Abstract

We present some generic arguments demonstrating that an elective Lagrangian L_{eff} which, by de nition, contains operators 0^n of arbitrary dimensionality in general is not convergent, but rather an asymptotic series. It means that the behavior of the far distant term s has a speci c factorial dependence $L_{eff} = \frac{c_n O^n}{m}$; $c_n = n!$; n = 1.

We discuss a few apparently dierent problems, which however have something in common { the aforem entioned n ! behavior:

1 E ective long -distance theory describing the collective elds in QCD;

2 E ective Berry phase potential which is obtained by integrating over the fast degrees of freedom . As is known, the Berry potential is associated with induced local gauge symmetry and might be relevant for the compactication problem at the Planck scale.

3 N on local Lagrangians introduced by G eorgi[1] for appropriate treatm ent of the elective eld theories without power expanding.

4.The so-called improved action in lattice eld theory where the new, higher dimensional operators have been introduced into the theory in order to reduce the lattice artifacts.

 $5 \,\mathrm{C} \,\mathrm{osm}$ ological constant problem and vacuum expectation values in gravity.

W e discuss som e applications of this, seem ingly pure academ ic phenom enon, to various physical problem s with typical energies from 1G eV to the P lank scale.

¹ e-m ail address arz@ physics.ubc.ca

1 Introduction

Today it is widely believed that all of our present realistic eld theories are actually not fundam ental, but e ective theories. The standard model is presum ably what we get when we integrate out modes of very high energy from som e unknown theory, and like any other e ective eld theory, its lagrangian density contains term s of arbitrary dimensionality, though the term s in the Lagrangian density with dimensionality greater than four are suppressed by negative powers of a very large mass M. Even in QCD, for the calculation of processes at a few G eV we would use an elective eld theory with heavier quarks integrated out, and such an elective theory necessarily involves term s in the Lagrangian of unlimited dimensionality.

The basic idea behind e ective eld theories is that a physical process at energy E M can be described in terms of an expansion in E = M, see recent reviews [2], [3], [4]. In this case we can limit ourself by considering only a few rst leading terms and neglect the rest. In this paper we discuss not this standard formulation of the problems, but rather, we are interested in the behavior of the coe cients of the very high dimensional operators in the expansion. We shall demonstrate that these coe cients c_n grow as fast as a factorial n! for su ciently large n. Thus, the series under discussion is not a convergent, but an asymptotic one. Such a behavior rases problems both of fundamental nature, concerning the status of the expansion and of practical importance, as to whether divergences can be associated with new physical phenomena. It means, rst of all, that in order to make sense, such a theory should be dened by some speci c prescription, for example, by Borel transformation.

Let us note, that our rem ark about the factorial dependence of the series for large n 1 is an absolutely irrelevant issue for the analysis of standard problem s when we are interested in the low energy limit only. We have nothing new to say about these issues.

However, som etim es we need to know the behavior of whole series when the distant term s in the series m ight be important. In this case the analysis of the large order term s in the expansion has som e physical meaning.

Such a situation m ay occur in a variety of di erent problem s as will be discussed in a more detail later in the text. Now let us mention that in general it occurs when the energy scale E is close to M or/and when two or more interm ediate, not well separated scales, com e into the gam e[1].

This letter is organized in the following way. In the next section we argue, by analyzing a couple of examples, that the factorial behavior of the coe - cients in front of the high dimensional operators, is a very general property of e ective eld theories².

² The generality of this phenom enon can be compared with the well known property of the large order behavior in perturbative series [5]. As is known a variety of di erent eld theories (gauge theories, in particular) exhibits a factorial grow the of the coe cients in the

In the last section we discuss some possible applications of the obtained results to dierent eld theories with very dierent scales (from QCD problem s to the cosm ological constant problem).

2 Basic Exam ples.

2.1 Main Idea.

We begin our analysis with the following remark. An elective eld theory can be considered as an particular case of the more general idea of the Wilson operator product expansion (OPE). It has been demonstrated recently [6], that the OPE for some speci c correlation functions (heavy-light quark system Qq) in QCD is anasymptotic, and not a convergent series. The general arguments of the paper[6] have been explicitly tested in QCD₂ (where the vacuum structure as well as the spectrum of the theory is known) with the same conclusion concerning the asymptotic nature of OPE [7]. In both cases the arguments were based on the dispersion relations and the general properties of the spectrum of the theory. However, the experience with large order behavior in perturbative series[5] teaches us that the factorial grow th of the coe cients is of very general nature and it is not speci c property of som e G reen functions.

Thus, we expect that the asymptotic nature of the OPE has a much more general origin and it is not related to the speci c correlation functions, for which it was found for the rst time [6].

To be more speci c and in order to explain what is going on with the e ective theory when we integrate out the heavy degrees of freedom, let us consider QED with one heavy electron of mass M. The e ective eld theory for photons can be obtained by integrating out the ferm ion degrees of freedom. The most general solution of this problem is not known, however in the case of a speci c (constant) external electric eld E the corresponding expression for L_{eff} is known (see. e.g. the textbook [8]). In order to nd the OPE coe cients for the high dimensional operators Eⁿ one can expand L_{eff} in power of E:

$$L_{eff} = M_{n}^{4} C_{n} \left(\frac{E}{M^{2}}\right)^{n} :$$
 (1)

Of course, the eq.(1) is not the most general form, because it does not contain all possible operators, in particular those operators which would contain some terms with derivatives @E..Our goalnow is to demonstrate

perturbative expansion with respect to coupling constant. This growth in perturbative expansion is very di erent from the phenom enon we are discussing, where the factorial behavior is related to high dim ensional operators, and not to coupling constant expansion. However, in spite of the apparent di erence of these phenom ena, actually they have som e com m on general origin. W e shall discuss this connection later.

that we do have a factorial behavior already in this simple case where we select only some specic class of operators, namely those E^n .

