A bstract

W e study the zeros in the com plex plane of the partition function for the Ising $m$ odel coupled to $2 d$ quantum gravity for complex $m$ agnetic eld and real tem perature, and for com plex tem perature and realm agnetic eld, respectively. W e com pute the zeros by using the exact solution com ing from a two m atrix model and by M onte C arlo sim ulations of Ising spins on dynam ical triangulations. W e present evidence that the zeros form sim ple one-dim ensional curves in the com plex plane, and that the critical behaviour of the system is govemed by the scaling of the distribution of the singularities near the critical point. D espite the sm all size of the system $s$ studied, we can obtain a reasonable estim ate of the (known) critical exponents.

[^0]
## 1 Introduction

The understanding of the phase transition of a statistical m echanicalm odel has long been connected to the study of its partition function zeros. This line of research was pioneered by Yang and Lee [1] ], and has subsequently been pursued by $m$ any authors (for recent work see [3] and references therein). In the therm odynam ic lim it, the zeros of the partition function of such a system in the com plex coupling space accum ulate in nitely close to the critical coupling on the real axis. This de nes, in the in nite volum e lim it, disconnected regions in the com plex plane, w ith di erent analytic structure for the them odynam ic functions which describe the phases of the system.

The criticalbehaviour in the neighbourhood of a continuous phase transition can be extracted from the behaviour of the density of zeros near its singular points 2, 24, 5]. In the best-understood m odels, these points occur at the ends of lines on which the zeros accum ulate in the in nite volum e lim it. Such singular points, even when they occur at non \{physical values of the coupling, can be considered as ordinary critical points w ith distinctive critical exponents 7] (see also [8]). For a physical phase transition, these singularities coincide $w$ th the (real) critical coupling of the system .

Substantial progress, also from a practical point of view, has been $m$ ade by applying renor$m$ alization group argum ents to the $m$ otion of zeros, thereby deriving nite size scaling relations by which the critical exponents can be com puted [6]. This nite-size scaling technique applied to com plex zeros has been proven pow erful in num erical com putations of critical exponents.

A specialclass of statistical system $s$ are spin system $s$ de ned on random surfaces. In addition to being interesting system $s$ per se, they have received special attention for their relation to conform alm atter system $s$ coupled to two dim ensional quantum gravity. At criticality, the spin system s are described by conform al eld theories (C F T ) coupled to gravity. The critical exponents of such conform al theories have been found by K nizhnik, Polyakov and Zam olodchikov (K P Z) to be sim ply related to the critical exponents of the sam E CFT de ned in at space 9. In particular, the critical Ising m odel coupled to $2 d$ gravity can be recast in the form of a $c=1=2$ conform al eld theory coupled to 2d gravity. In addition, the equivalence of the Ising model on a random surface to a herm itean two $m$ atrix $m$ odel, discovered and studied by $K$ azakov and B oulatov [10, 11], renders it exactly solvable. T he critical exponents were rst com puted this way, outside of the CFT context. The system is found to have a third order phase transition from a high tem perature disordered phase to a low tem perature ordered phase. T he coupling betw een $m$ atter and the geom etry of the surface is found to change the critical exponents associated to geom etry only at the phase transition.
$T$ he location of the partition function zeros of the Ising $m$ odel in the com plex fugacity plane, the so called Lee\{Yang zeros, in the presence of gravity has been studied by Staudacher 12]. $T$ he som ew hat surprising discovery that the Lee\{Yang zeros lie on the unit circle in the com plex fugacity plane for each lattice size N w ill be con m ed below for slightly bigger lattioes than those considered in 12]. A s discussed by Staudacher, the Lee\{Yang theorem [1] guarantees that the roots of the partition function of the Ising $m$ odel on a xed lattige $Z$ at ( $G_{N}$ ) for a large class of not too pathological lattices $G_{N}$ will lie on the unit circle, but it is not a prioriexpected that the roots of the partition function $Z_{N}$, obtained by sum $m$ ing the $Z$ at ( $G_{N}$ )'s over all dynam ical
random lattioes $G_{N}$,

$$
\begin{equation*}
\mathrm{Z}_{\mathrm{N}}={\underset{f G_{\mathrm{N}} g}{\mathrm{X}} \mathrm{Z} \text { at }\left(\mathrm{G}_{\mathrm{N}}\right) ; ~ ; ~}_{\text {; }} \tag{1.1}
\end{equation*}
$$

will also be located on the unit circle. The sum $m$ ation in 1.1) corresponds to an integration over the additional quantum degree of freedom introduced by a uctuating metric. The Lee\{ Yang theorem for this case rem ains unproven. A priori the zeros can be located on di erent curves or even on sets $w$ th $m$ ore com plicated topology, or on tw o-dim ensional regions. T he latter cases have been observed for the com plex tem perature zeros of 2 d Ising and Potts models on hierarchical lattioes [27], for anisotropic lattices [28], and interestingly, also for a regular lattige m ade of di erent polygons 29]. (See also ref. 30], where a very interesting, albeit som ew hat inconclusive attem pt at studying the partition function zeros of Ising spin glasses is $m$ ade, and ref. [31], where the zeros for aperiodic system s w ere studied.)

In this paper we use the same m ethod as in 12] in order to com pute the exact partition function for system $s$ w th up to 14 squares. W e com pute the Lee\{Yang zeros of the partition function and con $m$ that they are located on the unit circle of the com plex fugacity plane. We also com pute the zeros of the partition function for com plex tem perature ( $F$ isher zeros) and nd that they $m$ ove on curves in the com plex tem perature plane as the lattioe size is varied. This indicates that in the in nite volum e lim it, the zeros accum ulate to form dense sets on these curves. W e test the scaling relations derived by Itzykson, Pearson and Zuber in the context of regular lattices 目] and extract from there som e (com binations of) critical exponents. These scaling relations are based on the assum ption that the spin \{spin correlation length diverges at the critical point. D espite the sm all size of the system s studied, we nd reasonable agreem ent w ith the critical exponents given in 10, 11]. T his result is expected from the non $\{$ trivial fact that the $m$ atter correlation length diverges at the phase transition [13] (see 15] for an exam ple where this is not true). This way we provide strong evidence that the phase transition is govemed by the singularities of the distribution densities at $H=0$ and $c$ of the Lee\{Yang and Fisher zeros respectively as is the case for the Ising model on a xed lattice. The pattem of zeros we observe con m s the observation in [14] that no antiferrom agnetic transition occurs for the Ising m odel on a square lattioe $w$ hen the spins are placed on the faces of the lattioe. U sing dualty, we can study the pattem of the $F$ isher zeros of the dualm odel where the spins are placed on the vertices. W e observe that the set of $F$ isher zeros $m$ aps onto itself under $\sim!\sim$. This indicates the existence of an antiferrom agnetic transition whose critical exponents are identical to the ones of the ferrom agnetic transition $]$. $T$ his con m s the results reported in 14].

