# CHAOTIC BEHAVIOR OF PARTICLE PRODUCTION IN BRANCHING PROCESSES

Zhen CAO and Rudolph C.HWA

Institute of Theoretical Science and Department of Physics University of Oregon, Eugene, OR 97403

#### A bstract

The notion of chaotic behavior is exam ined for particle production in branching processes. Two types of branching are considered: non-A belian gauge interaction and an Abelian cascade model. Properties of the production processes are investigated by M onte C arb stimulation. The \tem poral" behavior is studied by following the uctuations in the multiplicities of each generation as the branching evolves. The \spatial" behavior is described in terms of the uctuations of the normalized factorialm om ents from event to event. The information dimension and a new entropy index are determined. W hen all the measures are taken together, they collectively give a strong suggestion that the QCD branching process is chaotic, while the Abelian cascade model is not.

#### 1 Introduction

Recently we have reported on the results of an investigation in the possible signatures of chaos in branching processes [1]. The aim is to determ ine whether the nonlinear, non-Abelian dynam ics of the quantum Yang-M ills eld possesses chaotic behavior. Since in such a dynam ical system the number of degrees of freedom increases with tim e evolution, when the notion of time is not even well de ned in the branching process, new measures of trajectory, distance, entropy, etc. must be introduced. We have found that the perturbative QCD branching shows signs indicative of chaos, whereas a model lacking the characteristics of QCD does not. In this paper we give the details of our study.

In the case of classical non-A belian dynam ics special sim plifying conditions that reduce the equations of motion to manageable size have been considered and chaotic

solutions have been found [2, 3]. A more complete investigation of the gauge equations has to be done on the lattice, and it has been shown that the classical non-Abelian gauge theory generally exhibits determ inistic chaos, whose Lyapunov exponents can be num erically computed [4-6].

The extension of the above classical problem to the quantum theory of Y ang-M ills eld is extrem ely di cult. The current state of know ledge about quantum chaos hovers round sem i-classical problems in which classical trajectories are generalized to waves [7, 8]. That is totally inadequate for treating quantum elds, the proliferation of which in a collision process involves issues that are untouched in solving wave equations. The rst step toward form ulating a feasible program to attack the problem is to dissociate the complications of nonperturbative QCD from the quantum dynam ics of non-A belian elds. In the perturbative dom ain where the QCD coupling is small, the nature of nonlinear, non-A belian dynam ics is fully present so that the signature of chaotic behavior in gauge theory should nevertheless show up in hard processes. That is an important step of simplication that renders the problem manageable. M ore specifically, one can narrow the scope and focus on branching processes with QCD splitting functions. The issue then becomes the search for measures that can reveal chaoticity in branching processes.

In such a search it is necessary to keep in mind the special features of QCD. There are many processes that involve branching in realtime, such as cell division in biological systems. The emission of photons by an accelerated charge can be regarded as a branching process with sequential ordering. However, for gluons reproducing gluons in the pure gauge theory, the time variable plays no role in the description of a state with n gluons whose momenta are precisely specified. In multiparticle production one works with momenta (or their variants such as rapidity), since they are what can be measured in a collision process. Then in the momentum space the concept of trajectory for a system of increasing number of gluons becomes ill de ned. W ithout trajectories the notion of distance between trajectories is untenable, and the conventional method of exam ining chaos in classical nonlinear problems is inapplicable. It will therefore be necessary for us to look for other quantities that can describe the difference between states, which evolve from what correspond to nearby initial conditions in the classical problem.

The major di culty with the study of chaotic behavior of nonlinear gauge dynamics is that the gauge elds are not directly measurable and that the branching processes cannot be tracked experimentally. In collisions at high energies, where the question of chaos in gauge dynamics arises, only the particles in the nal states can be measured. Thus to verify any theoretical predictions about chaotic behavior, the loss of information at the end of the branching process must be quantiled and presented in a form suitable for experimental determination. To that end we shall introduce an entropy index q, which is measurable, and describes the degree of uctuation of the nalparticles from event to event.

Before going into details, it may be helpful to state the general idea underlying

the work. In classical dynamics if the coordinates q (t) and momenta p (t) specify the system, then the trajectory in phase space is well de ned in the fam iliar way. In classical eld theory the elds, E (x;t) and B (x;t) say, form a eld con guration de ned over all space x at any given time, and the change of the conguration as time evolves speci es a trajectory in a generalized sense. For quantized elds one works in the Fock space so that the number of quanta becomes a variable that species an in portant aspect of the state of the system . The distance between two trajectories in that case must therefore involve, among other quantities, the di erence between the numbers of quanta in the system. Thus in particle production at high energy where the multiplicity n of produced particles is an essential observable, the uctuation of n from event to event must be viewed as the consequence of swings of trajectories that have almost the same initial condition. With that connection in mind it is natural to generalize the conventional treatm ent of nonlinear dynam ics to an approach that places emphasis on tracking the multiplicity uctuations from event to event in high energy collisions. A fter describing the QCD dynamics of branching and a simple model in Sec. 2, we treat the tem poral behavior of the branching processes in Sec. 3. Then in Secs. 4 and 5 we consider the spatial properties of the nalstate. Concluding rem arks are given at the end.