Our next step is as follows. First of all we shall nd an exact form ula for the n dependence of the coe cients c_n ; secondly, we give a qualitative explanation of why such a factorial behavior takes place. Our argum entation will be so general in form that it will be perfectly clear that this phenom enon is very universal in nature.

The elective Lagrangian for the problem can be written in the following way [8]:

$$L_{eff} = \frac{1}{8^{-2}} \int_{0}^{Z_{-1}} \frac{ds}{s^{2}} \mathbb{E} \operatorname{cth}(\mathbb{E} s) = \frac{1}{s} \mathbb{e}^{-isM^{2}}; \qquad (2)$$

where we denote the external eld E together with its coupling constant e. W e expand this expression in E using the formula

$$\frac{1}{e^{x}} = \frac{1}{k} B_{k} \frac{x^{k-1}}{k!}$$
(3)

where B_k are Bernoulli numbers. For large k these numbers as is known exhibit factorial growth:

$$B_{2n} = 2(1)^{n+1}(2n)! \prod_{r=1}^{N} \frac{1}{(2 r)^{2n}} = 2(1)^{n+1}(2n)! \frac{1}{(2 r)^{2n}}; n 1: (4)$$

Thus, the coe cients c_n in the OPE (1) are factorially divergent for large n:

$$c_{2n} = \frac{1}{8^{-2}} 2^{2n} B_{2n} \frac{(2n-3)!}{(2n)!} \qquad (2n)!:$$
 (5)

In particular, for n = 2 this formula reproduces the well-known Euler-Heisenberg E ective lagrangian L_{EH} , which is nothing but the rst nontrivial term in the series (1):

$$L_{EH} = \frac{2}{45M^4} \left(\frac{e^2}{4}\right)^2 E^4;$$
 (6)

We have rede ned the coupling constant e in this expression to present the formula in a standard way.

Now, how one can understand this factorial behavior (5) in simple term s? We suggest the following almost trivial explanation which however is a very universal in nature.

Let us look at the function $L_{eff}(z)(1)$ as an analytical function of the complex variable $z = E = M^2$ for which the standard dispersion relations hold. The factorial growth of the coe cients in the real part of $L_{eff}(z)$ implies that the corresponding in aginary part has a very speci c behavior $Im L_{eff}(z) = e^{1-z}$ which follows from the dispersion relations:

$$f(z) = \int_{n}^{X} f_{n} z^{n} f_{n} (a)^{n} n! = \frac{dz^{0}}{(z^{0})^{n+2}} \operatorname{Im} f(z^{0}) ! \operatorname{Im} f(z^{0}) e^{\frac{a}{z^{0}}} (7)$$

Here we have introduced an arbitrary analytical function f(z) to be more general.

At the same time, an imaginary part of the amplitude, as is known, is related to to a realphysical process: the pair-creation in the strong external eld. We have fairly good physical intuition of what kind of dependence on the eld one could expect for such a physical process. Namely, as we shall discuss later, this process can be thought as a penetration through a potential barrier in the quasi-classical approximation. So, from a physical point of view we would expect that the E dependence should have the following form $Im L_{eff}(E) = e^{1=E}$. As we shall see this is exactly the case for our QED example (1) and in a full agreement with what the dispersion relations (7) tell us.

Now, we would like to present the explicit form ula for the probability of pair creation in the constant electric eld E. It is given by (see e.g.[8]):

$$w = \frac{1}{4^{2}} \int_{0}^{2} \frac{ds}{s^{2}} \mathbb{E} \operatorname{cth}(\mathbb{E} s) = \frac{1}{s} \operatorname{Im} (e^{-isM^{2}}): \qquad (8)$$

The \only" di erence with the form ula (2) is the replacement $Re(e^{-isM^2})$) Im (e^{-isM^2}) . However, this replacement completely modiles the analytical structure. Indeed, the explicit calculation of the coe-cients in the power expansion for in aginary part in the form ula (8) leads to the following integrals which are zero R^2 dz sin (z) z^{2n-3} sin [(n 1)] = 0. Thus, the in aginary part is not expandable at E = 0 in agreement with our arguments about a singular behavior at this point $e^{1=E}$.

Fortunately, a direct calculation³, without using an expansion in power of E can easily be performed with the following nal result, explicitly demonstrating the e 1^{-z} structure (see e.g.[8]):

$$w = \frac{E^{2} {nX^{-1}}}{4^{-3}} \frac{1}{n^{2}} \exp\left(-\frac{nM^{2}}{E}\right)$$
(9)

A few comments are in order. First, the behavior $w(z) = e^{1-z}$ is exactly what we expected. It can be interpreted as penetration through a potential barrier in the quasi-classical approximation. Indeed, the standard formula for the ionization of a state with bound energy V 2M and external eld E is proportional to

exp (
$$2 dx \frac{q}{2M} (V E x)$$
 exp ($\frac{const M^2}{E}$)

which qualitatively explains the exact result (9).