O ne of the $m$ ethods for com puting com plex zeros is provided by $M$ onte $C$ arlo sim ulations and histogram $m$ ing techniques. These techniques have been applied successfully to system $s$ de ned in at space 16, 17]. They have also been tried on several system s coupled to gravity (random surfaces coupled to extrinsic curvature, P otts m odels, 4d quantum gravity 22]), but it proved di cult to observe the partition function com plex zeros. H ere, we apply the $m$ ethod to Ising spins on dynam ical triangulations [18], and we are able to observe the zeros lying closest to the real axis for a range of lattice sizes w th up to 256 vertices. In general, it was easier to nd the Lee\{Yang zeros than the F isher zeros. In the latter case, we were able to locate only the rst

[^1]zero for any given lattice size. A fter determ ining the position of the zeros as a function of lattige size, we test their scaling and the critical exponents com puted are in reasonable agreem ent w ith their exactly known values.

In section 园 we de ne our m odel and review the expected scaling behaviour of the zeros on the assum ption of a diverging $m$ atter correlation length. In section 3 we describe in detail the $m$ ethods we use in order to com pute the zeros, and in section 4 we test their nite size scaling behaviour. Section 5 contains som e concluding rem arks.

## 2 The m odel

W e will study one Ising m odel on a dynam ical square or triangular lattice. In the form er case the spins are located on the N faces (squares) of the lattice, in the latter on the $\mathrm{N}_{\mathrm{v}}$ vertiges. T he partition function for a xed lattioe $G_{N}$ is given by
and the partition function $\mathrm{Z}(\mathbb{N} ; ~ ; H)$ for the model coupled to quantum gravity is obtained by sum $m$ ing $Z$ at $\left(G_{N} ; ~ ; H\right)$ over all lattices $G_{N} w$ th spherical topology and $N$ faces

$$
\begin{equation*}
\mathrm{Z}(\mathbb{N} ; ; H)=\mathrm{fG}_{\mathrm{N}} \mathrm{Z} \text { at }\left(\mathrm{G}_{\mathrm{N}} ; ; \mathrm{H}\right): \tag{2.3}
\end{equation*}
$$

In eq. 2.2. ${ }^{\mathrm{P}}{ }_{\text {hi;ji }}$ denotes a sum over the neighb ouring pairs of faces (in case of a square lattioe) or vertices (in case of a triangular lattice) of $\mathrm{G}_{\mathrm{N}}$. $\quad \mathrm{f} \mathrm{g}$ denotes the sum over all the possible spin con gurations, is the inverse tem perature and $H$ the magnetic eld. ${ }^{P} \mathrm{fG}_{\mathrm{N}} \mathrm{g}$ is the discrete analogue of sum $m$ ing over all possible $m$ etrics up to di eom orphism $s$ on a spherical surface of xed volum $e$, since $G_{N}$ de nes a $m$ etric on the discretized surface if we de ne each link to have the sam e xed length. T he class of lattioes we consider include degenerate ones which have double links and vertiges of order one.

The system 2.3) undergoes a third order phase transition whose universal properties are independent of the $m$ icroscopic details of the lattice [10, 11]. For the square lattioe, the critical inverse ${ }_{p}$ tem perature is given by $c=\ln 2 \quad 0: 69314718$, and for the triangular lattioe, $c_{c}=$ $\frac{1}{2} \ln \frac{13+}{14} \frac{p}{\overline{7}} \quad 0: 16030370$ [14]. T he critical exponents are given by 11]

$$
\begin{align*}
& =1=2  \tag{2.4}\\
& =2  \tag{2.5}\\
& =5  \tag{2.6}\\
d_{H} & =3 ; \tag{2.7}
\end{align*}
$$

which are de ned in the usual way by the behaviour of the magnetization $M \quad j \quad c j$, $M \quad H^{1=}$ and the $m$ agnetic susceptibility $M \quad j \quad c j$ in the critical region. is the spin \{spin correlation length exponent j cj, and $d_{H}$ denotes the $H$ ausdor dim ension of space.

For a given lattioe $G_{N}$, the partition function 22) can be wrilten (up to a m ultiplicative constant) as a polynom ial

$$
\begin{equation*}
Z \text { at }\left(G_{N} ; \quad ; H\right)=X_{m=0 n=0}^{X^{N}} X_{m n} X^{m} C^{n} ; \tag{2.8}
\end{equation*}
$$

where $c=e^{2}, y=e^{2 H}, N$ is the num ber of faces in $G_{N}$ (when we put the spins on the faces) and $N_{1}$ the num ber of links. $y$ is called the fugacity. In the follow ing we w ill also use the notation $u=e^{4} \quad$ and $K=u \quad u_{c}$.

Eq. 2.8) is a polynom ial in two variables, and its analytic structure is entirely determ ined
 $y$ and its zeros were show $n$ by $Y$ ang and Lee [1] to lie on the unit circle in the com plex fugacity plane. W e expect the theorem to be true for a large class of (not too pathological) lattices $G_{N}$. Then one can w rite the free energy of the system as

$$
\begin{equation*}
F \text { at }\left(G_{N} ; i y\right)=\ln _{k=0}^{\mathcal{Y}^{\mathrm{N}}}\left(\mathrm{y} \quad \mathrm{y}_{\mathrm{k}}(1)\right) ; \tag{2.9}
\end{equation*}
$$

where a factor has been absorbed into $F$ at ( $G_{N} ; ~ ; y$ ) and an additive constant has been suppressed (y $\left.\quad e^{2 H}\right)$. H ere $y_{k}()$ are the zeros of $Z$ at ( $\left.G_{N} ; ~ ; H\right)$ in the y plane, called the Lee\{Yang zeros. In the therm odynam ic lim it these zeros form dense sets on lines, which are Stokes lines for F at ( $\mathrm{G}_{1}$; ; y$)$. All the relevant inform ation is then encoded in the density of zeros $\mathrm{y} L$ (; ) ( $\mathrm{H}=\mathrm{i}$ ). The free energy per spin in the $\mathrm{l} \frac{\mathrm{m}}{\mathrm{i}}$ it of in nite volum e N ! 1 is then given by

