We propose a new algorithm of the finite lattice method to generate the high-temperature series for the Ising model in three dimensions. It enables us to extend the series for the free energy of the simple cubic lattice from the previous series of 26th order to 46th order in the inverse temperature. The obtained series give the estimate of the critical exponent for the specific heat in high precision.

The finite lattice method[1, 2, 3] is a powerful tool to generate the high- and low- temperature series for the spin models in the infinite volume limit. It avoids the tedious work of counting all the diagrams in the graphical method and reduce the problem to the calculation of the partition function. In two dimensions the total amount of the calculations for the finite lattice method increases exponentially with the maximum order N of the series. On the other hand in three dimensions the total amount of the calculations grows exponentially with N^2 and except for some cases[4, 5, 6, 7, 8, 9, 10, 11, 12] many of the expansion series have been calculated by the graphical method. Here we present a new algorithm of the finite lattice method for the high-temperature expansion in three dimensions in which the total amount of the calculation increase approximately exponentially with $N \log N$ and that enables us to generate the series to much higher orders than not only the standard algorithm of the finite lattice method but also the graphical method.

In the finite lattice method to generate the high-temperature series for the free energy in three dimensions we calculate the partition function $Z(l_x \times l_y \times l_z)$ for the finite size lattices with $2(l_x + l_y + l_z) \leq N$ and define recursively[2]

$$\phi(l_x \times l_y \times l_z) = \log [Z(l_x \times l_y \times l_z)] - \sum_{\substack{l'_x \leq l_x, l'_y \leq l_y, l'_z \leq l_z, \\ l'_x + l'_y + l'_z \neq l_x + l_y + l_z}} \phi(l'_x \times l'_y \times l'_z). \quad (1)$$

Here we use the notation for the lattice size such that the $1 \times 1 \times 1$ lattice means the unit cube composed of $2 \times 2 \times 2$ sites. The Boltzmann factor for each bond connecting the nearest neighbor sites k and k' is expressed as

$$\exp(\beta s_k s_{k'}) = \cosh(\beta) (1 + t s_k s_{k'}), \quad (2)$$

with $t = \tanh(\beta)$. We define the bond configuration as the set of bonds to which the factor $t s_k s_{k'}$ in (2) is assigned while the factor 1 is assigned to the other bonds

of the finite size lattice. Non-vanishing contribution to the partition function comes only from the bond configuration in which the bonds form one or more closed loops. Each of the closed loops is a polymer in the standard cluster expansion[13]. Then the Taylor expansion of $\phi(l_x \times l_y \times l_z)$ with respect to t includes the contribution from all the clusters of polymers in the standard cluster expansion that can be embedded into the lattice of $l_x \times l_y \times l_z$ but cannot be embedded into any of its rectangular sub-lattices $l'_x \times l'_y \times l'_z$ [2]. The expansion series of the free energy density in the infinite volume limit is given by

$$f = \sum_{2(l_x + l_y + l_z) \leq N} \phi(l_x \times l_y \times l_z) \quad (3)$$

The expansion series of $\phi(l_x \times l_y \times l_z)$ starts from the term of t^n with $n = 2(l_x + l_y + l_z)$, which comes from the cluster of a single polymer (one closed loop of bonds) that have two intersections with any plane perpendicular to the lattice bonds. Thus it is enough to restrict the lattice sizes for the summation in (3) to those that satisfy $2(l_x + l_y + l_z) \leq N$ to obtain the series for f to order t^N .

In the standard algorithm of the finite lattice method the full partition function for the finite size lattice is calculated with all the bond configurations taken into account. The point of the new algorithm is that, in order to obtain the series to a given order, however, it is enough to consider only a restricted number of bond configurations. Let us consider the anisotropic model of the simple cubic Ising model with $\beta_i = J_i/k_B T$ and $t_i = \tanh(\beta_i)$ ($i = x, y, z$). To obtain the series for $\phi(l_x \times l_y \times l_z)$ to order $N_z = 2l_z + \Delta N_z$ in t_z we introduce in the new algorithm $\phi(l_x \times l_y \times l_z, \Delta N_z)$ defined recursively by

$$\phi(l_x \times l_y \times l_z, \Delta N_z) = \log [Z(l_x \times l_y \times l_z, \Delta N_z)] - \sum_{\substack{l'_x \leq l_x, l'_y \leq l_y, l'_z \leq l_z, \\ l'_x + l'_y + l'_z \neq l_x + l_y + l_z}} \phi(l'_x \times l'_y \times l'_z, \Delta N_z). \quad (4)$$

Here the partition function $Z(l_x \times l_y \times l_z, \Delta N_z)$ is calculated only with the bond configurations taken into ac-

