# The Entropy of a $B$ inary $H$ idden $M$ arkov $P$ rocess 

O r Zuk ${ }^{1}$, Ido $K$ anter ${ }^{2}$ and Eytan D om any ${ }^{1}$<br>${ }^{1}$ D ept. of $P$ hysics of $C$ om plex System $s, W$ eizm ann Institute of Science, Rehovot 76100, Israel<br>${ }^{2}$ D epartm ent of P hysics, B ar Ilan U niversity, $R$ am at G an, 52900, Israel

## A bstract

The entropy of a binary sym $m$ etric $H$ idden $M$ arkov $P$ rocess is calculated as an expansion in the noise param eter. We map the problem onto a one-dim ensional Ising $m$ odel in a large eld of random signs and calculate the expansion coe cients up to second order in. U sing a con jecture we extend the calculation to 11th order and discuss the convergence of the resulting series.

K ey w ords: H idden $M$ arkov $P$ rocess, entropy, random - eld Ising m odel

H idden $M$ arkov $P$ rocesses ( H M P s) have $m$ any applications, in a w ide range of disciplines - from the theory of com $m$ unication [1] to analysis of gene expression [2]. C om prehensive review s on both theory and applications of HMPs can be found in ([1], [3]). Recent applications to experim ental physics are in ([4],[5]). Them ost widely used context of HMPs is, how ever, that of construction of reliable and e cient com m unication channels.

In a practical com $m$ unication channel the aim is to reliably transm it source $m$ essage over a noisy channel. $F$ ig 1. show $s$ a schem atic representation of such a com $m$ unication. The source $m$ essage can be a stream of words taken from a text. It is clear that such a stream of words contains inform ation, indicating that words and letters are not chosen random ly. R ather, the probability that a particular word (or letter) appears at a given point in the stream depends on the w ords (letters) that were previously transm itted. Such dependency of a transm itted sym bol on the precedent stream is m odelled by a M arkov process.
$T$ he $M$ arkov $m$ odel is a nite state $m$ achine that changes state once every tim e unit. The $m$ anner in which the state transitions occur is probabilistic and is govemed by a state-transition $m$ atrix, $P$, that generates the new state of the system. $T$ he $M$ arkovian assum ption indicates that the state at any given tim e depends only on the state at the previous tim e step. W hen dealing w ith text, a state usually represents either a letter, a word or a nite sequence of words, and the state-transition $m$ atrix represents the probability that a given state is follow ed by another state. Estim ating the state-transition $m$ atrix is in the realm of linguistics; it is done by measuring the probability of occurrence of pairs of successive letters in a large corpus.

O ne should bear in $m$ ind that the $M$ arkovian assum ption is very restrictive and very few physical system $s$ can expect to satisfy it in a strict $m$ anner. C learly, a $M$ arkov process im itates som e statistical properties of a given language, but can generate a chain of letters that is gram matically erroneous and lack logicalm eaning. Even though the $M$ arkovian description represents only som e lim ited subset of the correlations that govem a com plex process, it is the sim plest natural starting point for analysis. Thus one assum es that the original $m$ essage, represented by a sequence of $N$ binary bits, has been generated by som e $M$ arkov process. In the sim plest scenario, of a binary sym $m$ etric $M$ arkov process, the underlying $M$ arkov $m$ odel is characterized by a single param eter the ipping rate $p$, denoting the probability that a 0 is followed by 1 (the sam e as a 1 follow ed by a 0). The stream of $N$ bits is transm itted through a noisy com m unication channel. The received string di ers from the transm itted one due to the noise. T he sim plest way to $m$ odel the noise is
known as the B inary Sym m etric Channel, where each bit of the originalm essage is ipped w ith probability . Since the observer sees only the received, noise-cormupted version of the $m$ essage, and neither the originalm essage nor the value of $p$ that generated it are know $n$ to him, what he records is the outcom e of a $H$ idden $M$ arkov $P$ rocess. T hus, H M P s are double em bedded stochastic processes; the rst is the $M$ arkov process that generated the originalm essage and the second, which does not in uence the $M$ arkov process, is the noise added to the $M$ arkov chain after it has been generated.

E cient inform ation transm ission plays a central role in $m$ odem society, and takes a variety of form $s$, from telephone and satellite com $m$ unication to storing and retrieving inform ation on disk drives. Two central aspects of this technology are error correction and com pression. For both problem areas it is of centralim portance to estim ate $R$, the num ber of (expected) received signals.

