Abstract

The $_6$ is a \heavy axion" rem nant of dynam ical electrow eak symmetry breaking by a color sextet quark condensate. Electrow eak scale color instanton interactions allow it to be both very massive and yet be responsible for Strong CP conservation in the color triplet quark sector. It may have been seen at LEP via its two-photon decay mode and at TRISTAN via its hadronic decay modes.

W ork supported by the U S.D epartm ent of Energy, D ivision of H igh Energy P hysics, C ontract W -31-109-ENG -38 and contract DE-FG 02-91ER 40688-TaskA .

E lectroweak dynamical symmetry breaking by a chiral condensate of color sextet quarks[1] has many theoretically attractive features, including the special resolution of the Strong CP problem via a heavy axion that we outline below. However, it should also be emphasised that if this should turn out to be the path chosen by nature it provides a particularly inviting prospect for experimental high-energy physics. Because of the direct coupling of the strong and electroweak interaction, the spectrum of new phenomena that can be expected to appear, at both currently operating accelerators and the future LHC and SSC machines, is probably at least as large, if not considerably larger, than in any other symmetry-breaking scenario.

The purpose of this paper is to focus on the tantalizing possibility that a distinctive feature of the symmetry breaking, namely the \heavy axion" $_{6}$, has already been seen experimentally. This particle is expected to have both a major two-photon decay mode and characteristic high multiplicity hadron decays. It is therefore an excellent candidate for the new particle, with a mass of 59 GeV, suggested by the two-photon pairs seen at LEP [2]. That a sm allbum p is also seen [3] at TR ISTAN, at just this energy, can then be interpreted as due to its hadronic decay modes.

W e expect the strong interaction dynam ics of the sextet quark sector of QCD to be very di erent from that of the triplet sector. In particular we anticipate that relatively complicated instanton generated interactions (at and above the electroweak scale), which include \Strong" CP -violating e ects, will play an important role[4, 5]. As a result, only a m inim alam ount of rescaling of physics from the triplet to the sextet sector will be possible. W e will (if candidate sextet phenom ena begin to appear) be studying a new realm of gauge theory physics and it will not be surprising if, to a large extent, the theory has to follow along sem i-phenom enologically behind the experim ental discoveries.

A lthough it is correctly described as a heavy axion, the $_6$ is the \H iggs particle" of sextet symmetry breaking in the sense that its experimental discovery would be the most immediate conmation of this form of symmetry breaking. Motivated, in part, by the anomalous real part measured in elastic pp scattering at the apparent threshold energy [6], we suggested [7] that the $_6$ be identied with a very heavy state, with a mass [8] of 0 (60) GeV, seen in exotic Cosmic ray events [9]. Because of the axion nature of the $_6$, we proposed that this particle be looked for in accelerators via its two-photon decay mode.

As is by now well known [2], the L3, DELPHI, and ALEPH experiments at LEP have

1

recently reported several events of the form Z^{0} ! $I^{+}1 + ...$, in which the mass of the pair is 0 (60) G eV. The lepton pairs are either muons or electrons and we have separately plotted them distribution form uon and electron pairs in Fig. 1. There are as yet, no neutrino or pairs, although D E LP H I has one candidate quark pair event. While the kinem atics of some of the events may be compatible with Q E D radiation, others book in plausible explained this way. In particular the muon events in the 59 G eV bin are all large angle" events and do not book like naive radiative events. R ather they suggest the existence of a new logarticle", i.e. resonance, with a mass of 59 G eV and a width of (up to) 0 (1) G eV. C learly a case could be made from Fig. 1 that only the muon pair events suggest a new resonance. (Particularly since the two electron events close to 59 G eV are both good candidates for QED radiation.) This is potentially a signi cant feature, as we shall see.

Since we expect the $_6$ to have hadronic decay modes involving relatively complicated high multiplicity states, it is particularly interesting that the new \particle" may also have been seen at TRISTAN. In fact all three experiments saw [3] a small peak in the hadronic cross-section at 59.05 GeV. An error-weighted average of the TRISTAN results for R is shown in Fig. 2. AMY actually obtained a value more than 30% above the standard model value (although with a large error - giving at most a $\langle 2 \ e \ ect$ "). If this e ect is produced by the same new particle that appears in the LEP events, we can infer both that it couples to electrons and that it does indeed have major hadronic decay modes. If this particle had direct electroweak couplings to quark and lepton states in analogy, say, with the Z⁰, then the corresponding decays would surely have already been seen at LEP. It seem s more likely to us that the width is produced mostly by the photon pairs and high multiplicity hadron states which would not be so easily identi ed at LEP, but clearly would be registered at TRISTAN.