W e are not pretending here to have derived new result in QED. All these classical form ulae have been well known for a many years. Rather, we wanted

 $^{^3{\}rm T}\,h$ is integral can be reduced, in according to C auchy theorem , to the calculation of the contributions from the poles of the cthz function.

to explain, by analyzing this QED example, the main source of the n!dependence in the E ective lagrangian. The E ective lagrangian, by de nition, is a series of operators of arbitrary dimensions constructed from the light elds E. This is presumably obtained from some underlying eld theory by integrating out the heavy elds of mass M. It is perfectly clear that the probability of the physical creation of the heavy particles with mass M in external eld E is strongly suppressed exp($\frac{1}{E}$). The dispersion relations thus unam biguously im ply that the coe cients in the real part of the e ective lagrangian are factorialy large.

We believe that this simple explanation is so universal in form that it can be applied to almost arbitrary nontrivial eective eld theories leading to the same conclusion about factorial behavior. We shall consider another explanation of the same phenom enon later in the text, but now we would like to note that the relation between in aginary and real parts of the amplitudes of course is well known, and heavily used in particle physics. In particular, the recent analysis of the n! behavior in the perturbative $\frac{n}{s}$ expansion shows [9], that the physical multiparticle cross section (the imaginary part) is exponentially sm all. This important result is a simple consequence of dispersion relations sim ilar to eq.(7).

W e would like to com e back to form ula (5) to explain this factorial behavior in the OPE one more time from an absolutely independent point of view. A gain, we use QED as an example to demonstrate an idea, however, as we shall see, the arguments which follow are much more general and universal in nature.

As is known, alm ost all nontrivial eld theories exhibit factorial grow th of $\cos c$ eients in the perturbative expansion with respect to coupling constant $[5]^4$. This factorial dependence can be understood as the rapid grow th of the number of Feynm an graphs⁵.

Now, how one can understand the nature of the W ilson OPE in terms of the Feynm an graphs? As is known the computational recipe of the coe cients in the OPE is simple: it is necessary to separate large and small distance physics. Large distance physics is presented by operators of light elds; the small distance contribution is explicitly calculated from the underlying eld theory. Technically, in order to carry out this program, we cut the perturbative graphs in all possible ways over the photon lines (in general case, a photon eld will be replaced by som e light degrees of freedom). These lines present the external light elds. They are combined together in the speci c way to organize all possible operators. The coe cients in front of these operators can be explicitly calculated and they are determined by

 $^{^{4}}$ D o not confuse this perturbative expansion with OPE and E ective lagrangian we are dealing with. These series are very di erent in nature, but they both exhibit an factorial growth.

⁵ Here we do not discuss the so-called renorm alons which give the sam e factorial dependence, but have a very di erent origin.

the small distance physics.

From this technical explanation of the calculation of the coe cients in the W ilson OPE it should be clear, that if the underlying theory possesses factorial grow th in the perturbative expansion, the E ective lagrangian constructed from this theory exhibits the same factorial behavior for the high dim ensional operators. The moral of this argument is very simple: the factorial grow th of the perturbative expansion in the underlying theory can not disappear without trace. It will show up in the coe cients of the high dimensional operators in the E ective lagrangian obtained from the underlying theory.

Having demonstrated the main result on factorial growth of the coe - cients (in an E ective lagrangian) as universal phenomenon, we would like to discuss a few more examples.

2.2 Nonlocal Lagrangian.

The main goal of this section is the demonstration of the fact that in general the so-called nonlocal lagrangians [10],[1] exhibit the same feature we have been discussing in the previous section. Namely, irrespective of the \sm earing " prescription of the nonlocal part of interaction, the corresponding E ective action, obtained in the standard way, will exhibit the factorial growing coe cients for the high dimensional operators.

Before going into details, let us recall a few general results concerning nonlocal lagrangians. First of all, we refer to the old review paper [10] on this subject regarding the motivations. The recent interest on this subject was renewed in ref.[1] where it was advocated that such a lagrangians is the useful tool to deal with a physical situation in which the scales are not well separated. Anyhow, our main interest at the moment is not a physical application, but rather, the demonstration of some universal property for such kind of system. The next relevant remark concerning a nonlocal lagrangian is as follows: the nonlocal, lowest dimensional coupling constant (let us say, quartic) in general case can induce some changes in the coupling term s with larger number of elds (let say, six eight,..). Thus, we are forced to consider an elective Lagrangian with operators with an arbitrary number of low energy elds. To be more speci c, we shall consider the following elective lagrangian for the scalar eld discussed in ref.[1]:

$$L_{int} = \int_{r=1}^{X^{1}} G_{2r}^{2r}$$
(10)

Here, G_{2r} are some nonlocal functions which are analytical in the region of de nition, depend as a consequence of momentum conservation on 2r = 1 linearly independent momenta, and may have dimensions proportional to some power of an implicit scale of nonlocality . We assume in what follows that the nonlocal couplings in the bare action (10) are of order of one (we

m can by this that there is no strong dependence on r, like r! or so); we shall demonstrate in this case that the interactions will give the factorial growing coe cients for the high dimensional operators in the corresponding E ective lagrangian obtained from (10).