In the noise free case this equals the expected number of transm itted signals $s$; when the $M$ arkov process has ipping rate $p=0$, only two strings (all 1 or all 0 ) $w$ ill be generated and $s=2$, while when the ip rate is $p=1=2$ each string is equally likely and $s=2^{N}$.

In general, $R$ is given, for large $N$, by $2^{N H}$, where $H=H(p ;)$ is the entropy of the process. The im portance of know ing $\quad R$ for com pression is evident: one can num ber the possible m essages $i=1 ; 2 ;::: R$, and if $R<2^{N}$, by transm Itting only the index of the $m$ essage (whidh can be represented by $\log _{2} \mathrm{R}<\mathrm{N}$ bits) we com press the inform ation. N ote that we can get further com pression using the fact that the R m essages do not have equal probabilities.

Error correcting codes are com $m$ only used in $m$ ethods of inform ation transm ission to com pensate for noise corruption of the data during transm ission. T hese $m$ ethods require the use of additional transm itted inform ation, i.e., redundancy, together $w$ ith the data itself. $T$ hat is, one transm its a string ofM $>\mathrm{N}$ bits; the percentage of additional transm itted bits required to recover the source $m$ essage determ ines the coding e ciency, or channel capacily, a concept introduced and form ulated by Shannon. The channel capacity for the BSC and for a random i.id. source was explicitly derived by Shannon in his sem inalpaper of 1948 [6]. The calculation of channel capacity for a M arkovian source transm itted over a noisy channel is still an open question.

Hence, calculating the entropy of a H M P is an im portant ingredient of progress tow ards deriving im proved estim ates of both com pression and channel capacity, of both theoretical and practical im portance for m odem com munication. In this paper we calculate the entropy of a HMP as a pow er series in the noise param eter .

In Section 2 we map the problem onto that of a one-dim ensional nearest neighbor Ising m odel in a eld of xed $m$ agnitude and random signs (see [7] for a review on the $R$ andom $F$ ield Ising

M odel). Expansion in corresponds to working near the in nite eld lim it.
$N$ ote that the object we are calculating is not the entropy of an Ising chain in a quenched random eld, as show $n$ in eq. (17) and in the discussion follow ing it. In technical term s , here we set the replica index to $\mathrm{n}=1$ after the calculation, whereas to obtain the (quenched average) properties of an Ising chain one works in the n ! 0 lim it.

In Sec. 3 we present exact results for the expansion coe cients of the entropy up to second order. W hile the zeroth and rst order term s were previously known ([8], [9]), the second order term was not [10]. In Sec 4. we introduce bounds on the entropy that were derived by Cover and $T$ hom as [11]; we have strong evidence that these bounds actually provide the exact expansion coe cients. Since we have not proved this statem ent, it is presented as a con jecture; on it's basis the expansion coe cients up to eleventh order are derived and listed. W e conclude in Sec. 5 by studying the radius of convergence of the low -noise expansion, and sum $m$ arize our results in Sec 6 .

## 2 A $H$ idden $M$ arkov $P$ rocess and the $R$ andom $F$ ield Ising $M$ odel

### 2.1 De ning the process and its entropy

$C$ onsider the case of a binary signal generated by the source. B inary valued sym bols, $s_{i}=1$ are generated and transm itted at xed tim es it. D enote a sequence of $N$ transm itted sym bols by

$$
\begin{equation*}
S=\left(S_{1} ; S_{2} ;::::_{\mathrm{N}}\right) \tag{1}
\end{equation*}
$$

The sequence is generated by a $M$ arkov process; here we assume that the value of $S_{i+1}$ depends only on $s_{i}$ (and not on the symbols generated at previous tim es). T he process is param etrized by a transition $m$ atrix $P$, whose elem ents are the transition probabilities

$$
\begin{equation*}
P_{+} ;=\operatorname{Pr}\left(\mathrm{s}_{\mathrm{i}+1}=+1 \dot{\mathrm{~J}}_{\mathrm{i}}=1\right) \quad \mathrm{P} ;+=\operatorname{Pr}\left(\mathrm{s}_{\mathrm{i}+1}=1 \dot{\mathrm{q}}=+1\right) \tag{2}
\end{equation*}
$$

