M arch 24, 2024

#### A bstract

We re-exam ine the issue of the pQCD factorization scale in the exclusive production in di ractive D IS from the  $k_t$ -factorization point of view. We not that this scale di ers signi cantly from, and it possesses much atter Q<sup>2</sup> behavior than widely used value  $(Q^2 + m^2)=4$ . W ith these results in m ind, we discuss the Q<sup>2</sup> shape of the m eson production cross section. We introduce rescaled cross sections, which m ight provide further insight into the dynamics of production. We also comment on the recent ZEUS observation of energy-independent ratio ( p! p)= tot ( p).

## 1 Introduction

The exclusive production of vector m esons in di ractive D IS

<sup>()</sup>p! Vp

turned out to be an ideal testing ground [1, 2, 3] of many predictions of the famous color-dipole approach, [4, 5, 6]. W ithin this formalism, the basic quantity is the cross section of the color dipole interaction with the target proton  $_{dip}(x;r)$ , which can be approximately related to the conventional gluon density  $G(x_g;\overline{Q}^2)$  inside the proton, [4]. The hard scale  $\overline{Q}^2$ , at which the gluon density should be taken, is set both by the virtuality and the mass of the vector meson, and in the case of heavy quankonium is approximately equal to  $\frac{1}{4}(Q^2 + m_V^2)$ . The latter result can be also obtained in the direct D G LAP -inspired calculations of the relevant Feynman diagram s, see, for example, the calculations of the exclusive production of J= mesons in direct D IS [7].

A lthough the identi cation of the pQCD factoriozation scale with  $\frac{1}{4}(Q^2 + m_V^2)$  is valid only in the case of non-relativistic vector mesons, there is a hope that the same relation will hold for the light vector mesons and for large virtualities as well. This hope leads to the prediction of a remarkable universality: the cross section of light and heavy mesons will exhibit the same Q<sup>2</sup> behavior, if plotted against Q<sup>2</sup> + m<sub>V</sub><sup>2</sup> rather than Q<sup>2</sup> alone.

E-m ail: i.ivanov@ fz-juelich.de

On the experimental side, the rst data showed that cross sections of , !, and J=m esons, taken at equal values of  $Q^2 + m_V^2$  and corrected by corresponding SU (4) factors, were indeed very close to each other, [8]. It is interesting to note that a similar dependences on  $Q^2 + m_V^2$  were observed not only in the magnitudes of the cross sections of di erent vector m eson production, but also in the values of the energy grow th exponent, which is related to the Pom eron intercept, as well as in the slopes of the forward di raction cone.

However, with the advent of new, more accurate data of and J= production, it became clear that this scaling was only approximate. Recently, ZEUS concluded [9] that the J= production cross section is typically 40% higher that the cross sections of the light vector meson production. This difference is especially obvious on the plots of  $_{\rm L}$  and  $_{\rm T}$  separately, [8].

A natural question arises as to what extent the universality of the  $\overline{Q}^2 = (Q^2 + m_V^2) = 4$ as the relevant hard scale is valid. Since there is almost no room for doubt in the case of J= production, the question can be formulated as what is the relevant pQCD factorization scale of the high  $Q^2$  production of mesons<sup>1</sup>.

The answer to this question was, in fact, given already in [3]. W ithin the color dipole form alism , the pQ CD factorization scales for the longitudinally and transverse produced m esons were shown to be  $\overline{Q}^2(_{\rm L}) = 0.15$  (Q+ m  $_{\rm V}^2$ ) and  $\overline{Q}^2(_{\rm T}) = (0.07 - 0.1)$  (Q+ m  $_{\rm V}^2$ ). This is notably smaller than (Q<sup>2</sup> + m  $_{\rm V}^2$ )=4, and suggests that even the highest Q<sup>2</sup> experimental points in production correspond to, at most, sem iperturbative values of  $\overline{Q}^2(_{\rm T})$ .

In fact, the exact value of the pQCD factorization scale can be a ected by the shape of the unintegrated gluon distribution. Unfortunately, when [3] appeared, no num erically reliable param etrizations of dipole cross section or of the unintegrated gluon structure function were available, and one was bound to a sem iquantitative guess. The situation changed two years ago, when num erially accurate, sim ple, and ready-to-use param etrizations of the unintegrated gluon structure function F (x<sub>g</sub>;~) were obtained from the analysis of proton structure function F<sub>2p</sub>, [10]. These param etrizations were devised for x<sub>B j</sub> < 0.01 and for the entire dom ain of relevant Q<sup>2</sup> values. They were put in the basis of the k<sub>t</sub>-factorization calculations of both light and heavy vectorm eson production cross sections and yielded rather good description of the available data, [11, 12, 13]. These ts now allow for a quantitative reanalysis of the hard scale in the meson production.