We can brie y sum marise the essentials of sextet sym metry breaking [1] as follows. A massless avor doublet (U;D) of color sextet quarks with the usual quark quantum numbers (except that the role of quarks and antiquarks is interchanged) is rst added to the Standard M odel with no scalar H iggs sector. Within QCD, conventional chiral dynamics will break the sextet axial avor sym metries spontaneously and produce four massless pseudoscalar mesons (G oldstone bosons), which we denote as ${}^{+}_{6}$; ${}^{-}_{6}$; ${}^{0}_{6}$ and ${}^{-}_{6}$. The ${}^{+}_{6}$; ${}^{-}_{6}$, and ${}^{0}_{6}$ are \eaten" by the massless electroweak gauge bosons and respectively become the third components of the massive W⁺; W and Z⁰ – giving M_W gF₆, where F₆ is a QCD

2

scale. F _ 250G eV is consistent with an elementary \Casim ir Scaling" rule[1].

The $_6$ is not involved in generating mass for the electroweak gauge bosons and remains a Goldstone boson. A rst assumption might be that the $_6$ somehow acquires an electroweak scale mass which is nevertheless smallenough that we can utilize PCAC for the sextet U (1) axial current. The analog of the familiar 0 ! 2 calculation, but involving the sextet quark triangle anomaly, will give am plitudes for

$$_{6}!$$
; $Z^{0}!$ $_{6}+$ and $Z^{0}!$ $_{6}+Z^{0?}$: (1)

where the Z $^{0?}$ is an o -shell Z 0 .

Note that if the $_6$ is a pseudoscalar, and CP is conserved, the existence of just two independent momenta in plies that each of the vertices in (1) must have the \pseudotensor" kinematic form

$$= C (p;q) \qquad p q \qquad (2)$$

where p and q are the m on enta involved, and C (p;q) can be calculated from the anomaly. A ssum ing a mass of 60 G eV, gives[10] a very narrow width of 0.17 keV for $_6$! . For Z^0 ! $_6$ + the anomaly calculation [11] predicts one event in 20 m illion at LEP, while from the Z^0 ! $_6$ + $Z^{0?}$ calculation we obtain a rate for Z^0 ! $_6$ + $Z^{0?}$! $_6$ + $^+$ of 2 events in a billion. This is at least three orders of m agnitude too small to explain the two photon events. We conclude that, in general, the anomaly gives a set of am plitudes which are far too small to be compatible with the LEP events.

The sextet quark anomaly estimates for amplitudes can only be signicantly wrong if G oldstone boson intermediate states can contribute to the processes involved. At this point the special heavy axion" nature of the $_6$ becomes crucial. Apart from its high mass, the $_6$ is actually a \PecceiQuinn axion" and can be responsible for Strong CP conservation in the triplet quark sector in a conventional manner[12]. However, if the $_6$ is the origin of CP conservation in the triplet sector, then the sextet sector (and sextet G oldstone boson amplitudes in particular) will not be CP conserving. As a result, there will be intermediate states contributing to \longitudinal" Z⁰ and W amplitudes involving the $_6$ which do invalidate the anomaly estimates, and could give large enough cross-sections at LEP and TR ISTAN. We can brie y summarise the physics behind the CP -related properties of the $_6$ as follows.

The PecceiQuinn argument for Strong CP conservation requires [12] the existence of a Goldstone Boson axion a that couples to the QCD color anomaly and gives an elective lagrangian for the triplet quark sector of the form

$$L = L_{QCD} + \frac{q^2}{32^2} F F' + \frac{a}{v_{PQ}} \frac{q^2}{32^2} F F' + (3)$$

where L_{QCD} is the usual QCD lagrangian for the gauge and triplet quark sectors and, in a conventional notation, $\tilde{} = + \arg \det m_3$, where m_3 is the triplet quark mass matrix. v_{PQ} is the vacuum condensate which produces the Goldstone Boson axion a. An appropriate shift in a will absorb the CP-violating $\tilde{}$ term and a su cient condition for the minimum of the axion potential to occur at $\hat{} = 0$ (where now $\hat{} = + \arg \det m_3 + hai = v_{PQ}$) is that $\overset{D}{} = F$ vanishes like sin $\hat{}$ at $\hat{} = 0$. This is expected to be the case for normal instanton interactions. A mass for the axion is generated by the curvature of the potential at the minimum. If all of the relevant QCD dynamics involves only the normal QCD scale $_{QCD}$, this mass is inevitably of O ($_{OCD}^2 = v_{PQ}$) and hence very small[12].