### 2 Gluon Branching and the Model

To carry out this investigation it is necessary to use computer simulation to generate events of particle production through branching. Only then is it possible to study the nature of uctuations of the nal-state particles. For the simulation we shall use algorithms based on two opposite types of dynamics. One is, of course, the QCD dynamics. For simplicity we shall focus on only the pure gauge theory without quarks. At the end of the evolution we shall identify the partons as particles to avoid the complication of hadronization, which is inessential to the question of whether the gluon branching dynamics is chaotic. The other is a cascade model, to be called the model, which has none of the features of the QCD; in particular, it does not have infrared and collinear divergences. It is studied in order to provide a contrast to the gauge theory so that our measures for chaoticity can be tested on these two contrasting branching dynamics.

In both branching processes the initial parton has virtuality  $Q^2$ , and successive branchings continue until the virtualities of all partons are  $Q_0^2$ . In pure-gauge QCD the splitting function at each vertex of branching is (for g ! gg)

$$P(z) = 6 \frac{1}{z} + \frac{z}{1} + z(1 - z) ; \qquad (1)$$

where z is the momentum fraction of the daughter parton in the frame where the mother parton's momentum is 1. In the model we keep only the last term of (1)

$$P(z) = 6z(1 z)$$
 (2)

so that it has no divergences at z = 0 and 1. The presence of those divergences is, of course, the source of complication for QCD that must be treated carefully.

We follow O dorico's procedure [9] to develop the algorithm for M onte C arlo sim – ulation of parton shower in QCD. Because of the soft gluon and collinear divergences m any partons are em itted at small z and small angles but are not resolvable. The probability that a parton at  $q^2 = Q^2$  can survive w ithout em itting a resolvable parton until  $q^2 = Q_0^2$  is the Sudakov form factor [9, 10]

$$(Q; Q_{0}^{2}) = \exp^{\left(\frac{Z_{0}^{2}}{Q_{0}^{2}} - \frac{dt^{0}}{t^{0}} - \frac{s(t^{0})}{2} - \frac{s(t^{0})}{z_{0}(t^{0})} -$$

where the lim its of the z integration de new hat is meant by resolvable. The rst step of the simulation is to set  $z_0 = Q_0^2 = Q^2$  and calculate from  $(Q^2; Q_0^2)$  whether a parton starting from  $Q^2$  evolves to  $Q_0^2$  without branching. If not, then the value of  $q^2$  at which the branching occurs is determined by solving

$$\frac{1}{1 - (Q^{-2}; Q_0^{-2})} = (q^{-2}; Q_0^{-2}) = R_{\#} ; \qquad (4)$$

where  $R_{\#}$  is a random number between 0 and 1. W ith that  $q^2$ , the value of z is then generated in accordance to the distribution P (z) given in (1) keeping only what is in the range  $Q_0^2 = q^2$  z 1  $Q_0^2 = q^2$ . W ith that z, the daughter partons are assigned the maximum virtualities  $t_1 = zq^2$  and  $t_2 = (1 - z)q^2$ , from which further evolutions are carried out by repeating the above procedure starting with  $t_1$  and  $t_2$ . W hen the virtuality of a descendant reaches  $q^2 - Q_0^2$ , then that branch of the tree term inates. We shall put  $Q_0 = 1$  GeV, to be denite. In the simulation we shall set N<sub>c</sub> = 3, N<sub>f</sub> = 0 so that

$$_{s}(q^{2}) = 4 = 11 \log(q^{2} = 2)$$
; (5)

where  $^2$  will be set at 250 M eV.

We have also tried to simulate the parton shower using the algorithm of Weber [10] and found that the result diers very little from that based on the above algorithm of O dorico [9] for the type of measures we calculate. Since O dorico's method is far more e cient, we have chosen to use it throughout this work.

model, because of no infrared and collinear divergences, there is no In the autom atic  $q^2$  evolution. However, in order to compare its properties with those of QCD, we introduce by hand  $Q^2$  dependence of the branching process by requiring that at each vertex the two daughter partons have virtualities  $zq^2$  and (1)  $z)q^2$ , when the mother virtuality is  $q^2$ , and z is generated by using (2) for 0 Ζ 1. As with QCD, we require branching to continue successively until the virtualities of  $Q_0^2$ . Since  $q^2$  is not degraded along a parton line, there are all partons becom e farm ore particles produced in the model than in QCD for the same  $Q^2$ , but that is immaterial, since our measure of chaoticity will not depend on  $Q = Q_0$ . Clearly, the dynamics of branching in the model is very dierent from QCD.We use it to exem plify the Abelian dynam ics that has no infrared and collinear divergences.