N um erically accurate understanding of the hard scale in the production is dem anded in m any applications. For example, a need for the hard scale arises when one attempts to understand the  $Q^2$  behavior of the -m eson electroproduction. The early data could be successfully parametrized by a simple law

$$(p! p) / \frac{1}{(Q^2 + m^2)^n}$$

with n = 2:32 0:10 (ZEUS, [14]) or n = 2:24 0:09 (H1, [15]). However, with the advent of high precision data in a much broader  $Q^2$  region, it became clear that such powerlike ts have very limited applicability domain. A natural question has been raised

<sup>&</sup>lt;sup>1</sup>To be de nite, we will deal with mesons, but the general conclusions are obviously valid for all light vector mesons.

as what would be the most insightful and physically motivated t to the Q $^2$  behavior of

(p!p).

In virtually any description of the exclusive m eson production, one has to dealwith the gluon content of the proton. C learly, in order to experimenally study the underlying m echanism of the vector m eson production, one m ight want to get rid of the \trivial" source of the Q<sup>2</sup> behavior that arises due to the gluon density. A simple way to do this would be to divide the cross sections by the conventional gluon density squared and study the Q<sup>2</sup> behavior of the result. However, this procedure requires know ledge of the hard scale, at which the gluon density should be calculated.

A nother issue that dem ands the understanding of the hard scale in production is related to the energy behavior of the ratio

$$r = \frac{({}^{()}p!p)}{tot};$$
 (1)

The pQCD improved Regge model predicts that these cross sections rise with energy as

$$({}^{()}p! p) / (W^{2})^{2} \mathbb{P}; tot({}^{()}p) / (W^{2}) \mathbb{P};$$
 (2)

where  $_{\mathbb{P}}$   $_{\mathbb{P}}$  1 is the Pom eron intercept, so that the ratio is predicted to rise as

$$r / (W^2) \mathbb{P}$$
: (3)

In last years, a large amount of data became available on the meson photo- and electroproduction in a broad range of the total photon-proton energy W and the photon virtuality  $Q^2$ , [14,15]. This enabled the ZEUS collaboration to study the energy behavior of r at several values of  $Q^2$ . The results, [9], posed an apparent challenge: throughout the whole  $Q^2$  range, from  $Q^2 = 0$  up to  $Q^2 = 27 \text{ GeV}^2$ , the ratio r was found to be energy independent. The conclusion of [9] was that neither Regge m odel, nor pQCD approach can explain this constancy.

However, the Pomeron intercept is known to signi cantly depend on the hard scale involved in the interaction, see experimental data [14, 15, 16, 17] and results of the phenomenological analysis of [10]. Thus, when testing prediction (3), one must make sure that both intercepts in (2) are taken at the same hard scale.

In [9] these scales were idential ed with  $Q^2$  for the total virtual photoabsorption cross section and with  $\overline{Q}^2 = \overline{Q}^2$  ( $Q^2 + m^2$ )=4 for the meson production cross section, so that the experimental results were given for the quantity:

$$r = \frac{({}^{()}p! p) (W^{2};Q^{2})}{t_{ot} ({}^{()}p) (W^{2};\overline{Q}^{2})}:$$

Note that here the meson production cross section and the total virtual photoabsorption cross section are taken at di erent virtualities.

As we argue in this paper, the true scale of the production can noticeably deviate from  $(Q^2 + m^2)=4$ , especially at very small and very large  $Q^2$ . Thus, it appears that the m ism atch of the scales can be at least one of the sources of the discrepancy observed.

The structure of the paper is the follow ing. In Section 2 we brie y review the results of the  $k_t$ -factorization approach to the exclusive production of vector m esons in di ractive D IS. For future guidance, we also show how these results simplify in the case of heavy vector m esons. In Section 3 we study which gluons are relevant for the interaction, and

settle the factorization scales  $\overline{Q}_{L}^{2}$  and  $\overline{Q}_{T}^{2}$  for longitudinal and transverse amplitudes for any Q<sup>2</sup>. Section 4 serves as an application of the results obtained to the study of the Q<sup>2</sup> behavior of the meson electroproduction cross section. In this Section we also propose new quantites, the rescaled cross sections, which m ight provide additional insight into the mechanism of the interaction. Finally, Section 5 is devoted to the discussion of the results and to the conslusions.

## 2 Exclusive production of vector m esons

W ithin the familiar color dipole form alism [4, 5], the production of a vector m eson is viewed as a three-step process. First, at distances of the order of the coherence length  $c_{\rm c} = 1 = (m_{\rm N} \, x_{\rm B\,j})$  (where  $x_{\rm B\,j}$  is B jorken x and  $m_{\rm N}$  is the nucleon m ass) upstream the target, the incident photon splits into a qq pair, a color dipole. Then, interaction between the color dipole and the target takes place. This qq pair receives longitudinalm on entum transfer, so that its invariant m ass squared turns positive and close to the m ass of a corresponding vector m eson. Then, at large form ation distances, this qq pair projects onto hadronic nal states.

At high energies, the typical longitudinally size of the interaction region, of the order of radius of the proton, is much sm aller than both the coherence length and the form ation length. This allows one to treat the color dipole frozen during the interaction, and the basic quantity that appears in the approach is the diagonal color dipole cross section

 $\begin{array}{l} \underset{\mbox{dip}}{\mbox{dip}} (x;r), \mbox{which is related to the gluon density of the target proton. The analysis of $\beta$] yielded the result that the pQ CD factorization scales for the longitudinally and transverse produced $m$ esons were $\overline{Q}^2(L)$ 0:15 ($Q+m_V^2)$ and $\overline{Q}^2(T)$ (0:07 0:1) ($Q-m_V^2)$.} \end{array}$ 

In this paper we reexam ine this issue within the  $k_t$ -factorization approach, which is closely related to the color dipole form alism. As said above, our analysis is based on the param etrizations of the unintegrated gluon structure function that were given in [10].