FIG. 1: Examples of the bond configuration for $Z(l_x \times l_y \times l_z, \Delta N_z)$ with $l_x = 3, l_y = 3, l_z = 4, \Delta N_z = 2$. Example (a) has $n_{z1} = 2, n_{z4} = 2, n_{z3} = 4$, and $n_{z4} = 2$ and it should be taken into account, while (b) has $n_{z1} = 0, n_{z4} = 4, n_{z3} = 4$, and $n_{z4} = 2$ and it should be neglected.

count that have orders n_{zi} in t_z for the i -th layer perpendicular to the z -axis ($i = 1, 2, \dots, l_z$) satisfying

$$\sum_{i=1}^{l_z} \max(n_{zi}, 2) \leq 2l_z + \Delta N_z. \quad (5)$$

Examples of the bond configuration for $Z(l_x \times l_y \times l_z, \Delta N_z)$ that should be taken into account or should be neglected can be seen in Fig. 1.

It is easy to prove that any bond configuration for the partition function that has $\sum_{i=1}^{l_z} n_{zi} \leq 2l_z + \Delta N_z$ but $\sum_{i=1}^{l_z} \max(n_{zi}, 2) > 2l_z + \Delta N_z$ does not contribute to the left hand side of (4) in the order lower than or equal to $N_z = 2l_z + \Delta N_z$. For such a bond configuration at least one of the n_{zi} 's should be zero, so they are disconnected configuration (composed of more than one polymer) or they can be embedded into a rectangular sub-lattice of the $l_x \times l_y \times l_z$ lattice and in either case they do not contribute to $\phi(l_x \times l_y \times l_z, \Delta N_z)$ in the order lower than or equal to $N_z = 2l_z + \Delta N_z$. They can contribute to $\phi(l_x \times l_y \times l_z, \Delta N_z)$ in higher order than $N_z = 2l_z + \Delta N_z$ by constituting the connected cluster of polymers together with other configurations with $n'_{zi} \geq 2$ for the layer i with $n_{zi} = 0$. Then total order of the cluster of polymers has the order higher than $N_z = 2l_z + \Delta N_z$.

The contribution of the bond configuration with $\{n_{zi}\}$ to the partition function of the finite size lattice can be calculated by the transfer matrix formalism as

$$Z(\{n_{zi}\}) = V_{0,j_1} t_z^{n_{z1}} V_{j_1,j_2} t_z^{n_{z2}} \dots t_z^{n_{zl_z}} V_{j_{l_z},0}. \quad (6)$$

Here $V_{j_i,j_{i+1}}$ is the transfer matrix element with incoming n_{zi} spins and outgoing $n_{z,i+1}$ spins and the summations over the spin locations j_1, j_2, \dots of the n_{z1}, n_{z2}, \dots spins, respectively, are assumed in the right hand side

FIG. 2: Total amount of the calculation to generate the series to order N by the old algorithm and the new algorithm of the finite lattice method.

of (6). This transfer matrix element itself is the partition function in two dimensions with $n_{zi} + n_{z,i+1}$ spins attached, which can be calculated to any order in t_x and t_y efficiently by the site-by-site construction [14, 15]. The amount of the calculation for each transfer matrix element is proportional to the combinatorial factor $C((l_x + 1)(l_y + 1), n_{zi} + n_{z,i+1}, 2^{l_x})$ and $l_x l_y$, which are the number of the cases for attaching the $n_{zi} + n_{z,i+1}$ spins to the $(l_x + 1)(l_y + 1)$ sites, the number of states in site-by-site construction for the partition function of the Ising model in two dimensions and the number of the relevant bonds, respectively.

To obtain the series to order N in the isotropic model, we calculate the expansion series for each of the $\phi(l_x \times l_y \times l_z)$'s defined by (1) in the anisotropic model to order $t_x^{N_x} t_y^{N_y} t_z^{N_z}$ with $N_x + N_y + N_z = N$ using the new algorithm described above and set $t_x = t_y = t_z = t$ finally. When we use the new algorithm for each lattice size $l_x \times l_y \times l_z$ and each of the orders N_x, N_y, N_z , we can make the simultaneous exchange of the lattice axes and corresponding orders as $(l_x \times l_y \times l_z; N_x, N_y, N_z) \rightarrow (l_x \times l_z \times l_y; N_x, N_z, N_y)$ or $(l_x \times l_y \times l_z; N_x, N_y, N_z) \rightarrow (l_y \times l_z \times l_x; N_y, N_z, N_x)$ that have the chance to reduce the amount of the calculation for the transfer matrix elements.