H ere we treat the case of a sym $m$ etric process, i.e. $P_{+} ;=P_{\text {; }}=p_{\text {; }}$ so that we have

$$
s_{\mathrm{i}+1}=\begin{array}{ccc}
( & & \text { prob }:=1  \tag{3}\\
\mathrm{~s}_{\mathrm{i}} & \text { prob }:=\mathrm{p}
\end{array}
$$

The rst symbol $s_{1}$ takes the values 1 w th equal probabilities, $\operatorname{Pr}(\mathrm{s}=+1)=\operatorname{Pr}\left(\mathrm{s}_{1}=1\right)=$ 1=2. T he probability of realizing a particular sequence $S$ is given by

$$
\begin{equation*}
\operatorname{Pr}(S)=\frac{1}{2}_{i=2}^{\mathrm{N}} \operatorname{Pr}\left(\mathrm{~S}_{\mathrm{i}} \dot{\zeta}_{i} \quad 1\right) \tag{4}
\end{equation*}
$$

T he generated sequence $S$ is "sent" and passes through a noisy channel; hence the received sequence,

$$
\begin{equation*}
R=\left(r_{1} ; r_{2} ;:: I_{\mathrm{N}}\right) \tag{5}
\end{equation*}
$$

is not identical to the transm itted one. T he noise can ip a transm itted symbolw ith probability :

$$
\begin{equation*}
\operatorname{Pr}\left(r_{i}=\quad s \dot{\xi}_{i}\right)= \tag{6}
\end{equation*}
$$

H ere we assum ed that the noise is generated by an independent identically distributed (id) process; the probability of a ip at time is independent of what happened at other tim es $j<i$ and of the value of i. W e also assum e that the noise is sym $m$ etric, i.e. the ip probability does not depend on $S_{i}$.

O nce the underlying $M$ arkov process $S$ has been generated, the probability of observing a particular sequence $R$ is given by
and the joint probability of any particular $S$ and $R$ to occur is given by

$$
\begin{equation*}
\operatorname{Pr}(\mathrm{R} ; \mathrm{S})=\operatorname{Pr}(\mathrm{R} \boldsymbol{j} \mathrm{~S}) \mathrm{Pr}(\mathrm{~S}) \tag{8}
\end{equation*}
$$

The original transm itted signal, $S$, is "hidden" and only the received (and typically corrupted) signal R is "seen" by the observer. Hence it is meaningful to ask - what is the probability to observe any particular received signal R ? T he answ er is

$$
\begin{equation*}
Q(R)={ }_{S}^{X} \operatorname{Pr}(R ; S) \tag{9}
\end{equation*}
$$

Furtherm ore, one is interested in the ${ }^{1}$ Shannon entropy $H$ of the observed process,

$$
\begin{equation*}
H_{N}=X_{R}^{X} Q(R) \log Q(R) \tag{10}
\end{equation*}
$$

and in particular, in the entropy rate, de ned as

$$
\begin{equation*}
\mathrm{H}=\lim _{\mathrm{N}} \frac{\mathrm{H}_{\mathrm{N}}}{\mathrm{~N}} \tag{11}
\end{equation*}
$$

### 2.2 C asting the problem in Ising form

It is straightforw ard to cast the calculation of the entropy rate onto the form of a one-dim ensional Ising $m$ odel. The conditional M arkov probabilities (3), that connect the sym bols from one site to the next, can be rew rilten as

$$
\operatorname{Pr}\left(s_{i+1} \dot{J}_{i}\right)=e^{J s_{i+1} s_{i}}=\left(e^{J}+e^{J}\right) \quad w \text { th } \quad e^{2 J}=\left(\begin{array}{ll}
1 & p \tag{12}
\end{array}\right)=p
$$

[^0]and sim ilarly, the ip probability generated by the noise, (6), is also recapitulated by the Ising form
\[

$$
\begin{equation*}
\operatorname{Pr}\left(r_{i} \dot{\beta}_{i}\right)=e^{K r_{i} s_{i}}=\left(e^{K}+e^{K}\right) \quad \text { with } \quad e^{2 K}=(1 \quad)= \tag{13}
\end{equation*}
$$

\]