## 3 Tem poral Behaviors of Branching

Each branching process can be represented by a tree diagram, since recombination of partons is not considered. The vertices of the tree could be ordered vertically in accordance to the values of  $q^2$  of the m other partons. Then there are m any diagram s with the same topology that can describe di erent evolution processes leading to the same number of particles at the end, but belonging to di erent nal states. If we defer the considerations of the m om enta of the nal particles until the next section, we can simplify the problem by focusing on only the topology of the tree diagram. In that way we study the uctuation of the particle multiplicity at the expense of ignoring their m om enta. W hat is gained is the possibility of de ning a trajectory in the multiplicity space for a branching process.

In emphasizing the topology of a diagram let us draw all diagram s in such a way that all partons of the same generation are placed at the same level regardless of their q<sup>2</sup>. An example is shown in Fig. 1. W here the partons are horizontally has no signi cance in that diagram . Vertically, the branching points of the sam e generation are placed at the same level. All partons that reach the nal state (represented by the dashed line) have  $q^2 = Q_0^2$ . No information concerning  $q^2 > Q_0^2$  is carried by the vertical position of the lines in the diagram . Let i denote the generation, staring with i = 0 for the initial parton at  $q^2 = Q^2$ . Let  $b_i$  denote the number of branching points at the ith generation. In Fig.1 we have  $b_i = 1;2;3;3;1$  for i = 0;;4.We can de ne a vector  $b = (b_1; b_1;$ ) with as m any components as there are nonvanishing Bhus for the diagram in Fig. 1 we have b = (1;2;3;3;1). If this description were to be applied to an electron radiating photons, then a brem sstrahlung diagram would have ). On the other hand, for cell reproduction where every cell subdivides b = (1;1;1;)into two, then b = (1;2;4;8;). The description can be further simplied, if we de ne

$$\mathbf{x}_{i} = \log_{2} \mathbf{b}_{i} \tag{6}$$

and the corresponding vector  $x = (x_0; x_1; )$ . Since them inimum is 0 and them aximum  $x_i$  is i, the two extrem evectors are x = (0;0;0; ) which is like brem sstrahlung, and x = (0;1;2;3; ) which is like cell-reproduction. They are shown in Fig. 2 by the thick lines, where  $x_i$  is plotted against i. All possible tree diagrams of branching processes are represented by a line in between the two boundary (thick) lines, as illustrated by the thin line in Fig. 2. Such a line speci es a trajectory.

For nite Q<sup>2</sup> the branching cannot go without end, so there is always a maximum i, which we denote by  $i_{m\,ax}$ . The value of  $i_{m\,ax}$  varies from event to event, even if Q<sup>2</sup> is xed for all events. Two paths with the same  $i_{m\,ax}$  may dier for  $0 < i < i_{m\,ax}$ , and the total numbers of partons produced would be dierent. In general, for any two trajectories x and x<sup>0</sup> one can de ne  $d_i = jk_i \quad x_i^0 j$  at every i where  $x_i$  and  $x_i^0$  exist simultaneously. O by bubusly,  $d_i$  can be regarded as the distance between the two trajectories. Since two trajectories in x space can cross,  $d_i$  may vanish at nonzero i.

Since i is an integer,  $x_i$  has discrete values. Thus the trajectories cannot be dense in the continuum space of i and  $x_i$ , but for the discrete support of the trajectories we may regard the collection of all possible trajectories as being dense in the sense that a trajectory can pass through any allowed value of  $(i; x_i)$ .

To relate the description even more closely to the classical treatment of chaos, we now address the question of sensitivity to initial condition. In classical nonlinear dynamics one can specify the point in phase space where a trajectory begins and vary that point n in as small a neighborhood N. as one chooses. In non-Abelian gauge dynamics or in the model, the initial condition is that the initial parton has virtuality  $q^2 = Q^2$ . Being quantum mechanical, it is not necessary to vary  $q^2$  in a small neighborhood of  $Q^2$ . Quantum uctuation is su cient to guarantee that the nal state of the branching process will vary from event to event, even if all events start out at precisely the same  $Q^2$ . Thus the relationship to the classical consideration of initial condition is as follows. Consider N random points in the neighborhood N . of the initial point in phase space of a classical trajectory. Any such point can be mapped to the beginning of a particular branching process. A set of N events in the M onte Carb simulation all starting out at the same  $Q^2$  then correspond to N trajectories beginning in the neighborhood N, in the classical case. W ith this correspondence between the two problems it is then sensible to suggest that instead of studying the distance between two neighboring trajectories, one should consider all N events in the Monte Carlo simulation and examine the mean deviation from the average of the parton multiplicities. Indeed, the study of uctuations of observable quantities will be the main them e of our approach to analyzing chaotic behavior of branching processes.