We estimate the total amount of the calculation time $T_{\text{calc}}(N)$ to generate the free energy series to order N by listing up all the transfer matrices needed and summing up the estimated time to calculate each of the matrices, which is plotted in Fig. 2 together with the estimated total calculation time for the old algorithm of the finite lattice method. The numerical estimation for the new algorithm agrees well with the actually used calculation time for $N \leq 46$. We see that the calculation time for the old algorithm grows exponentially

with N^2 , while that for the new algorithm can be fitted by $A \exp(BN \log N + CN + D \log N)$ with $B \sim 0.15$, $C \sim -0.24$ and $D \sim 3.6$. We can simply understand this $\exp(BN \log N + \dots)$ behavior as follows. The maximum size of the lattice to be taken into account is $l_x = l_y = l_z = N/6$, for which $\Delta N_z = 0$ and we have only to consider the bond configurations with $n_{zi} = 2$ for all $i = 1, 2, \dots, l_z$. The largest amount of the calculation is to be paid for the partition function of the lattice that has smaller size of $l_x \sim l_y \sim l_z \sim N/12$ for which the maximum of $n_{zi} + n_{z, i+1}$ is about $N/6$ and the product of the above factors is approximately proportional to $\exp(BN \log N + CN + D \log N)$ with $B = 1/6$ for large N .

Using the new algorithm of the finite lattice method we have calculated the high-temperature series for the free energy density of the simple cubic Ising model to order $N = 46$. The coefficients of the obtained series

$$f = 3 \cosh(\beta) + \sum_n a_n t^n; \quad t = \tanh(\beta) \quad (7)$$

are listed in Table I. They agree with those given by Bhanot et al[4] to order $N = 24$ and by Guttman and Enting[5] to order $N = 26$. We have add ten new terms to these previous series. To obtain the series of order $N = 26$ in our new algorithm we needed only the computer memory of 1 MBytes and the CPU-time of 5 minutes in a standard PC and to order $N = 46$ we used the total memory of 2 GBytes and the CPU time of 25 hours in CP-PACS at Tsukuba University.

FIG. 3: Critical exponent α versus the critical value β_c for the inhomogeneous differential approximants of the first order.

FIG. 4: Sequence α_n plotted versus $1/n$.

Following is the result of the preliminary analysis of the series for the specific heat $C(t) = \sum_n c_n t^n$. We plot in Fig. 3 the critical exponent α versus the critical value β_c for the first order inhomogeneous differential approximants of the series of $N = 40-46$. From the linear dependence of α on β_c we find $\alpha = 0.1045(1)$ or $\alpha = 0.1077(2)$ at the value $\beta_c = 0.22165459(10)$ [16] or $\beta_c = 0.2216595(15)$ [17] obtained in the recent Monte Carlo simulations. The second order inhomogeneous differential approximants give almost the same value. We also made the ratio analysis. The sequence $\alpha_n = (t_c^2 c_{2n}/c_{2n-2} - 1)n + 1$, which is expected to behave as $\alpha + b/n^\Delta + c/n + \dots$ with the correction-to-scaling exponent $\Delta \sim 0.5$, is plotted versus $1/n$ in Fig. 4 for $\beta_c = 0.22165459$. The sequence for $n = 14-23$ given by the new 10 coefficients has a bit different slope from the sequence for $n \leq 13$ given by the previously obtained series. Three-parameter fitting of the newly obtained

sequence for $\beta_c = 0.22165459$ gives $\alpha = 0.1036(10)$, $b = -0.007(10)$ and $c = 0.17(2)$ for $\Delta = 0.5$. As for the case of $\beta_c = 0.2216595$ it gives $\alpha = 0.1082(14)$, $b = -0.033(10)$ and $c = 0.21(2)$. These estimated values of α by the inhomogeneous differential approximation and by the ratio method are not inconsistent with each other. We see, on the other hand, that the estimated values of α depends crucially on the value of β_c and in order to determine α precisely in these biased method we need more precise value of β_c . We also notice that the correction-to-scaling term is very small, which was already pointed out in the analysis of the shorter series[4, 5].

From the hyperscaling relation $\alpha = 2 - d\nu$ the high-temperature series for the second moment correlation length gives $\alpha = 0.1088(39)$ [18] and $\alpha = 0.1096(5)$ [19] and the ϵ -expansion gives $\alpha = 0.1088(39)$ [20]. More direct estimation of $\alpha = 0.110(2)$ was also given by the high-temperature series for the magnetic susceptibility of the antiferromagnetic critical point[19]. We note that our estimated value of α using $\beta_c = 0.22165459$ is not consistent with these values but the value using $\beta_c = 0.2216595$ is rather closer to these values.

The basic idea presented here in the new algorithm of the finite lattice method can be applied to the high-temperature expansion of other quantities such as the magnetic susceptibility and the correlation length for the Ising model in three dimensions and it can also be applied to the models with continuous spin variables such as the XY model in three dimensions. Furthermore the idea can be used in the low-temperature expansion for the spin models in three dimensions. We can expect that it will enable us to generate the expansion series in much higher orders compared with the presently available series.