### 2.1 The basic am plitude

Figure 1: The QCD {inspired diagram s for p! V p process with two gluon t{channel. Only D iagr.(a) contributes to the imaginary part of am plitudes.

W ithin the  $k_t$ -factorization approach, the imaginary part of the amplitude of the vector m eson production is given by discontinuity of the diagram shown in Fig. 1a. The upper blob should be understood as sum of four diagram s, shown in Fig. 2. We denote the quark and gluon loop transverse m om enta and the m om entum transfer by  $\tilde{k}$ , ~, and ~, respectively. The fraction of the photon lightcone m om entum carried by quark is

Figure 2: The content of the upper blob in Fig.1a in the pQCD approach.

denoted by z, while the fractions of the proton light cone m om entum carried by the two gluons are  $x_1$  and  $x_2$ . W ith this notation, the imaginary part of the amplitude can be written in a compact form :

$$Im A = s \frac{c_V p \frac{1}{4 em}}{4^2} \frac{d^2 a}{a^4} s (q^2) F (x_1; x_2; a_1; a_2) \frac{dz d^2 \tilde{k}}{z (1 - z)} v (z; \tilde{k}) I(y; z; a_2)$$
(4)

where  $\sim_{1,2} = \sim \frac{1}{2}^{\sim}$ . The helicity-dependent integrands I (  $_{\rm V}$ ; ) have form I<sup>S</sup> (L;L) = 4Q M z<sup>2</sup> (1 z)<sup>2</sup> 1 +  $\frac{(1 2z)^{2}}{4z(1 z)M + 2m}$  <sup>#</sup> 2; I<sup>S</sup> (L;T) = (eV ) [m<sup>2</sup> 2 + ( $k^{\sim}_{1}$ )] + (1 2z)<sup>2</sup> (kV ) ( $e^{\sim}_{1}$ )  $\frac{M}{M + 2m}$ (ek) ( $V \sim_{1}$ ) +  $\frac{2m}{M + 2m}$  (ke) (kV ) 2; I<sup>S</sup> (L;T) = 2M z (1 z) (1 2z) ( $e_{1}$ ) 1 +  $\frac{(1 2z)^{2}}{4z(1 z)M + 2m}$  <sup>#</sup>  $\frac{M m}{M + 2m}$  (1 2z) (ek) 2; I<sup>S</sup> (L;T) = 2Q z (1 z) (1 2z) (k)  $\frac{M}{M + 2m}$  2: (5)

where

$$_{2} = \frac{1}{(x + \infty)^{2} + n^{2}} \frac{1}{(x - \infty)^{2} + n^{2}} + \frac{1}{(x + \infty)^{2} + n^{2}} + \frac{1}{(x - 2)^{2} + n^{2}} + \frac{1}{(x - 2)^{2} + n^{2}};$$

$$\sim_{1} = \frac{x + \sim}{(x + \sim)^{2} + u^{2}} = \frac{x - w}{(x - v^{2} + u^{2})^{2}} + \frac{x + w^{2} - 2}{(x - v^{2} + u^{2})^{2}} + \frac{x - 2}{(x - v^{2} + u^{2})^{2}} + \frac{x - 2}{(x - v^{2} + u^{2})^{2}};$$

with r  $\tilde{k}$   $(1 \quad 2z) = 2$  and  $"^2 = z(1 \quad z)Q^2 + m_q^2$ . Finally, the strong coupling constant is taken at  $q^2 \quad m \propto [r^2 + \tilde{k}^2; \sim^2]$ .

In the absence of  $\sim \sim$  correlations, and for a very asymmetric gluon pair, the o - forward gluon structure function F (x<sub>1</sub>;x<sub>2</sub>; $\sim_1$ ; $\sim_2$ ) that enters (4) can be approximately related to the forward gluon density F (x<sub>q</sub>; $\sim$ ) via

$$F(x_1;x_2 x_1;a_1;a_2) F(x_g;a_1) \exp \frac{1}{2}b_{3\mathbb{P}}a_2$$
:

Here  $x_g = 0.41 x_1$ ; the coe cient 0.41 is just a convenient representation of the o -forward to forward gluon structure function relation found in [18]. Num erical parametrizations of the forward unintegrated gluon density F ( $x_g$ ;~) for any practical values of  $x_g$  and  $\sim^2$  can be found in [10]. The slope  $b_{3\mathbb{P}}$  can be experimentally accessed in the high-mass elastic di raction.