The joint probability of realizing a pair of transm itted and observed sequences ( $\mathrm{S} ; \mathrm{R}$ ) takes the form ([12], [13])

$$
\begin{equation*}
\operatorname{Pr}(\mathbb{R} ; S)=A \exp J_{i=1}^{\mathbb{X}^{1} S_{i+1} S_{i}+K X_{i=1}^{X_{i}} r_{i} S_{i}, ~} \tag{14}
\end{equation*}
$$

where the constant $A$ is the product of two factors, $A=A_{0} A_{1}$, given by

$$
\begin{equation*}
A_{0}=\frac{1}{2} e^{J}+e^{J} \quad{ }^{(N 1)} \quad A_{1}=e^{K}+e^{K} \tag{15}
\end{equation*}
$$

The rst sum in (14) is the Ham iltonian of a chain of Ising spins with open boundary conditions and nearest neighbor interactions $J$; the interactions are ferrom agnetic ( $J>0$ ) for $p<1=2$. The second term corresponds, for sm all noise < 1=2, to a strong ferrom agnetic interaction K between each spin $s_{i}$ and another spin, $r_{i}$, connected to $s_{i}$ by a "dangling bond" (see $F$ ig 2).

D enote the sum $m$ ation over the hidden variables by $Z(R)$ :

$$
\begin{equation*}
Z(R)={ }_{s}^{X} \quad \exp \quad J_{i=1}^{\mathbb{K} X_{i+1}^{1} S_{i}+K}{ }_{i=1}^{X_{i}^{N}} r_{i} S_{i} \tag{16}
\end{equation*}
$$

so that the probability $Q(\mathbb{R})$ becom es (see eq. (9)) $Q(R)=A Z(R)$. Substituting in (10), the entropy of the process can be written as

The interpretation of this expression is obvious: an Ising chain is subm itted to local elds $h_{i}=K r_{i}, w$ ith the sign of the eld at each site being $w i t h$ equal probabilities, and we have to average $Z\left(h_{1} ;:: h_{N}\right)^{n}$ over the eld con gurations. This is precisely the problem one faces in order to calculate properties of a well-studied $m$ odel, of a nearest neighbor Ising chain in a quenched random eld of uniform strength and random signs at the di erent sites (there one is interested, how ever, in the lim it n! 0). This problem has not been solved analytically, albeit a few exactly solvable sim pli ed versions of the m odeldo exist ([14], [15], [16], [17]), as well as expansions (albeit in the weak eld lim it [18]).

O ne should note that here we calculate the entropy associated with the observed variables R . In the Ising language this corresponds to an entropy associated with the random ly assigned signs of the local elds, and not to the entropy of the spins S. Because of this distinction the entropy
$\mathrm{H}_{\mathrm{N}}$ has no obvious physical interpretation or relevance, which explains why the problem has not been addressed yet by the physics com $m$ unity.

W e are interested in calculating the entropy rate in the lim it of sm all noise, ie. 1 . In the Ising representation th is $\lim$ it corresponds to $\mathrm{K} \quad 1$ and hence an expansion in corresponds to expanding near the in nite eld lim it of the Ising chain.

## 3 Expansion to order ${ }^{2}$ : exact results

W e are interested in calculating the entropy rate

$$
\begin{equation*}
H=\lim _{N!1} \frac{1}{N}_{R}^{X} A Z(R) \log A Z(R) \tag{18}
\end{equation*}
$$

to a given order in . A few technical points are in order. $F$ irst, we will actually use

$$
\begin{equation*}
\mathrm{e}^{2 \mathrm{~K}}==(1 \quad) \tag{19}
\end{equation*}
$$

as our sm all param eter and expand to order ${ }^{2}$ afterwards. Second, we will calculate $H_{N}$ and take the large N lim it. Therefore we can replace the open boundary conditions w ith periodic ones (setting $s_{N+1}=s_{1}$ ) - the di erence is a surface e ect of order $1=N$. The constant $A$

$$
\begin{equation*}
A_{0}=e^{J}+e^{J} \tag{20}
\end{equation*}
$$

and the interaction term $J s_{1} S_{N}$ is added to the rst sum in eq. (14), which contains now $N$ pairs of neighbors.