If we identify a with the $_6$, the mass can be much higher just because of the intricate QCD dynamics at the sextet scale. To generate the usual quark and lepton masses it is necessary to add four-ferm ion couplings to the theory which combine appropriately with the $_{D}^{D}$ $_{E}^{E}$ gQ sextet condensate. If we then obtain (3) by integrating out the sextet quark sector, we must include $_6$ vertices induced [5] by the combination of QQ qq vertices, the $_{QQ}^{D}$ condensate, and instanton interactions involving sextet quarks. The instanton interactions are actually very high order ferm ion vertices. The simplest such vertex involves each avor of triplet quark (and antiquark) and ve of each avor of sextet quark (and anti-quark). When the condensate and four-ferm ion vertices are combined with the instanton vertices, a large array of interactions is obtained. (Indeed the resulting low order vertices may be enhanced by large factorial factors associated with the possibilities for pair condensation.) These ferm ion vertices can then be coupled by arbitrarily com plicated gluon interactions – which are e ectively infra-red interactions at the sextet scale.

Note that with the additional two avors of sextet quarks, the resulting evolution of s is negligible above the electroweak (sextet) scale. Indeed there is an electric infra-red xed-point controlling the dynam ics of the sextet QCD sector[4]. The associated absence of

the infia-red growth of the gauge coupling in plies that, in this sector, connement and chiral symmetry breaking will involve the instanton interactions we are discussing as an important \infra-red" e ect. (There are no infra-red renorm alons[4] and so instantons don't melt!). For our present purposes all that we need extract from this complicated dynamical situation is that the sextet instanton interactions generating $_6$ vertices all contain a factor[5] of $\cos[^2 + < _6 >]$. Therefore an axion potential of the form V (cos [$^2 + < _6 >]$) is generated. Such a potential will naturally retain the CP-conserving minimum at $^2 + < _6 > = 0$ while also giving an $_6$ mass (the curvature at the minimum) of order the electroweak scale – say 60 G eV !

Focussing now on the CP properties of the sextet sector, we note that the Peccei-Quinn argum ent is inapplicable since we can not write a lagrangian of the form (3) - that is involving both the 6 and the gluon eld - to describe sextet quark interactions. If the gluon eld is to be present, then we must use the fullQCD lagrangian, written in term s of elem entary elds, for the combined triplet and sextet sectors. This clearly has no axion. A loo, we know that the four-ferm ion QQ qq couplings that we add to the theory must be CP -violating since they have to produce the CP-violating triplet quark mass matrix. Because there is no axion, the induced ferm ion vertices involving instanton interactions will autom atically be CP (and separately C) -violating. In e ect, a consequence of the usual CP violation in the triplet quark masses is that the \bw -energy" e ective lagrangian for QCD interactions of the $_{6}$; $_{6}^{+}$; $_{6}$, and $_{6}^{0}$ is necessarily CP-violating. In unitary gauge, it is the \longitudinal" (or scalar) components of the gauge boson elds, i.e. $(Z^{0}; Q^{W})^{+}$ and $(Q^{W})^{+}$, that inherit the interactions of the Goldstone bosons ${}^{0}_{6}$; ${}^{+}_{6}$ and ${}^{-}_{6}$ respectively [13]. Therefore such interactions may give large, CP-violating, couplings of the form $_{6}$ \odot 0 \odot 0 \odot 0 , $_{6}$ \odot W $^{+}$ \odot W , 60 Z⁰0 W⁺0 W ... etc... We consider now how these couplings can contribute to processes at LEP and TRISTAN involving the 6.