The vector m eson wave function  $V(z; \tilde{k})$  describes the projection of the qq pair onto the physical vector m eson. It is normalized so that the forward value of the vector m eson form factor is unity, and the free parameters are chosen to reproduce the experimentally observed value of the vector m eson electronic decay width (V ! e<sup>+</sup>e). In what concerns the shape of the radial wave function, we followed a pragmatic strategy. N amely, we took a simple A nsatz for the wave function, namely, the oscillator type wave function and performed all calculations with it. In order to control the level of uncertainty, introduced by the particular choice of the wave function, we redid calculations with another wave function A nsatz, namely, the C oulom b wave function, and compared the results. Since these two wave functions represent the two extremes (very compact and very broad wave functions that still lead to the same value of the electronic decay width), this di erence gives a reliable estim ate of the uncertainty. It is given typically by factor of 1.5 for m agnitudes of the cross sections, while in the observables that involve ratios of the cross sections (including slopes and intercepts) this uncertainty is reduced. D etails can be found in [13, 11].

Note also that when deriving (5), we treated the vector m esons as 1S wave states and used the pure S-wave spinorial structure S instead of , [19].

## 2.2 The heavy m eson lim it and the scaling property

It is instructive to look at the production amplitude (4) in the heavy quarkonium limit. In this case, the vector m esons is essentially non-relativistic, z ! 1=2; $k^2 = m_{g}^2$ , and

$$\mathbf{w}^2 = z (1 - z)Q^2 + m_q^2 - \frac{1}{4}(Q^2 + m_V^2) - \overline{Q}^2$$

Even in the photoproduction lim it, the mass of the meson sets the hard energy scale of the interaction, and one should expect the DGLAP-inspired leading  $\log \overline{Q}^2$  approximation to be a viable approach to the problem. The DGLAP approximation of the heavy vector meson production implies the following ordering

$$\tilde{k}^2 \sim^2 \overline{Q}^2$$
;

which leads to simplications in the production amplitude. Consider the forward scattering. In this case only helicity conserving amplitudes survive, and one obtains

$$I(L;L) = \sim^{2} \frac{8Qm_{V}}{(Q^{2} + m_{V}^{2})^{2}}; \quad I(T;T) = \sim^{2} \frac{8m_{V}^{2}}{(Q^{2} + m_{V}^{2})^{2}}:$$

W e reiterate that this simplication works while  $\sim^2$  is su ciently small, namely,  $\sim^2 = \overline{Q}^2$ . In the spirit of the DGLAP approach, the integrands I( $_V$ ; ) do not depend on  $\sim^2$ , aside from the overall  $\sim^2$  factor, whose origin is the color neutrality of the proton. Then, integration of  $\sim^2$  immediately leads to the conventional gluon density:

$$\frac{Z_{1}}{0} \frac{d^{2}}{4} s(^{2})F(x_{g};^{2})I(T;T) ! \frac{8m_{V}^{2}}{(Q^{2}+m_{V}^{2})^{2}} \frac{Z_{Q}}{0} \frac{d^{2}}{2} s(^{2})F(x_{g};^{2}) \frac{8m_{V}^{2}}{(Q^{2}+m_{V}^{2})^{2}} s(^{2})F(x_{g};^{2})$$

The integration of the wave function can be related to the electronic decay widths of the vector m eson. The result for the forward di erential cross section reads, [7]:

$$\frac{\mathrm{d}}{\mathrm{d}\mathrm{j}\mathrm{j}_{\mathrm{t}=0}} = \frac{3}{12 \, \mathrm{em}} \mathrm{m}_{\mathrm{V}} \quad (\mathrm{V} ! \mathrm{e}^{+}\mathrm{e}) \frac{\mathrm{n}_{\mathrm{s}} (\overline{\mathrm{Q}}^{2}) - \mathrm{G} (\mathrm{s}\mathrm{s}\mathrm{v}\overline{\mathrm{Q}}^{2})^{\mathrm{L}_{2}}}{\overline{\mathrm{Q}}^{6}} : \tag{6}$$

Note that in this lim it the di erence between the pure S-wave vector meson and the vector meson with coupling vanishes.

Eq.(6) identi es the hard scale that de ned the gluon content of the proton in such a reaction with the quantity  $\overline{Q}^2 = (Q^2 + m^2)=4$ . A lthough this derivation is valid only for very heavy vector m esons, it is often hoped that for the light m esons the hard scale will have the same form . We show below that this is not true.

This result, although an approximation, suggests the scaling property of the vector mesons production: the Q<sup>2</sup> behavior of all vector mesons cross sections should be proportional to each other if taken at equal Q<sup>2</sup> + m<sub>V</sub><sup>2</sup>. Note that (6) does not suggest that the absolute values of the cross sections should be equal, even when corrected by the relevant avor content factors  $c_V^2$ , simply due to the fact that this approach does not predict universality of m<sub>V</sub> (V ! <sup>t</sup>ee ).

## 3 The scale in exclusive production

In this section we perform an analysis of the am plitude (4), taken for sim plicity at  $\sim = 0$ , and nd what values of the transverse gluon m om enta are essential in the interaction. These values will de ne the hard scale of the conventional gluon density. Again, this analysis is essentially sim ilar to what was done in [3].