Expanding $Z(R)$ : C onsider $Z(R)$ from (16). For any $x \in d=\left(r_{1} ; r_{2} ;:: I_{N}\right)$ the leading order is obtained by the $S$ con guration $w$ th $s_{i}=r_{i}$ for alli. For this con guration each site contributes $K$ to the " eld term " in (16). The contribution of this con guration to the sum $m$ ation over $S$ in (16) is

$$
\begin{equation*}
Z(R)^{(0)}=e^{N K} \exp J_{i=1}^{\mathrm{X}^{\mathrm{N}}} r_{i+1} r_{i} \tag{21}
\end{equation*}
$$

The next term we add consists of the contributions of those $S$ con gurations which have $s_{i}=r_{i}$ at all but one position. The eld term of such a con guration is $K$ from $N \quad 1$ sites and $K$ from the single site w ith $S_{j}=\quad r_{j}$. There are $N$ such con gurations, and the total contribution of these term $s$ to the sum (16) is

$$
\begin{equation*}
Z(R)^{(1)}=e^{N K} e^{2 K} \exp J_{i=1}^{X^{N}} r_{i+1} r_{i} \underbrace{X^{N}}_{j=1} \exp \left[2 J r_{j}\left(r_{j} 1+r_{j+1}\right)\right] \tag{22}
\end{equation*}
$$

The next term is of the highest order studied in this paper; it involves con gurations $S$ w ith allbut tw o spins in the state $s_{i}=r_{i}$; the other two take the values $s_{j}=r_{j} ; s_{k}=$ fre. i.e. are ipped w ith respect to the corresponding local elds. These $S$ con gurations belong to one of tw o classes. In class a the two ipped spins are located on nearest neighbor sites, e.g. $k=j+1$; there are $N$ such con gurations. To the second class, b, belong those con gurations in which the two jipped spins are not neighbors - there are $N(\mathbb{N} \quad 3)=2$ such term $s$ in the sum (16), and the respective contributions are ${ }^{2}$

$$
\begin{align*}
& Z(R)^{(2 a)}=e^{N K} e^{4 K} \exp J_{i=1}^{X^{N}} r_{i+1} r_{i}^{!} \operatorname{Ni}_{j=1}^{N} \exp \left[2 J\left(r_{j} r_{j} 1+r_{j+1} r_{j+2}\right)\right]  \tag{23}\\
& Z(R)^{(2 b)}=e^{N K} e^{4 K} \exp J_{i=1}^{x^{N}} r_{i+1} r_{i} \frac{1}{2}_{j=1 k \notin j ; j 1}^{N^{N}} \quad \exp \left[2 J r_{j}\left(r_{j} 1+r_{j+1}\right) \quad 2 J r_{k}\left(r_{k} 1+r_{k+1}\right)\right] \tag{24}
\end{align*}
$$

Calculation of $H$ is now straightforward, albeit tedious: substitute $A Z$ into eq. (18), expand everything in powers of , to second order, and for each term perform the sum $m$ ation over all the $r_{i}$ variables. These sum $m$ ations involve two kinds of term $s$. The rst is of the "partition-sum -like" form

$$
\begin{array}{lllll}
X  \tag{25}\\
R & e^{H(R)} \quad \text { where } \quad H(R)={ }_{j} J r_{j} r_{j+1} & \text { with } \quad j=1
\end{array}
$$

For the case studied here we encounter either all bonds $j J>0$, or two have a ipped sign (corresponding to eq. $(22,23)$ ), or four have ipped signs (corresponding to (24)). T hese "partitionsum -like" term s are independent of the signs of the $j ;$ in fact we have for all of them

$$
\begin{equation*}
A_{0}^{X} e^{H(R)}=1 \tag{26}
\end{equation*}
$$

The second type of term that contributes to $H$ is of the "energy-like" form :

$$
\begin{equation*}
\mathrm{X}_{\mathrm{R}}^{\mathrm{X}(\mathrm{R})} r_{\mathrm{k}} r_{\mathrm{k}+1} \tag{27}
\end{equation*}
$$

The absolute value of these term $s$ is again independent of the jr but one has to keep track of their signs. Finally, one has to rem em ber that the constant $A_{1}$ also has to be expanded in . The calculation nally yields the follow ing result (here we sw itch from $J$ to the "natural" variable $p$ using eq. (12)):

$$
\begin{equation*}
H(p ;)=\sum_{k=0}^{X^{\prime}} H^{(k)}(p)^{k} \tag{28}
\end{equation*}
$$

[^1]w ith the coe cients H k given by :
\[

$$
\begin{align*}
& H^{(0)}=p \log p \quad\left(\begin{array}{lll}
1 & p
\end{array}\right) \log \left(\begin{array}{ll}
1 & p
\end{array}\right) \quad f^{(1)}=2\left(\begin{array}{ll}
1 & 2 p
\end{array}\right) \log \frac{1}{p}  \tag{29}\\
& H^{(2)}=2(1 \quad 2 \mathrm{p}) \log \frac{1 \quad \mathrm{p}}{\mathrm{p}} \quad \frac{(1 \quad 2 \mathrm{p})^{2}}{2 \mathrm{p}^{2}(1 \quad \mathrm{p})^{2}} \tag{30}
\end{align*}
$$
\]

The zeroth and rst order term s (29) were known ([8], [9]), while the second order term is new [10].