Z

$$
\begin{equation*}
F \text { at }\left(G_{1} ; \quad ; y\right)=\quad \mathrm{X} \quad \mathrm{YL}_{\mathrm{L}}(;) \ln \left(\mathrm{y} \mathrm{e}^{2 i}\right): \tag{2.10}
\end{equation*}
$$

H ere 2 denotes the polar angle on the unit circle of the partition function zero in the com plex $y-p l a n e . T h$ is notation is $m$ otivated by the Lee\{Yang theorem. T he singularities of the partition function are expected to occur at the ends of the lines on which the partition function zeros condense. In the case of 2.2), in the high tem perature phase the zeros form a gap $0>0$ such that $y_{L}(;)=0$ for $j j<0$. The points $Y_{0}=e^{2 i} 0$ are the Lee\{Yang edge singularities and they can be regarded as conventional critical points 7]. The (only) characteristic critical exponent is
YL (; ) ( 0) ;
which implies that M ( 0) . In 26] it was shown that $=1=6$ in two dim ensions.
A s we approach the critical tem perature from above, the gap closes ( $0!0$ ) and the zeros pinch the real axis at $y=1$. $T$ his signals the onset of the phase transition, since the partition function has di erent analytic behaviour in the two disconnected parts of the y-plane. The inform ation on the universal scaling of the partition function is given by the scaling of y L (; ) near $=0$. At $=c r 0=0$ and ifwe de ne $M \quad H^{1=}$ we obtain
YL (c; ) 1= :

O ther critical exponents can be derived from scaling relations discussed in [a] and later in this section. For a nite system the zeros are never on the positive realaxis since $C_{m} n$ is positive and c > 0 for real in eq. (2.g). W hen the system is critical, i.e. when the correlation length L ( $L$ is the linear size of the system), the zeros approach the real axis in nitely close as $L$ ! 1 and one can apply nite size scaling in order to extract critical exponents.

If we $\mathrm{x} y$ in eq. 2.8, we obtain a polynom ial of order $\mathrm{N}_{1}$ in c . Its zeros in the c-plane are the so-called $F$ isher zeros [2] . For $m$ any system $s$ the $F$ isher zeros are located on curves $C$, but this is not necessarily true in general. For the 2d (zero-eld) Ising model on a square lattice, these curves $C$ are two intersecting circles (both in the c-plane and in the tanh ( ) plane). O ne of the curves intersects the real positive axis at the physical critical point. Sim ilarly to the case of Lee\{Yang zeros, the $F$ isher zeros condense on these tw o curves in the therm odynam ic lim it and the free energy per spin is given, in this lim it, by their density $F(; H)$ :

$$
\begin{equation*}
\mathrm{F} \text { at }\left(\mathrm{G}_{1} ; \quad ; \mathrm{H}\right)=\mathrm{C}^{0}{ }_{\mathrm{F}}\left({ }^{0} ; \mathrm{H}\right) \ln \left(\mathrm{c}\left(\mathrm{)} \mathrm{e}^{2}{ }^{0}\right) ;\right. \tag{2.13}
\end{equation*}
$$

where ${ }^{0}$ is a com plex num ber. N ear the critical tem perature and at $\mathrm{H}=0$,

$$
\begin{equation*}
F(; H=0) \quad j \quad c j^{+1} ; \tag{2.14}
\end{equation*}
$$

which implies that $F$ at $\left(G_{1} ; ~ ; H=0\right) j c^{j+2}$. Therefore is the speci cheat exponent.
T he possibility of extracting scaling exponents from the study of com plex zeros of the partition function relies on their scaling behaviour under the renom alization group 目]. Applying nite size scaling is a convenient $m$ ethod often used in num ericalsim ulations. Sim ple scaling argum ents目] give the position of the jth Lee\{Yang zero as

$$
\begin{equation*}
\mathrm{H}_{j}^{2} \mathrm{~N}^{2}=\left(\mathrm{d}_{\mathrm{H}}\right)=\mathrm{f}_{\mathrm{j}}\left(\mathrm{~K} \mathrm{~N}^{1=\left(\mathrm{d}_{\mathrm{H}}\right)}\right): \tag{2.15}
\end{equation*}
$$

where we have substituted $N^{1=d_{H}}$ for the linear size L of the system $\left(\mathbb{N}\right.$ is the volum e and $d_{H}$ is the $H$ ausdor dim ension). $f_{j}$ is an analytic function and the Lee\{Yang theorem im plies that $f_{j}(0)<0$. If we invert the above relation we obtain the positions of the $F$ isher zeros. H ence we can deduce that the jth Lee\{Yang zero will scale as

$$
\begin{equation*}
H_{j} \quad N \quad=\left(d_{H}\right) ; \tag{2.16}
\end{equation*}
$$

and the jth $F$ isher zero as

$$
\begin{equation*}
K_{j} \quad N^{1=\left(d_{H}\right)}: \tag{2.17}
\end{equation*}
$$

The gap of the Lee\{Y ang edge singularity will scale as

$$
\begin{equation*}
\mathrm{H}_{0}^{2} \quad \mathrm{CK}^{2} \text {; } \tag{2.18}
\end{equation*}
$$

where $\mathrm{C}>0$ and $\mathrm{H}_{0} \quad \mathrm{i}_{0}$. C onversely, in the scaling region the dependence of the jth F isher zero on the value of the (real) m agnetic eld willbe

$$
\begin{equation*}
K_{j} \quad e^{\frac{i}{2}}{\underset{\bar{C}}{\bar{C}}}^{1=(\quad)}: \tag{2.19}
\end{equation*}
$$

Eq. 2.19) im plies that the trajectories of the $m$ otion of the $F$ isher zeros in the $K$ plane w ith varying real nonzero $H$ will form an angle

$$
\begin{equation*}
=\overline{2} \tag{2,20}
\end{equation*}
$$

w ith the realK axis. U sing eq. 2.15) a stronger scaling relation can be derived:

$$
\begin{equation*}
\mathrm{H}_{\mathrm{j}}^{2}(\mathbb{N}=j)^{2=(+1)}=\mathrm{F} \quad \mathrm{~K}(\mathbb{N}=j)^{1=\left(d_{\mathrm{H}}\right)} \text {; } \tag{2.21}
\end{equation*}
$$

$w$ here $F$ is a universalanalytic scaling function such that $F(0)<0, H_{j}$ is the $j$ th Lee $\{Y$ ang zero. Sim ilarly

$$
\begin{equation*}
K_{j}=\frac{j}{N}^{1=\left(d_{H}\right)} F^{1}(0) ; \tag{2.22}
\end{equation*}
$$

where $K_{j}$ is the jth $F$ isher zero.
In [13], we provided evidence that there exists a divergent correlation length associated to $m$ atter elds coupled to gravity in the range of central charge $0<c<1$. Based on these results, we expected that the observed zeros, for large enough lattices, m ight show a behaviour com patible w ith the scaling hypothesis. It is the $m$ ain purpose of this $w$ ork to provide evidence that this is indeed the case.