#### 3.1 W eight functions: m apping the glue

W e start with a qualitative analysis of the production of longitudinal m esons at high  $Q^2$ . Let us for a moment neglect the scaling violations and the other sources of marginal  $\tilde{k}^2$  behavior, and rewrite the amplitude (4) in the following simplied form :

$$Im A_{L!L} / \frac{Z}{2} \frac{d^{2}}{z^{2}} F(x_{g}; \sim) \quad \Psi(\gamma^{2}); \quad \Psi_{L} = \frac{1}{z^{2}} \int_{0}^{Z} dz \, z \, (1 \, z) \, d^{2} \tilde{K}(z; \tilde{K}) \, z$$

with

$$_{2} = \frac{1}{(k + \sim)^{2} + u^{2}} - \frac{1}{(k - \sim)^{2} + u^{2}} + \frac{2}{k^{2} + u^{2}} :$$

At large Q<sup>2</sup>, the most of the  $\sim^2$  integration comes from the logarithm ic region with  $\aleph^2 \sim^2$  "<sup>2</sup>. This leads to simplications:

$$W_{L}(\sim^{2}) = \int_{0}^{Z_{1}} dz \, z \, (1 \, z) \, d^{2} \tilde{\kappa} \, (z; \tilde{\kappa}) \, \frac{2}{n^{2} (n^{2} + n^{2})}$$
(7)

If we denote by  $h^{"2}i$  the typical values of  $"^2 = z(1 - z)Q^2 + m_q^2$  that dom inate the integral (7), then the weight factor  $W_L$  ( $\sim^2$ ) stays alm ost constant at  $\sim^2 - h^{"2}i$ , and quickly decreases for  $\sim^2 > h^{"2}i$ . It should have a form of \sm oothed step function", and e ectively cuts o from above the  $\sim^2$  region essential for the interaction. If we further

approximate it by the exact step function  $(\sim^2 \overline{Q}_L^2)$  with properly dened cut-o scale  $\overline{Q}_L^2$ , then the integration (7) can be done exactly:

$$\sum_{0}^{Z} \frac{1}{2} \frac{d^{2}}{c^{2}} F(\mathbf{x}_{g}; \mathbf{a}) W_{L}(\mathbf{a}^{2}) W_{L}(\mathbf{a})$$

$$\sum_{0}^{Z} \frac{\overline{Q}_{L}^{2}}{c^{2}} \frac{d^{2}}{c^{2}} F(\mathbf{x}_{g}; \mathbf{a}) = W_{L}(\mathbf{0}) \quad G(\mathbf{g}; \overline{Q}_{L}^{2}) : (8)$$

This transition is precisely what is implied in the DGLAP approach, recall derivation of (6). Thus, a procedure that would yield the values of the relevant hard scale, at which the conventional gluon density should be taken, is the following: take the weight function  $W_{\rm L}$  (~<sup>2</sup>) and nd the value  $\overline{Q}_{\rm L}^2$  that would lead to the most justi ed replacement (8).

O by iously, the scale  $\overline{Q}_{L}^{2}$  should be close to  $h^{n^{2}} + \tilde{\kappa}^{2}i$ . Due to the broad wave function of the , the typical values of z(1 = z) will be less than 1=4. As a result, the scale of the gluon density in (8) should be noticeably softer than  $(Q^{2} + m^{2})=4$ .

In the case of the production of the transversely polarized mesons, the contribution of the very asymmetric qcpairs is enhanced. This leads to typical values of z stills maller, and the departure of the corresponding factorization scale  $\overline{Q}_T^2$  from  $(Q^2 + m^2)=4$  becomes even more prominent.

#### 3.2 Num erical results

The above expectations are corroborated by the numerical analysis. The functions W  $_{\rm L}$  (~^2) and W  $_{\rm T}$  (~^2) are de ned now via

$$\frac{1}{s} \operatorname{Im} A_{L!L} \xrightarrow{Z} \frac{d^{2}}{2} F(x_{g}; \sim) \quad \Psi(\sim^{2}); \quad \frac{1}{s} \operatorname{Im} A_{T!T} \xrightarrow{Z} \frac{d^{2}}{2} F(x_{g}; \sim) \quad \Psi(\sim^{2})$$

for all values of Q<sup>2</sup>. Their behavior for Q<sup>2</sup> = 100 G eV<sup>2</sup> is illustrated in F ig. 3, where we show the ratios W<sub>L</sub> (~<sup>2</sup>)=W<sub>L</sub> (0) and W<sub>T</sub> (~<sup>2</sup>)=W<sub>T</sub> (0) as a functions of ~<sup>2</sup>. One sees that these weight functions start decreasing at ~<sup>2</sup> Q<sup>2</sup> and reach 1=2 at ~<sup>2</sup> 15 G eV<sup>2</sup> and ~<sup>2</sup> 10 G eV<sup>2</sup>, respectively. This shows that the above mentioned e ect of the broad wave function leads to signi cant softening of the relevant scale.

The factorization scales  $\overline{Q}_{L}^{2}$  and  $\overline{Q}_{T}^{2}$  can be de ned, in principle, in several ways. As a trial de nition, one can bok at the  $\sim^{2}$  points, where  $W_{i}(\sim^{2})$  reach  $\frac{1}{2}W_{i}(0)$ . De ned so, the longitudinal and transverse scales were found to be approximately equal to  $\frac{1}{6}(Q^{2} + 2.0 \text{ GeV}^{2})$  and  $\frac{1}{11}(Q^{2} + 2.6 \text{ GeV}^{2})$ , respectively. The numbers  $\frac{1}{6}$  and  $\frac{1}{11}$  are very close to 0:15 and 0:07 0:1 obtained in [3].