## 4 U pper B ounds derived using a system of nite length

W hen investigating the lim it $H$, it is useful to study the quantity $C_{N}=H_{N} \quad H_{N} \quad 1$, whidh is also know $n$ as the conditional entropy. $C_{N}$ can be interpreted as the average am ount of uncertainty we have on $r_{N}$, assum ing that we know $\left(r_{1} ;::: ; r_{N} \quad 1\right)$. P rovided that $H$ exist, it easily follow $s$ that

$$
\begin{equation*}
\mathrm{H}=\lim _{N!1} \mathrm{C}_{\mathrm{N}} \tag{31}
\end{equation*}
$$

M oreover, according to [11], $\mathrm{C}_{\mathrm{N}} \quad \mathrm{H}$, and the convergence is m onotone :

$$
\begin{equation*}
C_{N} \& H \quad(\mathbb{N} \quad!\quad 1) \tag{32}
\end{equation*}
$$

$W$ e can express $C_{N}$ as a function of $p$ and by using eq. (17). For this, we represent $Z$ using the original variables p; (note that from this point of we work w ith open boundary conditions on the Ising chain of N spins) :
where we denote $1_{s ; s^{0}}=\left(1+s s^{0}\right)=2$. Eq. (33) gives $Z(R)$ explicitly as a polynom ial in $p$ and $w$ ith $m$ axim al degree $N$, and can be represented as:

$$
\begin{equation*}
Z(R)=\sum_{i=0}^{\mathrm{X}^{\mathrm{N}}} Z_{i}(R)^{i} \tag{34}
\end{equation*}
$$

$H$ ere $Z_{i}=Z_{i}(\mathbb{R})$ are functions of $p$ only.
Substituting this expansion in eq. (17), and expanding $\log Z(R)$ according to the Taylor series $\log (a+x)=\log (a) \quad P_{n=1}^{1} \frac{(x)^{n}}{n a^{n}}$, we get

W hen extended to term s of order ${ }^{k}$, this equation gives us precisely the expansion of the upperbound $\mathrm{C}_{\mathrm{N}}$ up to the k -th order,

$$
\begin{equation*}
C_{N}={ }_{i=0}^{X^{k}} C_{N}^{(i)} i^{i}+O\left({ }^{k+1}\right) \tag{36}
\end{equation*}
$$

For exam ple, stopping at order $L=2$ gives

$$
\begin{align*}
& H_{N}=\begin{array}{r}
X \\
Z_{0}(R) \log Z_{0}(R)+\left[Z_{1}(R)\left(1+\log Z_{0}(R)\right)\right]+ \\
\hline
\end{array} \\
& \frac{" Z_{1}(\mathbb{R})^{2}}{2 Z_{0}(\mathbb{R})}+Z_{2}(\mathbb{R})\left(1+\log Z_{0}(\mathbb{R})\right)^{\#}{ }^{2}+O\left(^{3}\right) \tag{37}
\end{align*}
$$

The zeroth and rst order term scan be evaluated analytically for any N ; beyond rst order, we can com pute the expansion of $\mathrm{H}_{\mathrm{N}}$ Sym bolically ${ }^{3}$ (using M aple [19]), for any nite N . This was actually done, for $\mathrm{N} \quad 8$ and $\mathrm{k} \quad$ 11. For the rst order we have proved ([10]) that $\mathrm{C}_{\mathrm{N}}^{(1)}$ is independent of N (and equals $\mathrm{H}^{(1)}$ ). The sym bolic com putation of higher order term s yielded sim ilar independence of $N$, provided that $N$ is large enough. So, $\mathrm{C}_{\mathrm{N}}^{(k)}=\mathrm{C}^{(k)}$ for large enough N . For exam $\mathrm{ple}, \mathrm{C}_{\mathrm{N}}^{(2)}$ is independent of N for $3 \mathrm{~N} \quad 8$ and equals the exact value of $\mathrm{H}^{(2)}$ as given by eq. (30). Sim ilarly, $\mathrm{C}_{\mathrm{N}}^{(4)}$ settles, for $\mathrm{N} \quad 4$, at som e value denote by $\mathrm{C}^{(4)}$, and so on. For the values we have checked, the settling point for $C_{N}^{(k)}$ tumed out to be at $N=d \frac{k+3}{2} e$. This behavior is, how ever, unproved for k 2, and, therefore, we refer to it as a