## 3 C om putation of C om plex Zeros

O ur com putation of Lee\{Yang zeros (real , complex H) and $F$ isher zeros (real H, complex ) of the partition function $Z(\mathbb{N} ; ~ ; H)$ was done using exact results from $m$ atrix $m$ odels and $M$ onte $C$ arlo $m$ ultihistogram $m$ ing techniques. $W$ e describe these $m$ ethods in this section.

### 3.1 Exact determ ination of partition functions

The exact solution of the Ising $m$ odel on a square dynam ical lattice cam efrom solving the planar lim it of the tw o $m$ atrix $m$ odel de ned in 10, 11]. It $w$ as notioed that in this lim it the free energy of the $m$ odel

$$
\begin{align*}
& \text { Z } \\
& \mathrm{F}(\mathrm{n} ; \mathrm{g} ; \quad ; \mathrm{H})=\ln \quad \mathrm{d}^{\mathrm{n}^{2}}{ }_{1} \mathrm{~d}^{\mathrm{n}^{2}}{ }_{2} \\
& \left.\exp ^{\mathrm{h}} \operatorname{Tr}{\underset{1}{2}+{ }_{2}^{2} \quad 2 \mathrm{C}}_{1}^{2}{\underset{2}{2}}_{2}\left(\mathrm{ge}{ }^{\mathrm{H}}=\mathrm{n}\right){\underset{1}{4}+(\mathrm{ge}}^{\mathrm{H}}=\mathrm{n}\right)_{2}^{4}{ }^{\mathrm{i}} \text { ! } \tag{3.23}
\end{align*}
$$

where $1 ; 2$ are $n \quad n$ herm itean $m$ atrioes, equals the grand canonicalpartition function $Z(g ; ~ ; H)$ for the Ising $m$ odel coupled to gravity:

$$
\begin{equation*}
\lim _{n!1} \frac{1}{n^{2}} F(n ; g ; \quad ; H)=Z(g ; \quad ; H) \quad X_{N=1}^{X^{N}} e^{N} Z(\mathbb{N} ; \quad ; H) ; \tag{324}
\end{equation*}
$$

where $e=\quad 4 g c=\left(\begin{array}{ll}1 & c^{2}\end{array}\right)^{2}$. The solution for $Z(g ; \quad ; H)$ is given by [11, 11]

$$
\begin{equation*}
Z(g ; \quad ; H)=\frac{1}{2} \ln \frac{z(g)}{g}+{\frac{1}{2 g^{2}}}_{0}^{Z} \frac{z(g)}{z^{0}} g\left(z^{0}\right)^{2} \quad \frac{1}{g}_{0}^{z(g)} \frac{d z^{0}}{z^{0}} g\left(z^{0}\right) ; \tag{3,25}
\end{equation*}
$$

where

$$
\begin{equation*}
g(z)=\frac{1}{9} c^{2} z^{3}+\frac{1}{3} z \frac{1}{(1 \quad z)^{2}} \quad c^{2}+\frac{2 z(\cosh H \quad 1)}{\left(1 z^{2}\right)^{2}}: \tag{3.26}
\end{equation*}
$$

U sing eq. 325) and eq. 326) we can expand $\mathrm{Z}(\mathrm{g} ; ~ ; H$ ) in pow ers ofg and read o the coe cients $Z(\mathbb{N} ; \quad ; H)$ (corresponding to lattice size $w$ ith $N$ squares) in eq. (324).
$W$ e have done this using the sym bolic $m$ anipulation program $M$ athem atica for $N \quad 14$. We obtain
where [:] denotes integer part. The sam e calculation for $N \quad 6$ was done in [12] and our results are in complete agreem ent. Then the roots of $Z(\mathbb{N} ; ~ ; H)$ for either xed or xed $H$ were com puted num erically. N ote that, apart from a trivialm ultiplicative factor, the partition function is a polynom ial and has a nite num ber of zeros in the com plex c and y planes.

A s already discussed above, and in [12] for $N$ 6, the Lee\{Y ang zeros can be seen, som ew hat surprisingly, to lie on the unit circle in the com plex y-plane. N o Lee\{Y ang theorem has so farbeen proven for the partition function of the dynam ical lattice. $F$ ig. 11 show $s$ the results for lattice sizes 8 N 14 , at the (bulk) critical tem perature. This gure clearly show s that the zero closest to the real positive axis approaches the point $y=1$ as we increase the lattice size, indicating a vanishing gap at c as N ! 1 . W e will study this approach quantitatively using nite size scaling in the next section.

In F ig. 目 we show the m otion of Lee\{Yang zeros w th varying for the $\mathrm{N}=14$ lattice as we approach c from the hot phase. T he zeros close up tow ards the point $y=1(H=0)$ on the real axis, re ecting the expected vanishing of the gap in $y_{L}(;)$ for ! $c$ in the in nite volume lim it.

W e note from Fig. 3 and $F$ ig. 3 that also the $F$ isher zeros form curves in the com plex plane. In $F$ ig. 3 (a) we display the approach of the $F$ isher zeros for $H=0$ to the (physical and unphysical) critical points on the realaxis, $c=1=4$ for increasing lattice size. $T$ here are also $F$ isher zeros on the im aginary axis, which ow to $c=i 1$. In $F i g .3(b)$ we show the sam e curves m apped onto the eplane, where the tilde refers to the dualspin $m$ odel. $T$ he usualdually relation is given by $\mathrm{e}=\tanh \left(\mathrm{r} . \mathrm{W}\right.$ e note that our m odel is not self\{dual, so the critical point $\mathrm{c}_{\mathrm{c}}=1=4$ is di erent from the dual critical point $e_{c}=3=5$. $F$ ig. 3 (b) suggests the existence of an antiferrom agnetic phase transition for the Ising $m$ odel on a square lattice $w$ ith spins placed on the vertioes 14]. It happens at $e_{c}^{(a f)}=5=3$. This corresponds to the unphysical value of $c=1=4$, re ecting the fact that no antiferrom agnetic transition occurs for the Ising modelcoupled to $2 d$ gravity on a square lattice $w$ th spins placed on the faces. W e notioe that the zeros in the e\{plane are m apped exactly onto each other under the transform ation e! $1=e$. This im plies that the critical exponents of the antiferrom agnetic transition are identical to the ones of the ferrom agnetic transition, as was noted in 14].