In Fig. 3 we show schematically several possible trajectories of the branching processes, all started out at the same  $Q^2$ . Not only can trajectories that have the same  $\mathbf{i}_{max}$  be different, those with different  $\mathbf{i}_{max}$  are even more dissimilar. For the purpose of studying \temporal" behavior, which corresponds to the dependence on the generation i in the branching process, only trajectories with the same  $\mathbf{i}_{max}$  can be compared. Thus it is necessary to know the distribution P ( $\mathbf{i}_{max}$ ) of  $\mathbf{i}_{max}$  for all events. Fig. 4 shows the result of  $10^5$  simulations for each of the two type of branching processes discussed in the previous section. The initial virtualities are such that  $Q = Q_0 = 10^3$  for QCD and 15 for the model. These values are chosen so that the average multiplicities are comparable, as we shall show below. Both P ( $\mathbf{i}_{max}$ ) are G aussian-like distributions, with the width being larger for QCD. This is the rest indication of more uctuation for QCD as compared to the model. In choosing a narrow band of  $\mathbf{i}_{max}$  for further investigation, we select the shaded regions in Fig. 4 that are situated at the maximum of P ( $\mathbf{i}_{max}$ ).

A sm entioned before, time is not a well-de ned variable in the branching process. It is deem phasized when we focus on the topology of the tree diagram s. The generation label i carries only a rough notion of time, since it is well known, as in family genealogy, that a son can be younger than a grandson. However, there is one quantity that increases m onotonically with i; it is the parton multiplicity  $n_i$ 

$$n_{i} = 1 + \sum_{j=0}^{\dot{X}^{1}} b_{j} = 1 + \sum_{j=0}^{\dot{X}^{1}} 2^{x_{j}} ;$$
 (7)

even though  $x_i$  m ay rise and fall with i. D e ne the average parton multiplicity hn\_i at generation i by

$$hn_{i}i = \frac{1}{N} \sum_{e=1}^{X^{N}} n_{i}^{e}(i_{max})$$
; (8)

where  $n_i^e$  is the value of  $n_i$  at i for the eth event and the sum is over all N events having the same  $i_{max}$  chosen. This quantity  $hn_i i m ay$  be taken to play the role of time in the branching process, although no linear dependence is implied. In Fig. 5 we show the simulated results on  $hn_i i$  as functions of i for various values of  $Q = Q_0$ . In both types of branching processes  $hn_i i$  increases m onotonically with i, the rate being fastest at m idrange of i. The values of  $Q = Q_0$  are chosen such that  $hn_i i$  are roughly in the same range for the two types.

For the measure that describes the uctuation of the trajectories, and therefore of the multiplicities, we use the normalized variance

$$V_{i} = \frac{m_{i}^{2}i \quad m_{i}i^{2}}{m_{i}i^{2}} ; \qquad (9)$$

which clearly gives a measure of the average \distance" between trajectories. It is always positive, as a distance function should be. In Fig. 6 is shown the results of simulation for the two cases. The sustained increase in the lower half of i range for QCD is a distinctive feature that is not shared by the model.

A more transparent way of presenting this result is to plot  $V_i$  vs  $h_i$ i, as shown in F ig. 7. It corresponds to plotting the distance d(t) against t in the classical problem, except that here  $h_i$  is not exactly t, but some representation of it. Now, the behavior for QCD appears universal, i.e., independent of  $Q = Q_0$  over a wide range. In the log-log plot the behavior is approximately linear. The same is not true for the model:  $V_i$  increases initially, then drops precipitously, as  $h_i$  is increased. Furthermore, the maximum decreases with increasing  $Q = Q_0$ . Thus the uncertainty in the parton multiplicity increases with  $h_i$  in the form or case, but saturates and then decreases in the latter case. If that uncertainty can be regarded as a measure of chaos, then the QCD dynamics is chaotic, while the model is not. We can express the dependence of  $V_i$  on  $h_i$  i in the QCD case in the form of a power law

$$V_{i} / hn_{i}i$$
 : (10)

Then from Fig. 7 we nd to be ' 0:4. Writing (10) in the form of an exponential

$$V_i / \exp(\ln h n_i i)$$
; (11)

we may compare it to the denition of Lyapunov exponent in d(t)  $e^{t}$ . If  $\ln \ln_{i}i$  can be interpreted to correspond to t, then may be said to play the role of the Lyapunov exponent. However, nothing m can be proven about these correspondences, so the above remarks should only be taken as a possible orientation in interpreting the implication of the result obtained.

From what has so far been done, it is not possible for us to nd a criterion on the magnitude of to signify robust chaoticity. Furtherm ore,  $hn_i i$  and  $V_i$  are aspects of the parton state at generation i before the completion of the branching processes. Thus they are not experimentally measurable. For particle production in high energy collisions, the tem poral behavior of branching is primarily a theoretical problem. For experimental veri cation of any theoretical prediction, it is necessary to focus on the nal state, which is the subject of the next two sections.