The gluon density, how ever, has itself signi cant ~<sup>2</sup> dependence, [10]. Namely, in the region ~<sup>2</sup> 1 10 GeV<sup>2</sup> and very small  $x_g (x_g < 10^3)$  (which corresponds, at xed W = 75 GeV, to values of  $Q^2 < 10 \text{ GeV}^2$ ), F ( $x_g$ ;~<sup>2</sup>) is a strongly rising function of ~<sup>2</sup>. At larger  $Q^2$ , the elective  $x_g$  grows, and the unintegrated gluon density becomes at. Finally, at large enough  $Q^2$  (for W = 75 GeV, this corresponds to  $Q^2 > 100 \text{ GeV}^2$ ), the unintegrated gluon density decreases with ~<sup>2</sup> grow th in the region ~<sup>2</sup> 1 10 GeV<sup>2</sup>. Therefore, the span of electively contributive ~<sup>2</sup> will extend to higher values of ~<sup>2</sup> (at small  $Q^2$ ) or reduce to smaller values of ~<sup>2</sup> (at high  $Q^2$ ).

In order to take this into account, it is more useful to de ne the hard scales via the following implicit relations:

$$\frac{1}{W_{i}(0)} \int_{0}^{Z_{1}} \frac{d^{2}}{c^{2}} F(x_{g}; c) W_{i}(c^{2}) \quad G(x_{g}; \overline{Q}_{i}^{2}); \quad i = L; T$$
(9)

Figure 3: The normalized weight functions W  $_{\rm L}$  ( $\sim^2$ )=W  $_{\rm L}$  (0) and W  $_{\rm T}$  ( $\sim^2$ )=W  $_{\rm T}$  (0) calculated at Q<sup>2</sup> = 100 GeV<sup>2</sup>. The  $\sim^2$  values where W  $_{\rm L}$  and W  $_{\rm T}$  reach 1=2 are noticeably softer than (Q<sup>2</sup> + m<sup>2</sup>)=4.

Figure 4: The  $Q^2$  !  $\overline{Q}_L^2$  and  $Q^2$  !  $\overline{Q}_T^2$  mapping in the production. The heavy meson analysis expectation ( $Q^2 + m^2$ )=4 is also shown.

Fig. 4 shows the values of  $\overline{Q}_{L}^{2}$  (solid line) and  $\overline{Q}_{T}^{2}$  (dashed line), de ned according to (9), as functions of  $Q^{2}$ . These values start from 0:63 GeV<sup>2</sup> and 0:4 GeV<sup>2</sup>, respectively, in the photoproduction limit, and slow ly grow with  $Q^{2}$  rise. At  $Q^{2} = 27 \text{ GeV}^{2}$  (the highest  $Q^{2}$  data point from H1 data on production), these values are only around

4.5 GeV<sup>2</sup> and 3 GeV<sup>2</sup>, respectively. This con m s the conclusion of  $\beta$ ] that even at largest  $Q^2$  where data are available, we still deal with sem iperturbative situation. It is interesting to note that a better t to these curves is given by a non-linear, rather than linear approxim ation:

$$\overline{Q}_{\rm L}^2$$
 1.5  $\overline{Q}_{\rm P}^2$  0.45  $(Q+1.5)^{0.7}$ ; (10)

where all quantities are expressed in  $\operatorname{GeV}^2$ .

The same F igure shows also, by dotted line, the expectation  $(Q^2 + m^2)=4$  inspired by the heavy m eson analysis. This expectation starts from 0:15 G eV<sup>2</sup>, which is noticeably sm aller than  $\overline{Q}_{L}^{2}$  (0) and  $\overline{Q}_{T}^{2}$  (0), and rises with  $Q^2$  signi cantly faster than  $\overline{Q}_{L}^{2}$  and  $\overline{Q}_{T}^{2}$ .

## 3.3 The $Q^2$ dependence of the weight functions

In the heavy m eson approximation (6), the scale  $\overline{Q}^2 = (Q^2 + m_V^2)=4$  de nes not only the hard scale of the gluon density, but also the absolute value of the cross section. It is interesting to check whether such a universality holds for the production.

This can be done by studying the Q<sup>2</sup> dependence of the W<sub>L</sub> (0) and W<sub>T</sub> (0). Motivated by (6), we introduce the \e ective twists"  $_{L}^{2}$  and  $_{T}^{2}$  via the following relations:

$$W_{L}(0) = 0:153 Q \quad \frac{s(\mathbf{n}_{L}^{2})}{(\mathbf{n}_{L}^{2})^{2}}; \quad W_{T}(0) = 0:153 m_{V} \quad \frac{s(\mathbf{n}_{T}^{2})}{(\mathbf{n}_{T}^{2})^{2}}: \quad (11)$$