F ig. 4 (a) show sthe ow of F isher zeros w th varying $m$ agnetic eld H for a xed lattice size $\mathrm{N}=14$. The zeros on the arcs ow aw ay from the im aginary axis as H increases, while the zeros on the im aginary axis again appear to $m$ ove tow ards $c=i 1$ (note that these points are $m$ apped onto $e=(1 ; 0)$ in $F$ ig. 4 (c)). For $H=0$ the zeros should pinch the real axis like in Fig . 3 , but for $H \in 0$ they seem to avoid the real axis. $T$ his is com patible $w$ th the absence of a phase transition in the presence of a sym $m$ etry breaking eld. In $F$ ig. 4 (c) we show the sam e ow in the eplane.

### 3.2 M ultih istogram m ing of M onte C arlo data

For system $s w$ th $m$ ore than a few spins, the study of com plex zeros $m$ ust rely on num erical $m$ ethods. M onte C arlo m ethods are very pow erfiulin studying a system using the fullham iltonian. They can be used to study singularities of observables in the complex plane as was done in the pioneering work ref. 16]. W ith the developm ent of (single) histogram $m$ ing techniques the partition function could be calculated for a continuous region in the coupling space and its zeros determ ined in the com plex plane [17]. U sing $m$ ultih istogram $m$ ing 20], where $M$ onte $C$ arlo data taken at di erent couplings are com bined optim ally, a m ore accurate determ ination of the partition function is possible over a w ide range of couplings. Thism ethod for com puting com plex zeros was rst used in 21]. H ere we provide a briefdescription of the m ethod, in order to describe the procedure we follow ed. For details see 32].

T he M onte C arlo updating of the triangulations w as perform ed by the so \{called ip algorithm and the spins w ere updated using a standard cluster algorithm. O ne updating sw eep of the lattige consisted of approxim ately $N_{1}$ accepted ins where $N_{1}$ is the num ber of links of the triangu lated surface. A fter a sw eep of the lattioe we updated the spin system. All this is by now standard and we refer to [18, 19] for details. W e use the high quality random num ber generator RAN LUX 34] whose excellent statistical properties are due to its close relation to the K olm ogorov K \{system originally proposed by Savvidy et al. 33].
$T$ he lattice sizes that we sim ulated ranged from 32 to 256 vertices. In order to $m$ in im ize nite size e ects, we took the spins to be on the vertioes of the triangulations and inchded degenerate triangulations w th double links and vertiges of order one [19]. First we made a rough map of the partition function. Since the partition function is invariant under ! $\quad+i k=2$ and $H!H+i k=2$ it is not necessary to calculate $z_{N} \jmath$ for $\operatorname{Im}()>=2$ or $\operatorname{Im}(H)>=2$. In our calculation we took $H$ to be purely im aginary. T hen we scanned the region where we expected to see the rst zeros, and ultim ately we took a denser grid ofm easurem ents around the points where the partition function touched zero w th in errors. For the largest lattice, 55 m illion sw eeps were perform ed at each of 11 values $k$ around the location of the zeros, in order to get a su ciently accurate determ ination of the partition function in this region. For each $k$ we com puted energy and $m$ agnetization histogram $s^{k}(E ; M)$, where $E$ is the total energy and $M$ the (absolute value of the) $m$ agnetization, from which one can obtain an approxim ate estim ate of the density of states:

$$
\begin{equation*}
(E ; M)={ }_{k}^{X} w_{k}(E) k(E ; M)=w_{k}^{x} w_{k}(E) h^{k}(E ; M) e^{k^{E}}: \tag{3.28}
\end{equation*}
$$

The coe cients $\mathrm{w}_{\mathrm{k}}(\boldsymbol{E})$ are the appropriate w eights for an optim al determ ination of ( $\mathrm{E} ; \mathrm{M}$ )

$$
\begin{equation*}
\mathrm{w}_{\mathrm{k}}(E ; \mathrm{M})=\frac{1}{\mathrm{P}^{\frac{\mathrm{n}^{1}}{\mathrm{n}^{k}} \frac{\mathrm{k}}{1}} \exp \left((\mathrm{k} \quad 1) \mathrm{E}+\mathrm{F}_{1}\right)} ; \tag{3,29}
\end{equation*}
$$

where $n^{k ; l}$ is the num ber of $m$ easurem ents at $k_{; 1}$, and $k_{j 1}$ the respective autocorrelation tim es. $F_{1}$ is the free energy at ${ }_{1}$, determ ined self\{consistently from

$$
e^{F_{1}} Z\left({ }_{1}\right)=X_{E ; M ; k}^{P} \frac{h^{k}(E ; M)}{j^{j} \frac{n^{k}}{n^{k}} \frac{k}{j} \exp \left(\left(\begin{array}{ll}
j \tag{3.30}
\end{array}\right) E+F_{j}\right)}:
$$

Then the partition function Z ( ) and any observable ho ( E ; M ) i for real is given by:

$$
\begin{align*}
Z() & =X_{E ; M}^{X}(E ; M) e^{E}  \tag{3.31}\\
\text { ho (E;M)i } & =\frac{1}{Z()}_{E ; M}^{X} O(E ; M) \quad(E ; M) e^{E}: \tag{3.32}
\end{align*}
$$

Lee\{Yang zeros are com puted from the $m$ inim a of

$$
\begin{equation*}
\frac{Z(; H)}{Z(~)}=\operatorname{hoos}(\operatorname{Im}(H) M) i \quad i h s i n(\operatorname{Im}(H) M) i \tag{3.33}
\end{equation*}
$$

for real and im aginary $H$ and $Z() \quad Z(; 0)$. The $F$ isher zeros were com puted from the $m$ inim a of
for complex values of and $H=0$. The errors in the partition function and in the position of the com plex zeros w ere com puted by a standard binning procedure.