# 4 Factorial M om ents, Entropy, and Information D im ension

In the nal state the complete information about the partons, now identied as observable particles, is registered by their momenta. If the branching trajectories never change, then there is certainty in where to nd those particles in the momentum space, and the entropy (to be de ned below) is zero, corresponding to no loss of information. However, quantum uctuation alone is su cient to cause uctuation in the nal-state momenta, so entropy is not expected to vanish. In multifractal analysis of complex patterns, the information dimension is a compact way of summarizing the dependence of the entropy on resolution scale [11]. Since multifractal analysis of the multiplicity uctuation in high-energy collisions has been proposed [12, 13] and carried out [14, 15], it is natural to exam ine the information dimension for the branching processes considered here

If  $p_j$  denotes the fraction of particles in an event that fall into the jth bin of size , then in the lim it of m any such bins in the system under study, the entropy is de ned by [13]

$$S = \sum_{j=1}^{X} p_{j} \ln p_{j} ; \qquad (12)$$

and the information dimension D $_1$  is [16]

$$D_1 = \lim_{i \to 0} S = \ln \quad : \tag{13}$$

The study of self-sim ilar behavior of particle production has been greatly facilitated by the use of norm alized factorialm on enta  $F_q$ , suggested by B ialas and Peschanski [17], who rst showed that the statistical uctuations are litered out by those moments. However, since  $F_q$  is de ned for integer q 2, it cannot be used to determ ine the

inform ation dimension, which involves the derivative of  $F_q$  with repect to q at q = 1. For that reason the  $G_q$  m on ents for all real q, positive and negative, were introduced for analyzing the multifractal structure of particle production data [12, 13, 15]. Their drawback is that the statistical uctuations must be taken out of  $G_q$  explicitly by hand. M ore recently, a method for continuing  $F_q$  to noninteger q, while maintaining its virtue of not being contaminated by statistical uctuations, has been developed [18]. We shall therefore make use of it to determ ine D<sub>1</sub>.

Before describing the details of the calculations, let us rst m ake clear the space in which the self-sim ilar behavior is exam ined. W ith  $z_i$  denoting the momentum fraction of an ith generation daughter parton at a branching vertex, where the mother parton has momentum 1, the momentum fraction of a nalparticle is then

$$\mathbf{x} = \bigvee_{i}^{\mathbf{Y}} z_{i} \quad : \tag{14}$$

where the product is taken over all generations of a particular path in the branching tree, leading from the initial parton to the nalparticle under consideration. Since all  $z_i$  are known in a simulated event, the values of x for all particles can be calculated; they are all crowded in the x = 0 region, since their sum is 1. This is especially true for QCD branching because of the soft gluon divergence in (1). If we expand the x = 0 region by using the variable  $= \log_{10} x$ , we get a broad G aussian-like distribution, as shown is F ig. 8, with the peak at = 3 corresponding to  $x = 10^{-3}$ . The situation is not as bad for the model, but still most particles are found in the sm all x region, as shown in F ig. 9. This highly uneven distribution of x is inappropriate for data analysis that involves the partition of the space into sm all bins.

One can de ne another variable X, in terms of which the distribution is much smoother [19]. Let the inclusive distribution in x, averaged over many events, be (x). Then the cumulative variable X is de ned by

$$X (x) = \int_{x_1}^{Z_x} (x^0) dx^0 = \int_{x_1}^{Z_{x_2}} (x^0) dx^0 ; \qquad (15)$$

where  $x_1$  and  $x_2$  are two extrem e points in the distribution (x), between which X varies from 0 to 1. In terms of X the inclusive distribution (X) is constant. For QCD branching we shall take ( $x^0$ ) to be the distribution as in Fig. 8; for the model ( $x^0$ ) will be just the x distribution as in Fig. 9. An illustration of the (X) distribution for QCD is shown is Fig. 10 after simulating 5 10<sup>4</sup> events at  $Q = Q_0 = 10^3$ . Note the expanded scale along the vertical axis.

Now, in X space we divide the interval 0 X 1 into M bins of width = 1=M. Let  $n_j$  be the number of nalparticles in the jth bin in any given event. The factorial m om ent of qth order is

$$f_q(M) = M^{-1} M_{j=1}^{M} n_j(n_j - 1) j(nq+1)$$
 : (16)

The norm alized factorialm om ent after averaging over all events is

$$F_{q} = hf_{q}i = hf_{1}i^{q} :$$
 (17)