We start our analysis from the well understood ⁴ interaction. The issue of whether the interaction is local or nonlocal is not relevant for the analysis of the large order behavior in E ective theory. As we have discussed in the previous section, in order to calculate the coe cients for the high dimensional operators, we have to: a) calculate the number of graphs for the given order n, b). cut the internal lines to organize the operators of the maximal dimensions. For ⁴ theory, it is well known [11], [5], that the large order behavior of perturbative series is n!. When we cut lines in order to produce the external operators, each cut gives two external ² elds. Thus, we get operator ²ⁿ in the corresponding E ective lagrangian with coe cient n! in front of it (or, what is the same, we expect the following behavior for the n them $L_{eff}^{(n)}$ in the ective Lagrangian $L_{eff}^{(n)}$ $\frac{n}{2}$)! ⁿ).

We would like to generalize this result for the bare action with arbitrary dimensions (10). In the course of these calculations we shall reproduce the $\left(\frac{n}{2}\right)$! behavior mentioned above. We shall demonstrate also that the essential result will not be changed with the increasing of dimensions of the vertices r (10) provided that n r. The last condition is required for the method to be applicable.

Let us rem ind that the Lipatov's idea [11],[5] of the calculation of large order behavior in a eld theory is to present the coe cients Z_k in the perturbative expansion $Z(g) = {}^{P} Z_k g^k$ through a contour integral in the com plex g plane:

$$Z_{k} \qquad D \qquad \frac{dg}{q^{k+1}} e^{-S(\cdot)}; \qquad (11)$$

where S () is the action of the scalar eld theory $\frac{g}{4}$ ⁴ and D is the standard measure for the functional integral which denes the theory (W e discuss here the perturbative expansion for the G rand Partition Function Z (g). An arbitrary correlation function can be considered in an analogous way.). If the theory possesses the classical instanton solution, then the calculation of the integral over g can be done through steepest descent method. This method is justiled only for small g. But for the large order k, the integral over g is dominated by the small g contribution. Indeed, in our specil c case of ⁴ eld theory the classical instanton solution has the following property $_{cl}$ $1 = \frac{p}{g}$, [11]. This can be seen from the saddle point equations for $_{q_0}(k)$ and $_{cl}(k)$ (the actual equations are dimensional equations, of course,

 $g_0(k)$ and $c_1(k)$ (the actual equations are dimensional equations, of course, but we are keeping the track only on external parameter k, disregarding all complications related to the coordinate x dependence):

$$\frac{k}{g_0} + \frac{\frac{4}{cl}}{4} = 0; \qquad c_l + g_0 \quad \frac{3}{c_l} = 0; =)$$
(12)

$$_{\text{cl}} \frac{1}{p_{\overline{q_0}}} \stackrel{p_{\overline{k}}}{\longrightarrow} g_0 \frac{1}{k}; S_{\text{cl}} \stackrel{2}{\underset{\text{cl}}{\longrightarrow}} \frac{1}{q_0} k:$$

From these equations it is clearly seen that the classical action $S_{\rm cl}$ 1=q₀ k is param etrically large for the large external param eter k. Thus, the sem iclassical approximation is completely justied.

The generalization of these formulae for the more complicated action ^{2r} is straightforward: Instead of (12) we have the following behavior:

$$p_{cl} = \frac{p_{r}}{kr}; g_0 = \frac{1}{k^{r-1}}; S_{cl} = \frac{2}{cl} k:$$
 (13)

Thus, the method is applicable for the large k and for any nite number r, where the classical action is large and the coupling constant is sm all. From these form use one can calculate the the large order behavior in perturbative q^{2r} . The result is q^k (rk k)!. This growth is series with bare action much faster than we found previously for 4 theory with r = 2. However, the coe cients in the E ective lagrangian for the operator ⁿ grow in the same $\frac{n}{2}$)!. The technical explanation for that is simple: when we way as before cut the lines in order to produce an external operator, the dimension of the obtained operator $2^{k(r-1)}$ would be higher than for ⁴ theory. Thus, for the operator " the coe cients in E ective lagrangian have the sam e grow th

 $\frac{n}{5}$)! as we already mentioned.

It would be interesting to understand this result in som ewhat di erent way. Essentially, what we need to calculate is the number of graphs which contribute to the n point correlation function $Z^{(n)}$ h (x_1) (x_2) ::: (x_n) i. Such a calculation can be done within the same Lipatov's technique. The only technical di erence in comparison with the calculation of the large order behavior for the G rand Partition Function Z (g) itself is following: We have to substitute in the rst approximation the classical solution _{cl} in place of the external elds. M ore precisely,

$$Z^{(n)} = D = \frac{dg}{g} (x_1) (x_2) \dots (x_n) e^{S(1)}$$
 (14)

^Z D
$$\frac{\mathrm{d}g}{\mathrm{g}} \mathrm{e}^{\mathrm{s}(_{\mathrm{cl}})} \operatorname{_{cl}}(\mathrm{x}_1) \operatorname{_{cl}}(\mathrm{x}_2) ::: \operatorname{_{cl}}(\mathrm{x}_n) (\overline{n})^n (\overline{n})^n (\overline{2})!$$

In this formula we took into account that the classical eld depends on n \overline{n} , (13) and the total number of external elds in the correlation as _{cl} function is equal n. The sem iclassical approximation we have used in the derivation (14) is justilled as far as number $(\frac{n}{2})$ 1. Only in this case the integral over g is dom inated by the small g contribution and instanton calculus can be applied.