Table 1 and Table 2 contain our results for the zeros. W e rst checked that m ultihistogram m ing was w orking quite wellw ith our data by looking at multihistogram s of the speci c heat and susceptibility. It w as relatively easy to observe the rst few Lee\{Yang zeros. For Fisher zeros the com putation was harder and in a sim ilar way we could only clearly observe the zero closest to the real axis. Delicate cancellations in $-z \jmath$ betw een contributions from the two term $s$ in eq. 3.34) $m$ ake the zeros located further aw ay from the real axis disappear in the statistical noise. $T$ his sets lim itations to the size of the surface on which we were able to observe $F$ isher zeros.

## 4 Veri cation of scaling relations

In this section we discuss the extent to which the scaling relations eqs. 2.15 ( 2.22 ) hold for the Ising $m$ odel on a dynam ical lattioe. T here is no a priori reason to expect these relations to hold. A s discussed earlier, for the xed lattice, their validity is due to the divergence of the spin \{spin correlation length in the critical region. For the Ising $m$ odel on a dynam ical lattice, we expect the correlation length associated to geom etry uctuations to diverge 25, 23, 24], but the sam e need not necessarily be true for the spin \{spin correlation length even at a continuous transition 15]. R ecently how ever, num erical evidence indicated that this is indeed the case, and that the system behaves as an ordinary statistical system near a third order phase transition [13].
$N$ um ericalsim ulations $23,24,13]$ further indicate that the $H$ ausdor dim ension of the system is very close to 4. From this value we can estim ate the linear size $L \quad N^{1=d_{H}}$ of the system $s$ that we are studying and nd that it is indeed quite sm all. In spite of substantial nite size e ects, our results $w$ ill provide evidence that the scaling relations are indeed satis ed by the $m$ otion of the com plex zeros w ith varying lattice size, couplings, or the order of the zero. W e can, in general, observe reasonable agreem ent $w$ th the known critical exponents (we w ill refer to these as the

KPZ exponents). In the cases where a deviation from the expected value is observed, we can observe an asym ptotic approach to this value w ith increasing lattioe size.

### 4.1 Zeros of the exact partition functions for sm all square lattices

At $\mathrm{K}=0$ and large enough N eq. 2.16) im plies

$$
\begin{equation*}
\ln { }_{H}{ }_{j} j=\quad \overline{d_{H}} \ln (\mathbb{N})+C_{j}: \tag{4.35}
\end{equation*}
$$

The slope on a $\log \left\{\log p l o t\right.$ of $H_{j}$ vs. $N$ is expected to take the value

$$
\begin{equation*}
\overline{d_{H}}=\quad 5=6=0: 8333::: \tag{4.36}
\end{equation*}
$$

for all j. Fig. f $^{\text {fand }} \mathrm{T}$ able 3 show our results for the rst three Lee\{Yang zeros. The extracted exponent com bination is in reasonable agreem ent $w$ th the K P Z exponents, especially for the rst zero. The errors reported in Table 2 are not true statistical errors (w hich are $m$ eaningless in this case). They are com puted from the standard form ula giving least squares linear $t$ errors and in this case they are sim ply a $m$ easure of the system atic deviation of the points from a straight line. W e will follow this practice for our ts throughout this section.

| $j$ | Slope |  |
| :---: | :---: | :---: |
| 1 | -0.871 | 0.002 |
| 2 | -0.935 | 0.002 |
| 3 | -0.951 | 0.002 |

Table 3. Predictions for the com bination of critical exponents $\overline{d_{H}}$ from scaling of the rst three Le\{Yang zeros of exactly known partition functions $\mathrm{Z}_{\mathrm{N}}$.

Eq. 222) im plies

$$
\begin{equation*}
\ln K_{j} j \quad \ln j u_{j} \quad u_{c} j=\frac{1}{d_{H}} \ln \frac{j}{N}+C: \tag{4.37}
\end{equation*}
$$

$$
\begin{equation*}
\ln j_{j} \quad c j=\frac{1}{d_{H}} \ln \frac{j}{N}+C ; \tag{4.38}
\end{equation*}
$$

w here the slope should be given by

$$
\begin{equation*}
\frac{1}{d_{H}}=\frac{1}{3} \tag{4.39}
\end{equation*}
$$

and the constant $C$ should be independent of j. Table 4 show s the results of ts to eq. 4.38), and sim ilar ts $w$ ith $N$ replaced by $N{ }_{v}$, the num ber of vertices of the lattice. $T$ he corresp onding ts using the scaling variable $K$ did not yield straight lines in a log\{log plot, as can be seen from Fig . 6. In this gure, we have plotted $\mathrm{K}_{1} \mathrm{j}^{(l o w e r ~ c u r v e) ~ r e s p . ~} \mathrm{j}_{1} \mathrm{c}$ (upper curve)
vs. $N$ on a logarithm ic scale. The di erence betw een the scaling behaviour of the two di erent scaling variables (which are expected to be identical for very large system $s$ ), show $s$ that we are not deep in the scaling region and that nite size e ects are im portant for the system sizes that we consider. T he sam em ust be said about the di erence betw een the slopes and intercepts $C$ of Table 4. From eq. 4.38) it is expected that the slopes and C should take the sam e value for all j, so that the data points would fall on one and the sam e curve. T he di erence betw een the results obtained by using $N$ and $N_{v}$ should asym ptotically decrease as the lattioe size goes to in nity. (In the table, $n$ denotes the num ber of points included in the $t$.)

| Q uantity tted | $j$ | Slope |  | $C$ |  | C |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| $\ln j$ | $\mathrm{c} j v s . \ln (j=N)$ | 1 | 0.327 | 0.001 | 0295 | 0.002 |
|  |  | 2 | 0.377 | 0.002 | 0.490 | 0.005 |
| $\ln j$ | cjvs. $\ln \left(j=N_{v}\right)$ | 1 | 0.383 | 0.002 | 0.492 | 0.006 |

Table 4. Slopes and intercepts from the ts to eq. (4.3申). The theoretical value for the slope is $\frac{1}{d_{H}}=1=3$. The dependence of the slope and of $C$ on $j$ indicates nite size e ects, as does the di erence betw een N and $\mathrm{N}_{\mathrm{V}} . \mathrm{n}$ is the num ber of degrees of freedom in the ts.