Here, factor 0:153 GeV =  $q \frac{(! e^{i} e^{-})^{4}m}{3 e^{i}}$  is the num erical value of all the residual factors present in the de nition of W<sub>i</sub>. This de nition of the \e ective twists" " $_{L}^{2}$  and " $_{T}^{2}$  is such that in the heavy m eson limit one would recover the familiar  $\overline{Q}^{2} = 0.25$  ( $\hat{Q} + m_{V}^{2}$ ). These \e ective twists" were found to be approximately equal to

$$\mathbf{I}_{\rm L}^2 \quad 0.23 \quad (Q+1:1); \quad \mathbf{I}_{\rm T}^2 \quad 0.16 \quad (Q+1:3): \tag{12}$$

Again, all quantities are expressed here in  $\text{GeV}^2$ . It is interesting to note that here, as well as in (10), the virtuality  $Q^2$  sum s with M<sup>2</sup> 1 1:5 GeV<sup>2</sup> instead of widely assumed m = 0:6 GeV<sup>2</sup>. This is not surprising, since the mass of the meson does not have much relevance to the interaction of the qq dipole with the proton.

# 4 The Q<sup>2</sup> behavior of the production cross section

Let us turn to an issue that is closely related to the above discussion of the hard scales in the production, namely, to the  $Q^2$  behavior of the exclusive meson production cross section.

As mentioned in the Introduction, the early data on m esons were successfully parametrized (in the moderate and high-Q<sup>2</sup> region) by a simple law

$$(p! p) / \frac{1}{(Q^2 + m^2)^n}$$

with n = 2.32 0:10 (ZEUS, [14]) or n = 2.24 0:09 (H1, [15]). However, subsequent data m ade it clear that such power ts have very limited applicability. One thus can ask

what would be the best way to parametrize this behavior. Note that this is not merely a question of how to t the data, but rather a question of what are the main sources of  $Q^2$  behavior of the cross section.

Let us take the heavy meson limit result (6) as a starting point. It states that the cross section should quickly fall with  $Q^2$  due to powers of  $Q^2 + m_V^2$ , the fall being just slightly tamed by the rise of the gluon density. In order to check whether or not these are the only sources of the  $Q^2$  behavior of the meson cross section, let us consider a rescaled cross section

$$(Q^{2}) = (p! p) \frac{(\overline{Q}^{2})^{3} b(\hat{Q})}{\prod_{g \in X_{g}; \overline{Q}^{2}} s(\overline{Q}^{2})^{\frac{1}{2}}}:$$
 (13)

Here, as before,  $\overline{Q}^2$  ( $Q^2 + m^2$ )=4. Note again that the gluon density is taken here at constant energy (W = 75 GeV), so that  $x_g = 0.41 (Q^2 + m^2) = W^2$  also depends on  $Q^2$ . From the heavy meson limit expression (6) one might hope that ( $Q^2$ ) is roughly independent of  $Q^2$ , since all the sources of  $Q^2$  dependence are removed.

Fig.5 show sthe  $k_t$ -factorization predictions for (Q <sup>2</sup>) as function of Q<sup>2</sup>. One observes that this rescaled cross section has quite a at shape, from very low to very high Q<sup>2</sup>, regardless of the exact wave function used.

In principle, all the observables used in (13) are accessible in experiment. The only delicate issue would be the choice of the gluon density, especially at low  $Q^2$ , since the DGLAP ts to conventional gluon density are available only for  $Q^2 > 1 \text{ GeV}^2$  and can dier significantly from the  $k_t$ -factorization result, see [10]. It would be still interesting to see, whether the experimental data possess such a scaling.

In the light of the results of the previous section, it is som ewhat surprising that (13), inspired by the heavy meson limit, is nevertheless rather at. If, however, we take a look at  $_{\rm L}$  and  $_{\rm T}$  separately, and de ne

$${}_{L}(Q^{2}) = \frac{L}{Q^{2}} \frac{\overline{Q^{8}} b(\underline{\hat{Q}})}{\prod_{g \in \mathbf{X}_{g}; \overline{Q}^{2}} \sum_{g \in \overline{Q}^{2}} (\overline{Q^{2}})^{\frac{1}{2}}; \qquad {}_{T}(Q^{2}) = \frac{T}{m^{2}} \frac{\overline{Q^{8}} b(\underline{\hat{Q}})}{\prod_{g \in \overline{Q}^{2}} \sum_{g \in \overline{Q}^{2}} (\underline{14})$$

we will see that this rem arkable  $Q^2$ -independence holds for  $_L(Q^2)$ , but not for  $_T(Q^2)$ , Fig. 6, left panel. This di erence between  $_L(Q^2)$  and  $_T(Q^2)$  can be regarded as a direct proof that the hard scales relevant for longitudinal and transverse cross sections are di erent.

Figure 6: (left panel) The rescaled cross sections  $_{\rm L}$  (Q<sup>2</sup>) and  $_{\rm T}$  (Q<sup>2</sup>) de ned according to (14). The Q<sup>2</sup> behavior of  $_{\rm L}$  (Q<sup>2</sup>) and  $_{\rm T}$  (Q<sup>2</sup>) are very di erent. (right panel) The rescaled cross sections  $\sim_{\rm L}$  (Q<sup>2</sup>) and  $\sim_{\rm T}$  (Q<sup>2</sup>) de ned according to (15). The two quantities are close to each other and both have at Q<sup>2</sup> behavior.