Since  $hf_q i$  is the average of  $n_j \models (n_j q)!$  over all bins and over all events, we may write it as

$$hf_{q}i = \frac{\dot{x}}{n - q} \frac{n!}{(n - q)!} P_{n} \quad :$$
 (18)

where  $P_n$  is the multiplicity distribution in a bin. In general,  $P_n$  may be expressed as a convolution of the statistical (S) and the dynamical (D) contributions to the multiplicity uctuations:

$$P_n = S \quad D = \int_{0}^{Z_{1}} dt \frac{t^n}{n!} e^{t} D(t) ;$$
 (19)

where a Poissonian distribution has been used for S. Putting (19) into (18) yields

$$hf_{q}i = \int_{0}^{Z_{1}} dt t^{q} D(t) :$$
 (20)

This is the standard moment of the dynam ical distribution that has no statistical contam ination [17]. If D (t) = (t n), so that  $P_n$  is Poissonian, then  $hf_q i = n^q$  and  $F_q = 1$ . Any deviation of  $F_q$  from 1 is an indication of the presence of dynam ical uctuation.

Phenom enologically, one does not have access to D (t). Using  $P_n$  as input from experiment or from simulation, one can determ ine  $hf_q i$ , but only for integer q. One may replace the factorials in (18) by gamma functions in order to continue (18) to noninteger q [20]. But that procedure does not result in  $F_q = 1$  for Poisson distribution for all q. In Ref. [18] a continuation procedure is developed that guarantees  $F_q = 1$  for all q when D (t) is trivial. That method will not be described here, but will be used to determ ine  $F_q$  for our branching processes.

For notational brevity let us write the RHS of (20) as  $ht^q i_p$ . Then we have

$$F_{q} = h(t=hti_{D})^{q}i_{D} = h(pM)^{q}i_{D}$$
; (21)

where p is the fraction of event multiplicity in a bin, as in (12). Thus from (12) we get

$$S = M hp \ln pi_{D} = \ln M \quad \frac{d}{dq} \ln F_{q} \qquad (22)$$

If  $F_q$  has a power-law behavior near q = 1, i.e.,

$$F_{q} / M'^{q}$$
; (23)

it then follows from (13) that in the large M limit

$$D_1 = 1 \quad \frac{d'_q}{dq}_{q=1}$$
 : (24)

Note that this relationship is derived under the assumption that (22) is meaning-ful, which demands that  $F_q$  is well de ned in a range of q around q = 1 and that  $dF_q=dq$  contains only dynamical information without spurious contribution arising from improper continuation procedure [18].

If dynam ically the bin multiplicity is evenly distributed among all M bins so that D (t) = (t  $t_0$ ), then  $F_q = 1$  for all q (including non-integer q) and (22) gives S = lnM . On the other hand, if dynam ically only a fraction a of the M bins are populated, the rest empty, i.e.

$$D(t) = a(t + 1 a)(t);$$
 (25)

then  $hf_q i = at_1^q$  and  $F_q = a^1 q$  for all q. Hence, (22) yields S = ln (aM). If, in particular, only one bin is non-empty, i.e., a = 1-M, then S = 0. Thus (25) o ers a simple way of seeing how the entropy increases from 0 to lnM, as the fraction of non-empty bins increases from 1=M to 1. If there is only one non-empty bin, the dynam ics is like one with a classical trajectory that has no dispersion in where the particles are to be found in the momentum space. W ithout loss of information the entropy is zero. If there is maximum dispersion corresponding to all bins being equally likely to be populated, then the entropy is maximum.

We now apply thism ethod of analysis to our simulated branching processes. First, we show in Fig. 11 the multiplicity distributions in QCD for various bin sizes ( =1=M ) after  $10^5$  events. It should be understood that F ig. 10 shows the inclusive  ${\rm X}$ distribution after summing over all events. But event by event the uctuation in X space is much greater. Upon dividing the interval 0 Х 1 into M bins and counting the multiplicity in each bin, one then obtains  $P_n M$  ) after averaging over all the events. The degree of uctuation around the decreasing hi, relative to that average, as M is increased, is what is measured by the norm alized factorial m om ents  $F_{\alpha}$  de ned by (17) and (18). This is unlike our theoretical calculation based on (20) and (25) because D (t) is not known explicitly in the simulation. The results are shown in Fig. 12 for both QCD and model. Since  $F_{q=1} = 1$  by de nition, we see that  $F_q$ increases with q in QCD, but decreases with increasing q in the model. It means that the distributions  $P_n(M)$  for QCD are wider than Poisson, but for the model they are sub-Poissonian. Fig. 12 also shows that there is very little M dependence in either case. For non-integer q values a substantial amount of work is needed to continue  $F_q$  according to the method of [18]. The result is shown in Fig. 13. It is clear that for q > 1 all  $F_q$  are greater in QCD than in the model. It corresponds to more uctuations in QCD than in the model, a result that is consistent with the nding of the previous section.

