the given iteration. Assuming that in the serial algorithm all the work is useful, and that the algorithm performs the same computation as its parallel counterpart, the speed-up of the parallel computation is the average e ciency times the number of PEs involved. Here the averaging is done with equal weights over all the iterations.

In the general algorithm s, next t(c) is determ ined using the states of the neighbors of c. However, in the important applications, such as an Ising model, next t(c) is independent of states. The following assessment is valid only for this special case of independence. Here the con guration is intelevant and whether the test succeeds or not can be determined knowing only the times at each iteration. This leads to a simplified model in which only local times are taken into account: at an iteration, the local time of a cell is incremented if the time does not exceed the minimum of the local times of its neighbors.

A simple (serial) algorithm which updates only local times of cells t(c) according to the nules form ulated above was exercised for dimensions: for an n-element circular array, and n n toroidal array, and for n n array with periodic boundary conditions. Two types of asynchronies are tried: the Poisson asynchrony for

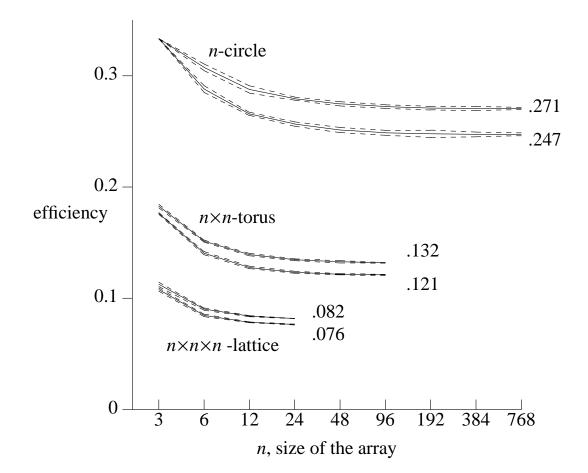

Figure 4.1: Perform ance of the Ising m odel simulation. One-cell-per-one-PE case

which next t is distributed exponentially, and the asynchrony for which next t is uniform by distributed in (0,1). In both cases, random time increments for dimensional error cells are independent.

The results of these six experiments are given in Figure 4.1. Each solid line in Figure 4.1 is enclosed between two dashed lines. The latter represent 99.99% Student's condence intervals constructed using several simulation runs, that are parametrically the same but fed with diment pseudo-random sequences. In Figure 4.1, for each array topology there are two solids lines. The Poisson asynchrony always corresponds to the lower line. The corresponding limiting values of performances (when n is large) are also shown near the right end of each curve. For example, the end of each curve. For example, the end of each curve, it is about 0.121, with the other asynchrony, it is about 0.132.

No analytical theory is available for predicting these values or even proving their separation from zero when n ! +1. It follows from Figure 4.1 that replacing exponential distribution of next t t with the uniform distribution results in e ciency increase from 0.247 to 0.271 for a large n-circle (n ! +1). The e ciency can be raised even more. If next t t = r^{1-8} , where r is distributed uniform ly in (0,1), then in the limit n ! +1, with

the Student's con dence 99.99%, the e ciency is 0:3388 0:0012. It is not known how high the e ciency can be raised this way (degenerated cases, like a synchronous one, in which the e ciency is 1, are not counted).

An e ciency of 0.12 m eans the speed-up of 0.12 N; for N = 2^{14} this com est om one than 1900. This assessment is con med in an actual full scale simulation experiment performed on $2^{14} = 128$ 128 PEs of a Connection Machine (R) (a quarter of the full computer). This SIM D computer appears well-suited for the synchronous execution of the one-cell-per-one-PE algorithm in Figure 3.2 on a toroidal array, Poisson asynchrony law. Since an individual PE is rather slow, it executes several thousand instructions per second, and its absolute speed is not very in pressive: It took roughly 1 sec. of real time to update all 128 128 spins when the trac generated by other tasks running on the computer was small (m ore precise measurement was not available). This includes about 8:3 (0:12) ¹ rounds of the algorithm, several hundred instructions of one PE per round.

The 12% e ciency in the one-cell-per-one-PE experiments could be greatly increased by aggregation. The many-cells-per-one-PE algorithm in Figure 3.6 is implemented as a C language parallel program for a Balance (TM) computer, which is a shared memory M MD busmachine. The n narray was split into m m subarrays, as shown in Figure 3.3, where n is a multiple of m. Because the computer has 30 PEs, the experiments could be performed only with $(n=m)^2 = 1;4;9;16$, and 25 PEs for dierent n and m.

A long with these experiments, a simpli ed model, similar to the one-cell-per-one-PE case, was run on a serial computer. In this model, quantity $h(C) \stackrel{\text{def}}{=} T(C)$ is maintained for each PE, C = 1; :::; (n=m)². The update of h(C) is arranged in rounds, wherein each h(C) is updated as follow s:

(i) with probability $p_0 = (m - 2)^2 = m^2$, PEC updates h(C):

$$h(C) = h(C) = \ln^{r} (C; n(h(C)));$$
 (8)

where r and ln are the same as in Step 5 in Figure 3.6. Here p_0 is the probability that the PE chooses a cell c so that \mathcal{W} (c) j= 0;