An essential rst step is to write an e ective lagrangian for the strong (unitary gauge) longitudinal amplitudes. This will be quite di erent from conventional chiral lagrangians because of the CP violating amplitudes. Indeed these amplitudes are all zero in the exact chiral limit (that is in the absence of four-ferm ion QQ qq couplings) and so we shall assume they are not constrained by PCAC etc.. From our present perspective, they are simply parameters that should, presum ably, be of comparable order of m agnitude. We can then add the electroweak interaction and, in rst approximation, compute to lowest order in the

5

electroweak couplings. For the moment we use this procedure only implicitly to obtain some order of magnitude estimates. We shall initially assume that, unless we argue otherwise, all momentum and mass factors are $0 \ M_{Z^0}$) and electroweak couplings, small to large mass ratios, and the order of magnitude of electroweak couplings, small to large mass ratios, and the

First we note that, as illustrated in Fig. 3, $_6$! is given by a @ W loop which, because of the unitary gauge propagators, is clearly dom inated by momenta O (M $_{Z^0}$). If we denote the $_6$ @ W $^+$ @ W vertex by V₁ and the full $_6$ width by $_6$, we obtain a branching ratio

 $B_{6!} \qquad {}^{2}_{EM} V_{1}^{2} = m_{6} \quad ! \quad V_{1} \quad 10^{3} \quad {}^{q} \quad (4)$

If (as we shall give arguments for below) this ratio 10^{-1} , and we assume $_{6} < 1 \text{ GeV}$, (4) in plies that V_{1} is 0 (1–10) on the electroweak scale.

There are contributions to $_{6}$! I[†]1 from similar boops to that of Fig. 3 involving longitudinal W 's or Z⁰'s but with one boson propagator replaced by a lepton propagator. These amplitudes should therefore be smaller by O (1=M_W). In fact, to produce the scalar combination of helicities, the amplitudes must involve m₁ and are actually O (m₁=M_W) 10⁻⁵ for an electron pair. This gives too small a coupling to allow the $_{6}$ to be seen at TR ISTAN .A larger amplitude is obtained by producing two photons via Fig. 3 which scatter electrom agnetically into a lepton pair, via lepton exchange. (The infra-red behavior of the photon propagators prevents the process from vanishing as the electron m ass goes to zero and so gives an O ($_{EM}$) amplitude rather than O (m $_{e}$ =M $_{Z^{0}}$)[14]). The resulting coupling gives a cross-section

(
$$e^+e!$$
 hadrons) $B_{e!} = \frac{2}{EM}$ (5)

10% of the total hadronic cross-section at TRISTAN (assuming again that $_{6} < 1 \text{ GeV}$). This is not a major elect but it is the right order of magnitude to be compatible with the data shown in Fig. 2 and provides one argument why the two photon branching ratio of the $_{6}$ should be 10%. However, the error bars on the data would clearly have to be signi cantly in proved to determ ine that the elect was de nitively present.

In general photon em ission will be strongly favored over leptons because of the direct coupling of the photon to sextet G oldstone bosons at large m om entum. Indeed if C P and C are not conserved, as we are assuming, then after two photon decay, the three photon m ode could be the next most important electroweak decay for the $_6$.

Consider next the hadronic decay modes of the $_6$. We anticipate that perturbative gluon emission automatically exposes the large sextet quark constituent mass (which is presumably 300 400 GeV) and so is very suppressed. Instead we expect instanton interactions to provide the major communication between the sextet and triplet sectors. The simplest possible nal state for a decay of the $_6$ mediated by an instanton interaction would be an isotropic distribution of ve quarks and ve antiquarks (one of each avor), giving a high multiplicity hadron state with many (mini-)jets. (There is some suggestion in the data [15] that the increased cross-section at TR ISTAN is in the higher multiplicities). At LEP, the combination of such a state with a hard lepton pair (i.e. m₁₊₁ 20 30 GeV as in the two photon events) could be looked for and some examples should be isolatable if there are indeed a substantial number of such events.

At present we have now ay of estimating the ratio of hadronic to two photon branching ratios theoretically. Another phenom enological estimate, which is clearly independent of that based on TRISTAN data, is obtained by appealing to our suggestion [7] that hadronic di ractive production of the $_6$ is responsible for G em inion and M ini-C entauro C osm ic ray events [9], and is also responsible (via a threshold e ect) for an anom alous contribution to the real part of the hadron elastic scattering am plitude [6]. The number of G em inion events thought to be associated with a 60 G eV state, suggests a two photon cross-section of 0 (100–500) bs., while the M ini-C entauros and the threshold e ect suggest a hadronic cross-section 0 (2-8) m bs. Again we conclude that the two photon branching ratio should be 10%.