The scaling relation eq. 2.19) predicts the angle that the trajectories of the zeros will form w ith respect to the $R e(K)$ axis as $H$ is varied for large $L$. In our case the angle is expected to be

$$
\begin{equation*}
=\frac{}{2}=36: \tag{4.40}
\end{equation*}
$$

$T$ his prediction is valid for large system sizes $L$ and $s m$ all magnetic eld. In $F$ ig. 7 (a) we show the trajectories of the rst $F$ isher zero for $N=4 ; 6 ; 8 ;:: ; 14$ and $m$ agnetic elds in the interval $0.2<\mathrm{H}<0.2$. A s expected from eq. 2.19), $\mathrm{H}=0$ corresponds to the \tuming point" closest to the Re(K ) axis. Fig. $\bar{\square}(b)$ and $T a b l e 5$ show the corresponding values of tan , calculated from ts in the sm allH range $0: 03<H<0: 02$. A though does not reach its in nite volum e value, Fig. $\bar{\square}(\mathrm{b})$ show s the approach to it w ith increasing lattice size. T he breakdow $n$ of scaling for very strong H can be observed in $F$ ig. $\nabla_{\text {(c) }}$ ( w here a tra jectory for jH jbetw een zero and 2.6 are shown.

| N | $\tan$ | $\tan$ |
| :---: | :---: | :---: |
| 6 | 6.489 | 0.162 |
| 8 | 3.295 | 0.036 |
| 10 | 2.308 | 0.001 |
| 12 | 1.792 | 0.006 |
| 14 | 1.450 | 0.002 |
| 1 | 0.727 |  |

Table 5. M easured ( $N=6$; 8; :::; 14) and expected (eq. 4.40)) slopes of trajectories of zeros in the com plex K plane as the magnetic eld H is varied, as a function of the size of the lattice.

We also checked the validity of the scaling relation given by eq. 221). Taking $K$ real, we plotted $H_{j}(\mathbb{N}=j)^{5=6}$ vs. $(\quad c)(N=j)^{1=3}$. The scaling function $F$ is shown in $F$ ig. 8 . A ll zeros of order $j>1$ for lattice sizes (10 $\mathrm{N} \quad 14$ ) are included in the sam e graph. W e observe that there exists a range of in the hot phase where the data points lie approxim ately on a univeral curve de ning the function $F$.

By varying the value of the exponent $=(+1)=5=6$ of the scaling variable $=j=N$ on the $y$-axis aw ay from its K P Z value, we observed a broadening of the curve and in this way we obtained a (som ew hat sub jective) determ ination of the exponent com binations

$$
\begin{equation*}
\overline{+1}=\frac{}{d_{H}} \quad 0: 85 \quad 0: 05 \tag{4.41}
\end{equation*}
$$

(the equality of these follow from the general exponent equalities and was used in the derivation of the scaling relation 2.21)). This is in excellent agreem ent w ith the $\mathrm{K} P \mathrm{Z}$ value of $5=6$.

### 4.2 Zeros determ ined from multh istogram m ing

In this section we describe the scaling of the zeros determ ined num erically from $M$ onte C arlo data. The lattice sizes investigated here range from 32 to 256 vertioes ( $60\{508$ triangles). We were able to determ ine the rst ve Lee\{Yang zeros for the biggest lattice size, while for the sm aller ones at m ost three zeros were visible. For the F isher zeros, only the zero closest to the real axis w as observed for any lattioe size.

The Lee\{Yang zeros we observed w ith multihistogram m ing are listed in $\mathrm{T} a \mathrm{ble} 1$. The leastsquares ts to eq. (4.35) give for the rst and second Lee\{Yang zero,

$$
\begin{align*}
& \overline{d_{H}}=0: 773 \quad 0: 013 \quad(j=1)  \tag{4.42}\\
& \overline{d_{H}}=0: 788 \quad 0: 033 \quad(j=2): \tag{4.43}
\end{align*}
$$

Alldata points with $j 2$ show $n$ in $T a b l e 1$ were included in the ts. $U \operatorname{sing} N_{v}$ instead of $N$ for the volum e of the system we obtain:

$$
\begin{align*}
& \overline{\mathrm{d}_{\mathrm{f}}}=0: 787 \quad 0: 013 \quad(j=1)  \tag{4.44}\\
& \overline{\mathrm{d}_{\mathrm{f}}}=0: 800 \quad 0: 034 \quad(j=2) ; \tag{4.45}
\end{align*}
$$

which gives a m easure of the presence of nite size e ects. T he results are in quite good agreem ent $w$ th the expected value of $=\Phi=5=6$. From the exactly known value $d_{H}=3$ we obtain

$$
\begin{array}{lll}
=2: 36 & 0: 04 & (j=1) \\
= & 2: 40 & 0: 10 \tag{4.47}
\end{array} \quad(j=2): ~ \$
$$

The exact value of this com bination of exponents is 2.5 .
The value of $d_{H}$ extracted from eq. 4.37) is som ew hat lower than 3, but still rem arkably close to $\dot{1}$ given the sm all size of the system $s$ considered. T he plot of the observed zeros is show $n$ in $F i g .10(\ln j k j r e s p . \ln j \quad c j v s . \ln (\mathbb{N})) . W$ e also calculated the slope of $\ln k j v s . \ln \left(\mathbb{N}_{v}\right)$ and of $\ln j \quad c j v s . \ln \left(\mathbb{N}_{v}\right)$. The results are shown in $T$ able $6 . W$ e note that by discarding the sm allest lattioes the value of $d_{H}$ approaches 3, albeit $w$ ith an increasing error. For exam ple, including only the three largest lattioes we obtain (using $N$ for volum e):

$$
\begin{equation*}
\frac{1}{d_{H}}=0: 350 \quad 0: 067: \tag{4.48}
\end{equation*}
$$

| Q uantity tted | $1=\left(d_{H}\right)$ |  |
| :---: | :---: | :---: |
| $\ln j K$ jvs. $\ln (\mathbb{N})$ | 0.392 | 0.016 |
| $\ln \mathrm{~K}_{\mathrm{K}}$ jvs. $\ln \left(\mathbb{N}_{\mathrm{v}}\right)$ | 0.407 | 0.017 |
| $\ln j \quad$ cjvs. $\ln (\mathbb{N})$ | 0.386 | 0.014 |
| $\ln j \quad$ cjvs. $\ln \left(\mathbb{N}_{\mathrm{V}}\right)$ | 0.401 | 0.014 |

Table 6. F in ite size scaling for the rst $F$ isher zero.

## 5 C onclusion

W e have com puted the positions of the singularities of the partition function for the two dim ensional Ising $m$ odel coupled to gravity in the complex plane. B oth Lee\{Yang and Fisher zeros w ere studied.