C on jecture: For any order $k$, there is a critical chain length $N_{C}(k)=d \frac{k+3}{2} e$ such that for $\mathrm{N}>\mathrm{N}_{\mathrm{C}}(\mathrm{k})$ we have $\mathrm{C}_{\mathrm{N}}^{(\mathrm{k})}=\mathrm{C}^{(k)}$.

It is known that $C_{N}!H$, and $C_{N}$ and $H$ are analytic functions of at $=0^{4}$, so that we can expand both sides around $=0$, and conclude that $C_{N}^{(k)}!H^{(k)}$ for any $k \quad 1$ when $N$ ! 1 . $T$ herefore, if our con jecture is true, and $C_{N}^{(k)}$ indeed settles at som e value $C^{(k)}$ independent of $N$ (for $\mathrm{N}>\mathrm{N}_{\mathrm{C}}(\mathrm{k})$ ), it im m ediately follow s that this value equals $\mathrm{H}^{(k)}$. N ote that the settling is rigourously supported for $\mathrm{k}=0 ; 1$, while for $\mathrm{k}=2$ we showed that indeed $\mathrm{C}^{(2)}=\mathrm{H}^{(2)}$, supporting our con jecture.
The rst orders up to $H^{(11)}$, obtained by identifying $H^{(k)}$ with $C^{(k)}$, are given in the A ppendix, as functions of $=1 \quad 2 \mathrm{p}$, for better readability. The values of $\mathrm{H}^{(0)} ; \mathrm{H}{ }^{(1)}$ and $H^{(2)}$ coincide $w$ ith the results that w ere derived rigorously from the low -tem perature/high- eld expansion, thus giving us support for postulating the above C on jecture.

[^2]Interestingly, the nom inators have a sim pler expression when considered as a functions of , which is the second eigenvalue of the $M$ arkov transition $m$ atrix $P$. N ote that only even pow ers of appear. A nother interesting observation is that the free elem ent in $\left[\mathrm{p}\left(\begin{array}{ll}1 & \mathrm{p}\end{array}\right)^{\left.\mathcal{F}^{(k}{ }^{1}\right)^{H} \mathrm{H}^{(k)} \text { (when treated as a }}\right.$ polynom ial in $p$ ), is $\frac{(1)^{k}}{k(k \quad 1)}$, which $m$ ight suggest som e role for the function $\log \left(1+\frac{}{[2 p(1 \quad p)]^{2}}\right)$ in the rst derivative of $H$. A ll of the above observations led us to con jecture the follow ing form for $H^{(k)}$ (for k 3):

$$
\begin{equation*}
H^{(k)}=\frac{\left.2^{4(k} \quad 1\right)^{P} d_{k}^{d_{k}} j=0 a_{j k}{ }^{2 j}}{k(k \quad 1)\left(1 \quad{ }^{2}\right)^{2(k \quad 1)}} \tag{38}
\end{equation*}
$$

$w$ here $a_{j ; k}$ and $d_{k}$ are integers that can be seen in the A ppendix for $H^{(k)}$ up to $k=11$.

## 5 The R adius of C onvergence

If one wants to use our expansion around $=0$ for actually estim ating $H$ at some value, it is im portant to ascertain that lies $w$ thin the radius of convergence of the expansion. The funda$m$ ental observation $m$ ade here is that for $p=0$, the function $H()$ is not an analytic function at $=0$, since its rst derivative diverges. A swe increase p, the singularity points ' $m$ oves' to negative values of , and hence the function is analytic at $=0$, but the radius of convergence is determ ined by the distance of $=0$ from this singularity. D enote by ( p ) the radius of convergence of $H$ ( ) for a given $p$; we expect that ( p ) grow $s$ when we increase $p$, while for $p!0$, ( p ) ! 0 .