If the LEP events are indeed produced by $Z^0 ! _6 + Z^{0?} ! [] + [l^+ 1]$ and CP is not conserved, we can add an additional tensor vertex to (2) of the form

$$V = {}^{h}(p;q)q q^{2}p T(p;q)[(q;p)p p^{2}q] + L(p;q)[q^{2}p]$$
(6)

where now p is the momentum of the Z^{0?}, so that T and L are respectively invariant $\trans-verse$ " and $\oldsymbol{longitudinal}$ " amplitudes. From the above discussion we may assume that L contains a large Z⁰ ! (2 Z⁰ + ₆ coupling (which could again be thought of as proceeding via a (W loop).

There is an electroweak coupling of the initial transverse Z^0 involved in L and so we will estimate it as 0 (gV₂), where g is the SU (2) gauge coupling and V₂ is a (potentially

large) pure sextet QCD am plitude. We note, however, that the longitudinal component of a Z⁰ propagator coupled to a lepton pair reduces to

$$u(k)\frac{\oint}{M_{z_0}^2} [v_1 \quad a_{1,5}]v(p \quad k) = 2\frac{m_1}{M_{z_0}^2} a_1 u_{5}v$$
(7)

where m_1 is the lepton m ass and u and v are lepton spinors. v_1 and a_1 are the vector and axial Z⁰ couplings to the lepton pair. The suppression factor ($m_1=M_{Z^0}$) in plies there will be no neutrino pairs, a negligible num ber of electron pairs, and, at rst sight, an overwhelm ing num ber of tau pairs compared to m uon pairs!

Using
$$_{W}$$
 (= g^2 =4) 1=30, we estimate the branching ratio for Z⁰! 2 + + as

$$V_2^2 {}_W^2 (m = M_z^\circ)^2 10^{-1} = M_z^\circ {}_Z^\circ V_2^2 10^{-12} ! V_2 10^3 GeV$$
 (8)

- if (for our present purposes) we take the width of the Z⁰ to be O (1) G eV and we estimate the LEP branching ratio to be 10⁶. C learly (8) is nicely consistent with (4) in giving the order of magnitude of the QCD sextet quark interaction.

W hile the predicted absence of electron pairs is, perhaps, consistent with the experim ental situation the big question is now why there are not 300 tau pairs for every muon pair? A perturbative correction to the tree am plitude for tau pairs would be the loop diagram shown in Fig. 4, involving another sextet pion vertex $-V_3$. G iven that V_3 is C P -violating (and therefore complex) we obtain a potentially negative am plitude if we take the internal lepton line on-shell. Since this am plitude is then 0 (m²) we m ight suppose it to be sm all. However, if Q is the resulting average momentum in the loop (after the lepton line is taken on-shell) we estim ate that there is an elective perturbative expansion parameter

$$gV_{3}m = M_{Z} \circ Q \quad 1 \tag{9}$$

if we take Q 10 GeV, and assume that V_3 is of the same order of magnitude as V_1 and V_2 . So the elective perturbation parameter involves the lepton mass directly and for tau pairs is su ciently large that the expansion breaks down. Therefore the tau pair amplitude could well not be larger than the muon pair amplitude.

W e must also discuss the production of light mass quark pairs by the $Z^{0?}$. If we carry over the above analysis of leptons directly to quarks, we would conclude that only the strange quark (with a mass of the same order of magnitude as the muon) gives an observable

cross-section which can be reliably estimated perturbatively. However, since quark pairs carry color, they will also interact with the initial sextet quark vertex, via QCD, and for this reason alone, the amplitude can not be evaluated perturbatively. Therefore, although we can not calculate the amplitudes, there is no immediate con ict in the relative lack of quark (or tau) pairs.

Note that there may be a further source of lepton pairs accompanying $_{6}$ production. Four-ferm ion sextet/lepton couplings could provide a direct (short-distance) coupling of lepton pairs into electroweak scale instanton interactions – without going via the electroweak interaction – and give direct Z⁰ ! $_{6}$ + l⁺ l vertices. If C P is conserved, these am plitudes can not be large. If C P is not conserved, there could be couplings that are independent of the mass generation mechanism (involving right-handed leptons and sextet quarks) which give large am plitudes. There are strong constraints on such couplings which we shall not elaborate on here. We note only that they could ultimately turn out to be necessary to understand tau pair am plitudes. They would certainly have to play a major role ifm uon pairs do not dom inate over electron pairs in two photon events at LEP that are to be explained in term s of the $_{6}$.

In conclusion we can say that, at the order of magnitude level, a consistent picture of the properties of the $_6$ has emerged which implies that it may indeed have been seen at both LEP and TRISTAN.