The factorial dependence (14) can be interpreted as the rapid growth of the number of Feynm an graphs. A swe see the dependence on n remains the

same irrespectively to the form of the bare vortices provided that n r.This is in agreem ent with what we discussed before and related to the fact that the essential part of classical solution cl n remains the same for arbitrary r. Such a behavior suggests that all terms from the bare action give more or less the same contributions to the coe cients in the E ective theory. To obtain the total number of graphs with contribute to the operator n we should sum up all term s com ing from all possible vertices r n. It gives essentially the same (n=2)! behavior because $\prod_{r=2}^{P} c_r r^{n=2}$ (n=2)! (n=2)! n 1. $W \in do$ not expect any special cancellations between di erent term swhich m ay kill this growth. The contribution from the higher order operators r' n can not be estimated in the same way, but one could expect that the growth of the coe cients could be even m ore severe in this case.

The moral is: W e certainly have a divergent series for E ective Lagrangian induced by som e unknown full theory no matter what the starting point is. W e shall discuss som e applications of this result in the conclusion.

2.3 A few more examples

In this subsection we are going to discuss a few more examples from very di erent elds of physics:

- a).Collective elds in QCD;
- b). Berry phase as a dynamical eld in com pacti cation problem;
- c). Lattice eld theories.
- d)G ravity at Plank scale.

We shall dem onstrate that the phenom enon of the asymptotic nature of an E ective lagrangian is a very universal one. This universality is the comm on feature which characterizes these so dierent elds of physics we mentioned above. a). We start from the QCD, as underlying theory. The problem in this case can be formulated in the following way (see recent paper [12] on this subject and refences therein). How one can integrate over sm all distance physics in order to extract the long-distance dynam ics? An appropriate way to implement this program m is: a). introduce the collective degrees of freedom, colorless m esons, as the external sources into the underlying lagrangian; b) integrate over the quarks and gluons with high frequencies by introducing the normalization point . The obtained E ective lagrangian is the 1= expansion where operators are expressed in terms of the external elds as well as low energetic quarks and gluons. Our remark is: the coe cients in this expansion grow factorially with the dimension of the operators. We postpone the discussion of the physical meaning of this result to the Conclusion. Let us note, that the procedure of obtaining the E ective lagrangian in this case is not much di erent from the case we discussed previously. The only new element is the introduction of the collective elds which were not present in our original lagrangian. However, this does not e ect the general argum ents on the n! behavior.

Indeed, one can consider the quark-antiquark external lines (instead of the collective meson elds) for the calculation of the coe cients in the OPE, as discussed in the previous section. In this case, all arguments on n!behavior can be applied in a straightforward way. Thus, we expect a factorial behavior of the coe cients for the E ective QCD lagrangian, as well as for the chiral lagrangian, as its particular case. An exact formula for the coe cients depends on the operator under consideration. This is because the dierent elds (gluons, quarks, mesons), which are constituents of the operator are not equally weighted. However the precise expression for the coe cients in terms of constituents of these operators is not a relevant issue at the moment. We shall discuss consequences of this result in the Conclusion.

b). We continue our short review of di erent models by analyzing the so-called Berry phase as a dynamical gauge eld[13]. There are a few applications of this idea. We consider only one of them. As is known, the standard philosophy of compactication at the Plank scale is the assumption of a very high gauge invariance at this scale which will be broken at lower scales. It is quite possible that some of gauge symmetries are dynamically induced rather than a required principle. We refer to the recent paper [14] on this subject for details and references. Here we would like to demonstrate that the E ective lagrangian for the induced dynamical Berry eld is not a convergent, but an asymptotic series. As usual, the E ective lagrangian is obtained by integrating over the fast degrees of freedom; the Berry eld itself is considered as a slow variable. The E ective lagrangian is understood as a theory describing the dynamics of these slow elds.

To be more specic, if one integrates over the compactified space coordinates, than one obtains an E ective lagrangian which depends on Berry's potential A = ii (0 u. Here u is an original ferm ion eld considered as a fast variable. Now the situation clearly resembles QCD where the underlying lagrangian does not contain meson elds. They will appear and become dynamical variables after integrating over the fast quark elds. The same situation takes place in the case under consideration where the Berry potential can be thought of as a composite of u and u^y original elds.

Now all previous QCD - arguments regarding the n! growth of coecients in the E ective lagrangian can be applied to the present case. We end up with the same conclusion that the E ective lagrangian I_{eff} (A) as a function of the Berry potential is an asymptotic series⁶. Of course, there is a huge di erence in scales between QCD and the theory under consideration: in former case the parameter of expansion is 1 = w ith ' 1G eV; in later one the scale is the P lank scale M $_{\rm P}$ ' 10^{19} G eV. However, there is no fundamental di erence between these two models in the way of obtaining the corresponding E ective lagrangians: in both cases the slow elds can

⁶The very di erent approach [15] leads assentially to the similar conclusion about the asymptotic nature of the adiabatic expansion

be considered as the composite of the original elds. A symmetry prevents them from getting a mass: for the meson it is the chiral symmetry; for the Berry eld A it is a gauge symmetry. Thus, both elds can be considered as soft variables and the philosophy of E ective lagrangian can be applied. The integration over the fast variables, as we argued earlier, leads to the n! grow th of the coe cients in the E ective lagrangians in both cases.