If we take into account the results of the previous section and introduce

$${}^{\sim}_{\rm L} (Q^2) = \frac{{}^{\rm L}}{Q^2} \frac{({}^{\rm T}_{\rm L})^4 \quad b(\hat{Q})}{{}^{\rm T}_{\rm G} \quad {}^{\rm T}_{\rm g}; \overline{Q}_{\rm L}^2} \frac{{}^{\rm T}_{\rm L}}{{}^{\rm S}({}^{\rm T}_{\rm L})}; \quad {}^{\sim}_{\rm T} (Q^2) = \frac{{}^{\rm T}_{\rm T}}{{}^{\rm T}_{\rm g}} \frac{({}^{\rm T}_{\rm T})^4 \quad b(\hat{Q})}{{}^{\rm T}_{\rm G} \quad {}^{\rm T}_{\rm g}; \overline{Q}_{\rm T}^2} \frac{{}^{\rm T}_{\rm g}}{{}^{\rm S}({}^{\rm T}_{\rm g})}; \quad (15)$$

then these rescaled quantities have  $\text{ at } Q^2$  shape both for longitudinal and transverse cross sections, Fig.6, right panel. M oreover,  $\sim_L (Q^2)$  and  $\sim_T (Q^2)$  are close to each other, which should be expected by the construction of the \e ective twists" and factorization

scales. These curves are not exact constants due to non-zero average value of  $\sim^2$  and due to the presence of helicity- ip am plitudes.

Again, it would be very interesting to see a similar analysis of the experimental data in terms of  $\sim_i (Q^2)$ . In particular, it would be interesting to see whether such an analysis can help resolve the long-standing <sub>T</sub>-problem of the k<sub>t</sub>-factorization predictions [12, 13].

## 5 Discussion and conclusions

The most of the analysis of the prevous sections was done with the oscillator wave function. The same analysis with other wave function Ansatze will yield slightly di erent numbers in (10) and (12). Nevertheless, the general picture will remain the same. Namely, several observations are stable against the variations of the exact shape of the wave function:

at smaller  $Q^2$  (Q<sup>2</sup> < 3 5 GeV<sup>2</sup>) the DGLAP factorization scale is larger than (Q<sup>2</sup> + m<sup>2</sup>)=4;

at large enough  $\hat{\mathcal{Q}}$  (Q<sup>2</sup> > 10 G eV<sup>2</sup> for the transverse am plitude and Q<sup>2</sup> > 20 G eV<sup>2</sup> for the longitudinal am plitude), the factorization scale is signi cantly sm aller than (Q<sup>2</sup> + m<sup>2</sup>)=4. This should be taken as a word of caution against an unwarranted application of the DG LAP approach to the problem of m eson production even at high Q<sup>2</sup>;

the overall  $\hat{\mathcal{Q}}$  dependence of the pQCD factorization scale is significantly atter than  $(Q^2 + m^2)=4$ . This is mostly due to the specific way the  $\sim^2$ -behavior of the unintegrated gluon density changes, as the  $Q^2$  increases (at xed W).

the presence of m in the often used scale ( $Q^2 + m^2$ )=4 is m isleading, since the meson mass has little relevance to the color dipole interaction with the target proton. Instead,  $Q^2$  appears in combinations of the form of  $Q^2 + M^2$  with M<sup>2</sup> 1 1:5 G eV<sup>2</sup>.

The numerically accurate understanding of the relevant hard scales in the production allowed us to study in detail the Q<sup>2</sup> dependence of the production cross section. With the help of the rescaled cross sections (13) { (15), F igs. 5 and 6, we showed once more that the production of transverse and longitudinal vector mesons is governed by distinct hard scales. When we took into account the di erence of the scales just found, we observed a very close similarity between the rescaled cross sections ~<sub>L</sub> (Q<sup>2</sup>) and ~<sub>T</sub> (Q<sup>2</sup>). It would be very interesting to see the results of a similar analysis of the experimental data. This analysis might help resolve the long-standing problem of too small <sub>T</sub> at high Q<sup>2</sup>.

Let us also comment on a contribution to the recent puzzle of energy independence of r = (p! p) = tot(p) ratio. As was discussed in this paper, at higher Q<sup>2</sup>, the true factorization scale is smaller than  $(Q^2 + m^2)=4$ . Inverting the argument, one can state that  $tot(Q^2_{tot} = (Q^2 + m^2)=4)$  is expected to be harder than  $(Q^2)$ . This should enhance the expected value of the Pomeron intercept in tot and reduce the prediction of the energy behavior of r. Unfortunately, our numerical analysis showed that this e ect is marginal and does not lead to resolution of the problem.

I am thank fulto K olya N ikolaev form any valuable com m ents and to Igor A kushevich for his help in the early stage of the code developm ent. I also w ish to thank P rof. J Speth for hospitality at the Institut fur K emphysik, Forschungszentrum Julich. The work was

supported by INTAS grants 00-00679 and 00-00366, and RFBR grant 02-02-17884, and grant Universities of Russia" UR 02.01.005.