It is also evident from Fig. 13 that  $dF_q = dqj_{r=1}$  is essentially independent of M in both cases. W hereas S is still dependent on M according to (22), the M independence of  $dlnF_q = dqj_{r=1}$  requires, on account of (23), that  $d'_q = dqj_{r=1} = 0$ . This together with (24) entails

$$D_1 = 1$$
 (26)

in both cases. Thus there is no interesting multifractal property. This particular approach to nding a useful signature of chaotic behavior ends in failure.

The sm oothing of the phase space by use of the X variable in place of the momentum fraction variable x has undoubtedly contributed to eliminating some aspect of the fractal structure. But what has not been removed is the more interesting consequences of the dynamics. The triviality of  $D_1$  states only that there is no nontrivial self-similarity in the uctuations measured. The latter are quantiled by  $F_q$ , which involves both the bin and event averages of the factorial product in (16). The result suggests that some of the uctuations have been lost by the averaging process. In the next section we develop a scheme to recapture that which has been lost.

#### 5 Entropy Index

We know that event by event there are large uctuations in where the produced particles are in the X space. W hat we want to do now is to nd a way to register the uctuation (from event to event) of the uctuation (in the X distribution).

Let  $F_q^e$  denote the norm alized factorialm on ent of the eth event:

$$F_{q}^{e} = f_{q}^{e} = (f_{1}^{e})^{q}$$
; (27)

where  $f_q^e$  is as de ned in (16) for the eth event. C learly,  $F_q^e$  changes with e for xed q and M. In Fig. 14 we show the distribution P ( $F_q$ ) after 10<sup>5</sup> simulated events of QCD branching, the labele being om itted. For clarity, only q = 2 and 3 are exhibited for a wide range of M values. At small M the distribution has a peak at  $F_q$  1. Indeed, if M = 1 and event multiplicity is large, then  $F_q$  should be very nearly 1 for all events. At large M a peak at  $F_q = 0$  is developed, especially at high q, because the bin multiplicity for small is small and may in many events be less than q for all bins, in which cases  $F_q^e = 0$ . This large over all events. C learly we should take the moments of  $F_q$  before performing the average.

W e m ay think of  $F_q^e$  as the horizontal m on ents in the X space, and then de ne the vertical m on ents in the event space as follows:

$${}^{D}{}^{E}{}^{P}{}^{q}{}^{e}{} = \frac{1}{N} {}^{X^{N}}{}_{e=1} F^{e}{}^{p}{}^{p}{};$$
(28)

where N is the total number of events and p is a positive real number not restricted to integers. The norm alized m on ents of m on ents are

$$C_{pq}(M) = F_{q}^{p}(M) = hF_{q}(M) i^{p} :$$
(29)

If  $C_{pq} \, (\!\!M$  ) has a power-law behavior in M , i.e.,

$$C_{p,q}(M) / M^{q(p)};$$
 (30)

then we can de ne

$$q = \frac{d}{dp} q(p) \dot{p}_{=1} :$$
(31)

which will be referred to as the entropy index.

To see the connection between  $\ _{\rm q}$  and entropy, let us de ne

$$P_{q}^{e} = F_{q}^{e} = \prod_{e=1}^{N} F_{q}^{e}$$
(32)

and a (new) entropy in the event space

$$S_{q} = \sum_{e=1}^{X^{N}} P_{q}^{e} \ln P_{q}^{e}$$
 : (33)

Furtherm ore, de ne the mom ents

$$H_{p,q} = \sum_{e=1}^{X^{N}} (P_{q}^{e})^{p} ;$$
 (34)

which are related to  ${\rm S}_{\rm q}$  by

$$S_{q} = \frac{d}{dp} \ln H_{p,q} j_{p=1} : \qquad (35)$$

On the other hand, H  $_{pq}$  can be related to C  $_{pq}$  by

$$C_{pq} = N^{p-1} H_{pq} ; \qquad (36)$$

so we have

$$\frac{d}{dp} \ln C_{p,q} \dot{p}_{=1} = \ln N \qquad S_q \qquad (37)$$

In then follows from (30) and (31) that

$$S_q = \ln (N M q)$$
; (38)

apart from a possible additive term that is independent of N and M .

This entropy, as de ned in (33), is clearly di erent from the entropy S de ned in (12). To emphasize that  $S_q$  is de ned in the event space, we may call it eventropy. We can think of the event space as a one dimensional space with N sites. At each site we can register a number  $F_q^e$ . If  $F_q^e$  is the same at each site, then  $P_q^e = 1=N$ , and  $S_q = \ln N$ . We should think of this as being highly disordered in the event space, since  $F_q^e$  is spread out uniform ly over all space. The larger the number of events, the larger is the eventropy. This is very sim ilar to the situation where  $S = \ln M$ , when the bin multiplicity is uniform ly distributed in the X space that has M bins. A branching dynam ic that results in the same  $F_q^e$  for every event does not uctuate in the branching processes. It corresponds to nearby trajectories staying nearby throughout. In short, the dynam ics is not chaotic. For  $S_q$  to be lnN, we see from (38) that  $_q$  must vanish. Thus sm all  $_q$  corresponds to large eventropy, which in turn in plies no chaotic behavior.