c). Our next example is the lattice QCD. As is known, the main idea in lattice QCD is to replace continuous spacetime variables by a discrete lattice. Then the path integral dening the QCD can be evaluated numerically. If we denote a as the lattice spacing, then the standard discretization of the QCD action has errors of O (a^2) that are large when the lattice spacing is not small enough. This was the reason to suggest the so-called improved action for lattice QCD [16] (for recent development see [17]). The improved discretization has been designed in such a way that nite a errors are system atically rem oved by introducing new (nonrenormalizable) interactions into the lattice action. All coe cients of the new interactions are determined by demanding that the discretized action reproduces continuum physics to a given accuracy. In particular, the W ilson action contains all terms proportional to $a^2; a^4; :::$ beyond the desired gluon kinetic term [16]:

$$1 \quad \frac{1}{3} \text{Re} \,\text{Tr} \text{U}_{\text{pl}} = r_0^{X} \,\text{Tr} (\text{F} \,\text{F} \,) + a^{2}^{X} \,r_i \text{R}^{i} + \qquad (15)$$

$$0(a^4) + \dots + \sum_{n;i}^{x} a^{2n} r_{i;2n} Q^{i;2n};$$

where U_{pl} is the product of link m atrices on a plaquette P; Rⁱ is the set of operators of dimension six; the r_i are coecients in the OPE of the plaquette. For higher dimensional operators we introduced the corresponding notations Q^{ij2n} and r_{ij2n} with the index n labeling the dimension of the operator, and the index i classifying dimensions with given dimension.

Our remark is: The coe cients in the expansion (15) are factorially growing with the dimension of the operators. We shall discuss the physical consequences of this statement in the Conclusion. Now, we would like to explain this n! grow th in the following way: The lattice action is dened in terms of the link operator

$$U_{x;} = P \exp \left[ig A dy \right]$$
(16)

with the simplest choice of path for the integral as a straight line joining x and x + a. A single plaquette contribution can be thought of as a W ilson loop surrounding this point x with radius a. As is known, the W ilson loop can be interpreted as the creation of a heavy quark-antiquark pair which propagates for a time a and nally annihilates. It can be interpreted as a

forward and backward propagating of one heavy quark as well. A nyhow, one can interpret the action (15) as the elective action which is obtained after integrating out the heavy quarks with mass a ¹. As usual, to give some sense to the Elective lagrangian which presumably describes the dynamics of light degrees of freedom, the mass of the auxiliary heavy quark should be much larger than the characteristic scale in QCD: a ¹ IG eV. Once this interpretation in terms of the heavy quark has been made, we have reduced our problem to the previously discussed case (1).

d). Our last, but not least example is the eld theory of gravity. We refer to the recent review [18] on this subject for a general introduction and references. The only remark we would like to make here is the following. Now days it is generally accepted that the Einstein Lagrangian

$$S_{grav} = \int_{-\infty}^{Z} d^4 x^p \, \overline{g} \frac{2}{2} R \tag{17}$$

is only the rst local term of the expansion of a more complicated theory (string?). Thus, general relativity should be considered as an elective eld theory with in nitely many terms allowed by general coordinate invariance. As usual, in the elective theory description, only the rst term in the expansion plays a role at low energy E $M_{P \text{ lank}}$. If we were not interested in quantum elects at the P lank scale with E ' $M_{P \text{ lank}}$, eq. (17) would be the end of the story. However we intend to discuss physics at the P lank scale, thus we would like to write down the E lective lagrangian in the most general form :

$$S_{eff} = {}^{Z} d^{4}x^{p} \overline{g} [+ \frac{2}{2}R + c_{1}R^{2} + c_{2}R R + (18)]$$

$$X_{c_{n}}Q^{n} :::+ L_{m atter} + L_{dilaton} + L_{inflaton} :::+];$$

where the operators Q^n are high dimensional operators constructed from the relevant elds (R , dilaton, in aton , gauge elds F , etc). Our remark here is that the coe cients in the E ective lagrangian describing even the pure gravity theory, exhibit factorial grow th.⁷ The arguments which support this statement are the same as before: if the underlying theory (in our case it is given by lagrangian (17) possesses factorial grow th in the perturbative expansion, the E ective lagrangian constructed from this theory exhibits the same factorial behavior for the high dimensional operators.

A swe already mentioned, the factorial behavior of coe cients in the perturbative expansion can be understood as the fast increase in the number of Feynm an diagram s. In pure Y ang M ills theory we know well that such a growth does take place[5]. We can interpret this growth as a manifestation of the three- and four-gluon vertices which lead to the factorially divergent

⁷Any extra elds may only increase this grow th.

number of the diagram s. In the case of gravity (17) we expect the same factorial behavior because of the nonlinear nature of the interaction (17) sim ilar to a gauge theory. Of course, there is a big di erence between those two, related to the fact that gravity is not a renorm alizable eld theory. However the only relevant point for our purposes is that the coe cients are factorially growing the dimension of the operator increases. The possible physical consequences of this phenom enon will be discussed in the last section.

3 Instead of conclusion

3.1 General sum m ary

In this letter we have presented two independent sets of arguments which support the idea that almost any nontrivial E ective lagrangian obtained by integrating out some heavy elds and/or fast degrees of freedom, is nonconvergent, but an asymptotic series.

The rst set of arguments is based on the idea that the imaginary part of the amplitude related to the probability of the physical creation of a heavy particle, is exponentially small $\exp((\frac{1}{E}))$. The dispersion relations in this case unambiguously imply that the coe cients of the expansion in the real part of the corresponding amplitude exhibit an factorial dependence. Once these coe cients are found to be factorially large, we can forget about the way the result was derived, we can forget about the external auxiliary eld E which we heavily used in our arguments. Coe cients in the OPE do not depend on the applied eld E, no matter how small it is.