W e veri ed the result in [12] that the Lee\{Yang zeros are located on the unit circle of the complex fugacity plane. This presents us with the challenge of proving a corresponding Lee\{ Yang theorem for the case when a uctuating metric contributes an additional quantum degree of freedom. We also observed that the F isher zeros form one dim ensional curves in the com plex tem perature plane.

G iven the sm all size of the system swe studied, we obtained reasonable agreem ent w ith scaling law s derived from ordinary renorm alization group argum ents. A though one cannot use our results to accurately determ ine the scaling exponents, the extracted exponent com binations show a reasonable agreem ent $w$ ith their exactly known values 11]. This, together $w$ th the fact that a diverging $m$ atter correlation length exists in the system [13], gives us con dence to conclude that the criticalbehaviour of the system is given by the scaling of the distribution of the com plex zeros of the partition function.

Figure 1: Lee\{Y ang zeros in the com plex fugacity ( $\mathrm{y}=\mathrm{e}^{2 \mathrm{H}}$ ) plane for the Ising $m$ odelon square dynam ical lattioes of varying size $N=8(+), 9(10$ ( ) , $11(2), 12$ ) , 13 ( ) , 14 ( ) at the bulk critical tem perature.

Figure 2: Lee\{Yang zeros in the com plex fugacity plane for a square lattioe w ith $\mathrm{N}=14$ at the critical point ( $\left.c_{c}=e^{2} c=0.25(+)\right)$ and in the hot phase ( $c=0.35(), 0.45(), 0.55(2), 0.65($ ■).

Figure 3: (a) $F$ isher zeros in the com plex cplane ( $c=e^{2}$ ) for the Ising $m$ odel $w$ ith spins on the faces of square dynam ical lattices of varying size $(\mathbb{N}=8 ; 10 ; 12 ; 14)$ at $H=0$. The zeros $m$ ove on arcs and on the im aginary axis. The zeros ow tow ards il on the Im (c) axis, and tow ards the critical points $c=(1=4 ; 0)$ and $c=(1=4 ; 0)$ on the real axis as the them odynam ic lim it is approached. The physical critical point is $c=1=4$. (b) $T$ he trajectories in (a) show $n$ in the complex tanh ( ) plane. Recalling the duality relation $e=\tanh ()$, this corresponds to $F$ ig. 3 (a) for the $m$ odelw ith spins on the vertioes (w ith e related to the dual inverse tem perature
$\left.\sim_{\text {by }} \mathrm{e}=\mathrm{e}^{2 \sim}\right)$. The zeros approach the points $(1 ; 0),(3=5 ; 0)$ and $(5=3 ; 0)$ as N ! 1 . The point $e=3=5$ corresponds to the ferrom agnetic and the point $e=5=3$ to the antiferrom agnetic transition of the $m$ odel. The zeros are $m$ apped onto each other under e! $1=\mathrm{e}$ :

Figure 4: (a) $F$ isher zeros in the complex c plane for a square dynam ical lattice of size $N=14$ and at varying $m$ agnetic eld $\left(y=e^{2 H}=1: 0 ; 1: 6 ; 2: 5\right)$. For zero $m$ agnetic eld, the zeros $w$ ith $\operatorname{Re}(c)>0$ end in the vicinity of the physical critical point $c=(1=4 ; 0)$. (b) $T$ he rst quadrant in (a) show $n \mathrm{~m}$ agni ed for several values of the fugacity $y=1: 0 ; 1: 6 ; 2: 5 ; 5: 0$. (c) $T$ he trajectories in (a) show $n$ in the complex eplane for zero and nonzero $m$ agnetic eld. The fugacity takes the values $y=1: 0 ; 1: 3 ; 1: 6 ; 1: 9 ; 2: 5$ and $\mathrm{N}=14$.

Figure 5: Scaling of the rst three Lee\{Y ang zeros for the Ising m odelon square dynam ical lattioes of size N (j labels the zero). T he slopes are expected to be given by the exponent com bination $=($ ब $)=5=6\left(\mathrm{~d}_{\mathrm{H}}\right.$ is the H ausdor dim ension $)$. The tted slopes are given in Table 3.

Figure 6: Illustration of the scaling relation $\mathrm{K} \mathrm{j}^{( } \mathrm{N}^{1=\left(\mathrm{d}_{\mathrm{H}}\right)}$ for the rst F isher zero at $\mathrm{H}=0$. $D$ ue to nite size e ects, the curve for $\mathcal{K} j$ is not a straight line. On the other hand, $j \quad j$ scales well and yields a slope of $0: 327 \quad 0: 01$. T he expected slope is $1=3$.

Figure 7: (a) Tra jectories of the rst $F$ isher zero in the com plex $K$ plane for nonzero $m$ agnetic eld $0: 2<\operatorname{Im}(H)<0.2$. The tra jectories are for sm all square lattioes of size $N=4 ; 6 ; 8 ; 10 ; 12 ; 14$ in order from left to right. T he angle that the trajectories form $w$ th the $R(K)$ axis is expected to approach $==(2 \quad)=36$ as N ! 1 . (b) tan versus N for sm all lattioes. The dashed line corresponds to the expected asym ptotic value of tan for large N. (c) B reakdow $n$ of scaling for strong $m$ agnetic eld (up to $\ddagger j 2: 6$ ). The angle changes drastically for strong $H$.

Figure 8: C heck of the scaling relation for the jth Lee\{Y ang zero $H_{j}^{2} \quad 2=(+1)=F\left(K^{1=\left(d_{H}\right)}\right)$, where $=j=N$ and $F$ is a universal function. All values of $j>1$ for lattioe sizes in the range 10 N 14 have been plotted on the sam e graph. T he points are expected to fall on the sam e universal curve for large $j$.

Figure 9: The rst ( $j=1$ ) and second ( $j=2$ ) Lee\{Yang zero observed using $m u l t i h i s t o g r a m m$ ing on dynam ical triangular lattioes in the size range $64 \quad \mathrm{~N}_{\mathrm{v}} 256(124 \mathrm{~N} \quad$ 508) . T he slopes of the lines should be given by $\quad=(\Phi)=5=6$.

Figure 10: The rst $F$ isher zero observed using $m$ ultihistogram $m$ ing on dynam ical triangular lattioes in the size range $32 \mathrm{~N}_{\mathrm{v}} 256$ (60 $\mathrm{N} \quad 508$ ). The slopes of the lines are expected to be $1=\left(d_{H}\right)=1=3$.