(ii) with probability $p_1 = 4 \text{ (m } 2)=m^2$, the PE must check the h (C⁰) of one of its four neighbors C⁰ before making the update. The C⁰ is chosen uniform by at random among the four possibilities. If h (C⁰) h (C), then h (C) gets an increment according to (8); otherwise, h (C) is not updated. Here p_1 is the probability that PE will choose a cell c in an edge but not in a corner, so that j_{i} (c) j = 1

(iii) with the remaining probability $p_2 = 4=m^2$, the PE checks h (C⁰) and h (C⁰) of two of its adjacent neighbors (for example in Figure 3.3, neighbors PE2 and PE3 can be involved in the computation for PE1). The two neighbors are chosen uniform by at random from the four possibilities. Again, if both h (C⁰) h (C) and h (C⁰) h (C), then h (C) gets an increment according to (8); otherwise, h (C) is not updated. Here p_2 is the probability to choose a cell c in a corner, so that j_{V} (c) j = 2.

As in the previous case, this simplied model simulates a possible but not obligatory synchronous timing arrangement for executing the real asynchronous algorithm. Figure 4.2 shows excellent agreement between actual and predicted performances for the aggregated Ising model. The end ciency presented in Figure 4.2 is computed as

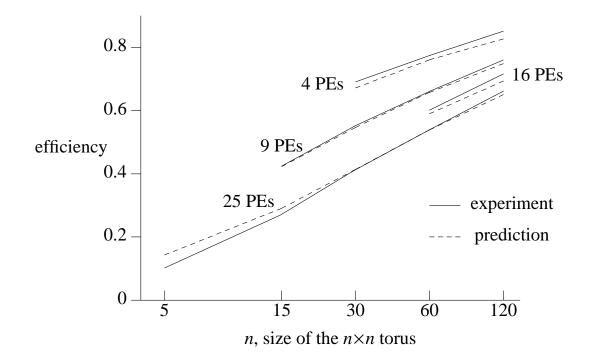

Figure 42: Perform ance of the Ising m odel simulation. M any-cells per-one-PE case

$$e \text{ ciency} = \frac{\text{serial execution tim } e}{\text{num ber of PEs parallel execution tim } e}$$
(9)

The parallel speed-up can be found as e ciency number of PEs. For 25 PEs simulating a 120 120 Ising model, e ciency is 0.66; hence, the speed-up is greater than 16. For the currently unavailable sizes, when 10^4 PEs simulate a 10^4 10^4 array, the simpli ed model predicts an e ciency of about 0.8 and a speed-up of about 8000.

In the experiments reported above, the lag between the local times of any two PEs was not restricted. As discussed in Section 3, an upper bound on the lag might result from the necessity to produce the output. To see how the bound a ects the e ciency, one experiment reported in Figure 4.2, is repeated with various nite values of the lag bound. In this experiment, an n n array is simulated and one PE carries an m m subarray, where n = 384 and m = 12. The results are presented in Figure 4.3.

In Figure 4.3, the unit of measure for a lag is the expectation of time intervals between consecutive arrivals for a cell. For lag bounds greater than 16, degradation of e ciency is alm ost unnoticeable, when compared with the base experiment where lag= 1. Substantial degradation starts at about 8; for the unity lag bound, the e ciency is about half that of the base experiment. However, even for lag bound 0.3, the simulation remains practical, with an e ciency of about 0.1; since 1024 PEs execute the task, this e ciency means a speed-up of more than 100.

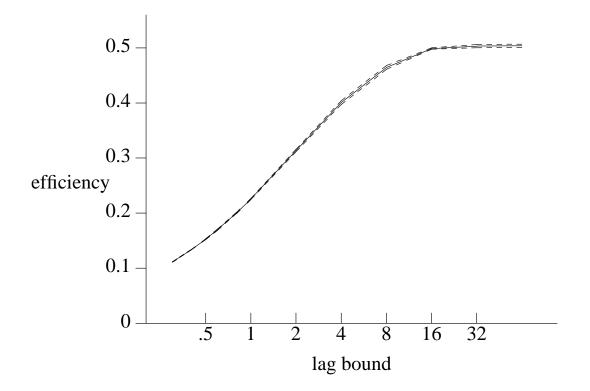

Figure 4.3: E ciency degradation caused by bounded lag

5. Conclusion

This paper dem onstrates an e cient parallelm ethod for simulating asynchronous cellular arrays. The algorithm s are quite simple and easily implementable on appropriate hardware. In particular, each algorithm presented in the paper can be implemented on a general purpose asynchronous parallel computer, such as the currently available bus machines with shared memory. The speed of such implementation depends on the speed of PEs and the e ciency of the communication system. A crucial condition for success in such implementation is the availability of a good parallel generator of pseudo-random numbers. To assure reproducibility, each PE should have its own reproducible pseudo-random sequence.

The proposed algorithms present a number of challenging mathematical problems, for example, the problem of proving that e ciency tends to a positive limit when the number of PEs increases to in nity.

A cknow ledgm ents.

I acknow ledge the personnel of the Thinking M achine Corp. for their kind invitation, and help in debugging and running the parallel *LISP program on one of their computers. Particularly, the help of Mr. Gary Rancourt and Mr. Bernie Murray was invaluable. A loo, I thank Andrew T.Ogielski and Malvin H.Kalos for stimulating discussions, D ebasis M itra for a helpful explanation of a topic in Markov chains, and Brigid M oynahan for carefully reading the text.