On the other hand, if we consider the other extrem e where all  $F_q^e$  are zero except one event  $e^0$ , then  $P_q^e = _{ee^0}$  and  $S_q = 0$ . This is highly ordered in the event space, but the uctuation of  $F_q^e$  from zero to a nonzero value is large. Generally speaking, if the distribution P ( $F_q$ ) is broad, the uctuation is large, initially nearby trajectories become widely separated in the nal states of dierent events, and the dynamics is chaotic. In order for the eventropy to be small,  $_q$  must be large. Thus large entropy index in plies chaotic behavior.

In Fig. 15 the results of our simulation are shown for q = 2, 3, 4 and p = 0.5, 1.0, 1.5, and 2.0. From the log-log plots one can identify approximate scaling behavior. We used the region M = 5 20 to determ ine the value of  $_{p}$ , for which  $C_{pq}$  for an incremental region of p around p = 1 has to be examined. We obtain

$$q^{(QCD)} = 0.0061; 0.054; 0.23 (q = 2;3;4);$$
  
 $q^{()} = 0.0014; 0.010; 0.046 (q = 2;3;4):$ 

This result is plotted in Fig. 16. Clearly,  ${}_{q}^{(QCD)}$  is much larger than  ${}_{q}^{()}$ . It is suggestive that the QCD dynamics is chaotic, while the model is not. However, at this point we have no quantitative criterion on how large  ${}_{q}$  must be in order to be chaotic. In classical nonlinear problems there is also no criterion on how long the time lapse must be in order for the distance between nearby trajectories to become su ciently far apart to qualify for divergent behavior. Nevertheless, the positivity of the Lyapunov exponent is a simple condition, the counterpart of which for the entropy index is lacking.

### 6 Conclusion

We have explored various ways of measuring chaoticity of branching processes. Because the problem is far more complicated than a classical nonlinear problem, the search has not been a straightforward extension of the conventional ideas. Our approach has been based on a simple premise: if a branching process is chaotic, then it should be hard to predict what the likely outcome of an event would be, given the know ledge of the result of a previous event. It means that there are large uctuations from event to event.

To be more concrete, we have focused rst on the tem poral developm ent of branching. The variance  $V_i$  of the multiplicities at a particular generation i can be regarded as a measure of the mean distance between \trajectories". We have found that  $V_i$  increases with  $hn_i i$  in a power-law fashion for QCD branching, but not for the model, an example of A belian branching dynam ics. That is the rst indication that the QCD dynam ics has the characteristics of being chaotic. We have not investigated the behavior of the higher moments,  $V_i$  being related to only the second moment. It is probably safe to predict that the higher moments would increase even more rapidly with  $hn_i i$ .

For uctuations in the nal state where experimental observations are feasible, we have considered  $F_q$ ,  $D_1$ ,  $C_{pq}$ , and  $_q$  as possible measures of chaoticity. It turns out that the information dimension is not elective, but the entropy index can be. W hat emerges is a realization that one should study the phase space and the event space simultaneously. More specifically, consider a two-dimensional lattice, where the horizontalaxishas M sites, corresponding to the M bins in the X space, and where the vertical axis has N sites, corresponding to the N events in the event space. For every event there is a horizontal array of M numbers, indicating the particle multiplicities in the M bins. The moments of moments  $C_{pq}$  summarize the distribution on this whole lattice without significant loss of information. The entropy index  $_q$  extracts from this lattice of numbers a simple numerical quantity that can characterize the degree of uctuations on the lattice. The larger  $_q$  is, the more chaotic the system is. Unfortunately, we do not have at this point a criterion on the threshold value of  $_q$ , above which chaotic behavior will de nitely occur. Further investigation on this aspect of the problem is undoubtedly warranted.

Each of the features studied reveals some aspect of the chaotic behavior of QCD dynam ics. Taken together collectively, they present a strong contrast from the results of the model. One may wonder what the mechanism s are in the branching processes that can lead to such diverse outcomes. Our view is that in QCD branching there is a tension between two opposing forces that is absent in the model. The collinear divergence in plies a strong preference for small angle emission of partons in the branching process. But if the emission angle is too small to be resolved, there is no branching. Since evolution without branching is suppressed by the Sudakov form factor, there is a competition between evolution by emitting a resolvable gluon and a preference for emitting a collinear unresolvable gluon. It is this tension that leads to large uctuations in the number of branching points and hence to chaotic behavior. The model has no collinear divergence and no q<sup>2</sup> evolution, so there is no tension to cause large uctuations. W hat we learn here may lay the foundation for noting ways

to treat nonperturbative processes, for which chaotic behavior m ay play a crucial role in the evolution of a large system of quarks and gluons, such as those produced in a heavy-ion collision at high energy.