It is usefiul to rst look at a sim pler model, in which there is no interaction betw een the spins. Instead, each spin is in an extemal eld which has a uniform constant com ponent $J$, and a sitedependent com ponent of absolute value $K$ and a random sign. For this sim ple i.i.d. m odel the entropy rate takes the form

$$
H=h_{b}\left[p(1 \quad)+\left(\begin{array}{ll}
1 & p \tag{39}
\end{array}\right]\right.
$$

$w h e r e h_{b}[x]=\left[x \log x+\left(\begin{array}{ll}1 & x\end{array}\right) \log (1 \quad x)\right]$ is the binary entropy function. $N$ ote that for $=0$ the entropy of this m odelequals that of the Ising chain. Expanding eq. (39) in (for p $>0$ ) gives :

$$
\begin{align*}
& H=\left(p \log p+\left(\begin{array}{lll}
1 & p
\end{array}\right) \log \left(\begin{array}{ll}
1 & p
\end{array}\right)\right)+\left(\begin{array}{ll}
1 & 2 p) \\
\log \left(\frac{1}{p}\right.
\end{array}\right)+ \\
& \mathrm{X}_{\mathrm{k}=2}^{\mathrm{A}} \frac{1}{\mathrm{k}(\mathrm{k}-1)} \frac{(2 \mathrm{p} \quad 1)^{k}}{\mathrm{p}^{k}}+\frac{(1 \quad 2 \mathrm{p})^{k^{\prime}}}{(112)^{k^{1}}} \mathrm{k} \tag{40}
\end{align*}
$$

$T$ he radius of convergence here is easily show $n$ to be $p=\left(\begin{array}{ll}1 & 2 p\end{array}\right)$; it goes to 0 for $p!0$ and increases m onoton ically w ith p .
Retuming to the HMP, the orders $H^{(k)}$ are (in absolute value) usually larger than those of the sim pler i.i.d. $m$ odel, and henœe the radius of convergence $m$ ay be expected to be sm aller. Since we
could not derive (p) analytically, we estim ated it using extrapolation based on the rst 11 orders. $W$ e use the fact that $(\mathrm{p})=\lim _{\mathrm{k}!} 1 \frac{\mathrm{H}^{(\mathrm{k})}}{\mathrm{H}^{(\mathrm{k}+1)}}$ (provided the lim it exists). The data w as thed to a rational function of the follow ing form (w hich holds for the i.i.d. m odel) :

$$
\begin{equation*}
\frac{H^{(k)}}{H^{(k+1)}} \quad \frac{a k+b}{k+c} \tag{41}
\end{equation*}
$$

For a given $t$, the radius of convergence was sim ply estim ated by $a$. The resulting prediction is given in $F$ ig. 3 for both the i.id. $m$ odel (for which it is com pared to the known exact (p)) and for the HMP.W hile quantitatively, the predicted radius of the HMP is much smaller than this of the i.i.d. $m$ odel, it has the sam equalitative behavior, of starting at zero for $p=0$, and increasing w th p .
W e com pared the analytic expansion to estim ates of the entropy rate based on the low er and upper bounds, for two values of (see Fig. 4). First we took $=0: 01$, which is realistic in typical com m unication applications. For p less than about 0.1 this value of exceeds the radius of convergence and the series expansion diverges, whereas for larger $p$ the series converges and gives a very good approxim ation to $H(p ;=0: 01)$. The second value used was $=0.2$; here the divergence happens for $p \quad 0: 37$, so the expansion yields a good approxim ation for a $m$ uch sm aller range. W e note that, as expected, the approxim ation is m uch closer to the upper bound than to the lower bound of [11].

## 6 Sum m ary

Transm ission of a binary $m$ essage through a noisy channel is m odelled by a $H$ idden $M$ arkov $P$ rocess. W e m apped the binary sym m etric HMP onto an Ising chain in a random extemal eld in therm al equilibrium. U sing a low -tem perature/high-random - eld expansion we calculated the entropy of the HMP to second order $k=2$ in the noise param eter. We have shown for $k \quad 11$ that when the know $n$ upper bound on the entropy rate is expanded in , using nite chains of length $N$, the expansion coe cients settle, for $N_{c}(k) \quad N \quad$, to values that are independent of $N$. Posing a con jecture, that this continues to hold for any $N$, we identi ed the expansion coe cients of the entropy up to order 11. The radius of convergence of the resulting series was studied and the expansion was com pared to the the know n upper and low er bounds.

By using methods of Statistical Physics we were able to address a problem of considerable current interest in the problem area of noisy com $m$ unication channels and data com pression.

## A cknow ledgm ents