The second line of reasoning is based on the analysis of the large order behavior of the perturbative series. As we have argued, if the underlying theory possesses factorial grow th of the coe cients of the perturbative series, than the corresponding E ective lagrangian constructed from this theory will exhibit the same factorial behavior for the high dimensional operators.

W e believe that both of these lines of arguments are so general in form that almost all nontrivial E ective lagrangian will demonstrate n!behavior. W e believe that this phenomenon is universal in nature.

Now we would like to discuss some physical consequences which m ight result from this phenomenon. As we mentioned in Introduction, we have nothing new to say in the case of analysis of low energy phenomena for which the small expansion parameter is E = M 1. In such a case, the exact formula is approximated perfectly well by the rst term of the asymptotic expansion and we can safely forget about all the rest. However, very often the situation is not so fortunate and the expansion parameter 1, (let say 1=3 or 1=2). In this event people try to improve the situation by considering the next to -leading terms or even next to next to -leading order. If the series were convergent, these e orts would be worthwhile. How ever, as we argued in this letter, an E ective Lagrangian , in general, is represented by an asymptotic, not a convergent series. Thus, one may ask the following general questions:

a) How many terms one should keep in the E ective Lagrangian for the best approximation of an exact formula for the given parameter ?

b) W hat is the fundam ental uncertainty (related to our lack of know ledge of the higher dimensional operators) one should expect for an E ective lagrangian represented as an asymptotic series?

Let us recall that the standard perturbative expansion in QCD is also asymptotic series. For this case the answers on the questions a). and b). are well known [9]. In particular, as is known, the pole mass of a heavy quark su ers from an intrinsic uncertainty of order $_{QCD}$. [6] Another example is the fundamental uncertainty of perturbative calculations of the correlation function for the light quarks[9].

We believe that the asymptotic nature of the OPE and E ective lagrangian, in particular, will lead to a similar fundamental uncertainty for somephysically interesting characteristics. In particular, as we argued in [7], any hopes to improve the standard QCD sum rules (like the idea advocated in [19]) by summing up a certain subset of the power corrections and ignoring all the rest, is fundamentally an erroneous idea because of the asymptotic nature of the OPE. A similar example which has been discussed recently is the OPE for decay [6]. It was argued that the tail of the condensate series may be quite noticeable in the nonperturbative analysis of the hadronic decay.

Therefore, the m oral is: if the param eter of the asymptotic expansion is not smallenough, the two questions formulated above might have some phenom enological relevance. The elective description of QCD which has been discussed in the previous section is one example. We believe that the lattice calculations (also discussed in the previous section) is another example of the same kind. Indeed, as we argued in the previous section the expansion (15) is an asymptotic series. Thus, we can formulate the following question: How many terms in the asymptotic expansion should be kept for the given lattice size a in order to get the best possible accuracy? The same question can be reformulated in somewhat dierent way: W hat is the fundamental uncertainty of the lattice calculations which are associated with the tail of the high dimensional operators in the Elective lagrangian (15)?

3.2 Cosm ological constant problem

W e wish to discuss some consequences of the factorial behavior in the E ffective lagrangian (18) for gravity separately. Let us recall that the natural scale of the cosm ological term is the P lank scale. Indeed, the most popular cosm ology today, the in ationary scenario (for a review see [20] and [21]) assumes that our universe passed through an era in which the cosm ological term dom inated, and it is a totalmystery why we should be left in a universe with an almost vanishing vacuum energy. Of course we do not know the answer to this question, but we would like to suggest the following scenario which is based on the asymptotic nature of the elective lagrangian (18).

Let us assume that at the very early epoch the gravity eld as well as other relevant for in ation elds (scalar,..) exhibit som e nonzero vacuum expectation values (VEV), which we shall call the condensates. We believe that this is very likely to happen in gravity at the P lank scale in analogy with the phenom enon of gluon condensation in QCD at 1G eV scale. We introduce the notation h i for the condensate of any relevant ed: a scalar ed which people usually introduce to describe in ation (in aton), dilaton or a gravity eld itself. The natural scale for such a condensate is, of course, the P lank scale. For the higher dimensional operators Q^n from eq.(18) we assume that there is a factorization rule which allows us to estimate the higher order h ⁿi condensates in the following way hQ^n i h i^n . W e note that this assumption is not crucial for our purposes, but, rather, is a simpli cation which allows us to demonstrate the main idea in a very simple way. The similar assumption in QCD is justified in the limit in which the number of $colors N_c ! 1$ G iven that these assumptions have been m ade, we can use the Borel representation form ula for the asymptotic series $(18)^8$:

$$hL_{eff}i = \prod_{n=0}^{n \times 1} n! (1)^n h i^n = \int_0^{L_1} \frac{dt}{t(t+h i)} \exp(\frac{1}{t})$$
(19)

Now we would like to brie y discuss the vacuum structure of de Sitter Space. In di erent words, we would like to discuss the parameter h i from eq. (19). We refer to the recent papers [23]-[24] on this subject (see references to previous papers therein). The main result of these investigations is the observation that the higher order quantum gravity corrections to the di erent physical values in general are infrared divergent. In particular, the divergence is observed in the vacuum correlator h²i. Probably, this divergence has power-like behavior in time rather than exponential one, as previously thought. It may force us to take som e nonperturbative dynam -

⁸ We assumed in this form ula that the series is B orel sum m able. This is m ay or m ay not be the case; how ever we believe that the B orel non-sum m ability of an expansion does not signal an inconsistency or am bigiuty of the theory. The B orel prescription is just one of m any sum m ation m ethods and need not be applicable everywhere. For B orel-nonsum able cases, one could expect the sign () in the denom inator of eq.(19). Thus, some prescription, based on the physics consideration, should be given in order to evaluate an integral like that. Some new physics usually accompanies such a phenom enon, but we do not go into details here. R ather, we would like to m ention the non-B orel sum able example of the principal chiral eld theory at large N [22]. In this case, the explicit solution is known. The coe cients grow factorially with the order and the series is non-B orel sum able. N evertheless, the physical observables are perfectly exist, the exact result can be recovered by special prescription which uses a non-trivial procedure of analytical continuation.

ics into account, which we do not know. Instead we introduce some small phenom enological parameter () into the VEV

in order to account for this new physics responsible for the infrared divergences mentioned above.

One can see in this case that the integral which describes the vacuum $energy^9$

$$hH_{eff}i = \int_{0}^{Z_{1}} \exp(\frac{1}{t}) \frac{dt}{t(t + \frac{hi}{t})} = \frac{1}{2} 0$$
 (20)

goes to zero at small . As we mentioned above, the e ect (20) does not crucially depend on our assumptions about the factorization properties for the condensates hⁿi h iⁿ as neither on our assumption of exact factorial dependence of the coe cients $c_n = n!$. Both of these e ects presumably lead (apart to n!) to some mild n dependence which can be easily im – plemented into the formula (20) by introducing some smooth function f (t) whose moments $f(t)t^{n-2}exp(\frac{1}{t})dt$ exactly reproduce an dependence of the coe cients as well as of the condensates. If this function is mild enough, it will not destroy the relation (20), but m ight change some num erical co-e cients. Besides that, a condensate m ight have, along with singular part proportional to $\frac{h i}{(\cdot)}$, a regular part as well $\frac{h i}{(\cdot)}$ + const: A s can be seen from the representation (20) this does not destroy the eq.(20).

Few remarks are in order. The vanishing of the vacuum energy is the consequence of the asymptotic nature of the elective lagrangian and the infrared properties of the VEVs. All others simplied assumptions which have been made for technical reasons do not a lect the phenom enon. Vanishing of the vacuum energy (20) can be interpreted (after in ation, when all relevant condensates presum ambly go to zero) as the vanishing of the cosm ological constant, the only relevant operator in the Elective lagrangian (all other terms are marginal or unrelevant operators).

As our last rem ark, we would like to note that the strong infrared dependence of the vacuum condensate h i is not a unique property of de Sitter gravity. Two-dimensional QCD with a large number of colors also exhibits a strong infrared dependence. In particular, the so-called mixed vacuum condensates can be exactly calculated in this theory in the chiral limit (m_q ! 0) and exhibit the following dependence on the infrared parameter m_q [25]:

$$\frac{1}{2^{n}}hq(ig \quad G \quad {}_{5})^{n}qi = \left(\frac{g^{2}hqqi}{2m_{q}}\right)^{n}hqqi; \qquad (21)$$

⁹W e could consider lagrangian instead of ham iltonian with the same result.

where q is a quark eld and G is a gluon eld of QCD₂ (N = 1). The chiral condensate hqqi in this theory can be calculated exactly [26]. It does not vanish without contradicting the Colem an theorem. The very important feature of this formula: it diverges in the chiral lim it m_q ! 0, where the parameter m_q plays the role of the infrared regulator of the theory. Now , if we considered the asymptotic series constructed from these condensates

$${}^{n_{X}^{1}}_{n=0}()^{n}n\,a_{n}hq(ig \ G \ {}_{5})^{n}qi \ {}^{Z_{1}}_{0}\exp(\frac{1}{t})\frac{dtf(t)}{t(t+\frac{1}{m_{q}})} \ m_{q} \ ! \ 0; \ (22)$$
$$a_{n} \ \frac{1}{n!} \sum_{0}^{Z_{1}} f(t)t^{n} \sum_{q}^{2}\exp(\frac{1}{t})dt \ 1;$$

we would get result of zero for this series, in spite of the fact that each term on the left hand side diverges in the chiral lim it and irrespective of the precise behavior of the coe cients a $_n$! Of course this is only a toy example which how ever can give us a hint of what m ight happen in real N ature.

We close this section by noting that the vanishing of the vacuum energy in this scenario does not require any ne tuning of parameters. Rather, it is a very natural consequence of the asymptotic origin of the Effective lagrangian and of the infrared behavior of the VEVs. The problem of naturality within an E ective lagrangian approach has been discussed more than once. In the given context the cosm ological constant problem has been discussed recently in [4]with the following main conclusion: If a relevant operator appears in the E ective eld theory with a coe cient much less than a typical scale without a symmetry reason, it should be taken as a warning for e ective eld theory dogma.

We hope to have suggested here a natural scenario for the vanishing of the coe cient for a relevant operator which is not based on symmetry considerations. We close this section with the following remark. If this scenario works (as we hope), it means inst of all, that all related problems should be explained at the same time within the same approach. In particular, we expect [27] that an in ationary scenario, which is the most popular cosm obgy today, can be understood in terms of the same physical variables within the same philosophy.

4 A cknow ledgm ents

I am grateful to Robert Brandenberger, for the extrem ely valuable lunchdiscussions about gravity problems. I also thank Sasha Polyakov for his useful critical com m ents.
