Abstract

We study the $\eta' \rightarrow \pi^0$ decay via the quark-box diagram in the three-flavor Nambu{Jona-Lasinio model that includes the $U_A(1)$ breaking effect. We find that the η -meson mass, the $\eta' \rightarrow \pi^0$ decay width and the $\eta' \rightarrow \pi^0$ decay width are in good agreement with the experimental values when the $U_A(1)$ breaking is strong and the flavor $SU(3)$ singlet-octet mixing angle is about zero. The photon energy and the photon invariant mass spectra in $\eta' \rightarrow \pi^0$ are compared with those in the chiral perturbation theory.

Chiral symmetry plays an essential role in the light-flavor QCD. Light pseudoscalar mesons are regarded as the Nambu-Goldstone (NG) bosons of spontaneous symmetry breaking of chiral $SU(N)_L \times SU(N)_R$ symmetry. Properties of the NG bosons have been studied in various chiral effective theories successfully.

Another interesting low-energy symmetry is the axial $U(1)$ symmetry, which is explicitly broken by the anomaly. The symmetry breaking is manifested in the heavy mass of η' meson, which has been studied as the " $U_A(1)$ problem". It is yet not clear how strong the anomaly effect is on the pseudoscalar spectrum mainly because of complicated interference of the explicit flavor symmetry breaking due to the strange quark mass. Two of the authors (M.T. and M.O.) argued in a previous paper[1] that a strong $U_A(1)$ breaking and consequently a large flavor mixing are favorable for the η' meson. The argument is based on the analysis of the η' system as a $q\bar{q}$ bound state in the three-flavor Nambu-Jona-Lasinio (NJL) model. We claim that the mass as well as the $\eta' \rightarrow \pi\pi$ decay rate supports a $U_A(1)$ breaking six-quark interaction much stronger than previously used [2]. This interaction causes a large flavor mixing resulting almost pure octet η'_{oct} .

The purpose of this paper is to extend the previous analysis to another decay process, $\eta' \rightarrow \gamma\gamma$ and to confirm our claim of the strong $U_A(1)$ breaking. We are interested in this process where the internal structure of the η' mesons plays essential roles because the photon does not couple to the neutral mesons directly. Furthermore, chiral perturbation theory (ChPT) gives too small prediction in the leading order and higher order terms are expected to be dominant.

The three-flavor NJL model is one of the phenomenologically successful chiral effective models of the low-energy QCD and the lagrangian density we have used is as follows,

$$\mathcal{L} = \mathcal{L}_0 + \mathcal{L}_4 + \mathcal{L}_6; \quad (1)$$

$$L_0 = \bar{\psi} (i \not{\partial} - \hat{m}) \psi ; \quad (2)$$

$$L_4 = \frac{G_S}{2} \sum_{a=0}^8 \bar{\psi} \gamma_5 \gamma_a \psi \bar{\psi} \gamma_5 \gamma_a \psi ; \quad (3)$$

$$L_6 = G_D \det_{(ij)} \bar{\psi}_i (1 + \gamma_5) \psi_j + \det_{(ij)} \bar{\psi}_i (1 - \gamma_5) \psi_j ; \quad (4)$$

where ψ is the quark field, $\hat{m} = \text{diag}(m_u; m_d; m_s)$ is the current quark mass matrix, and γ_a is the flavor $U(3)$ generator ($\gamma_0 = \frac{1}{2}I$). The determinant in L_6 is a 3×3 determinant with respect to the flavor indices $i; j = u; d; s$. The model involves the $U_L(3) \times U_R(3)$ symmetric four-quark interaction L_4 and the six-quark flavor-determinant interaction L_6 incorporating effects of the $U_A(1)$ anomaly.

Quark condensates and constituent quark masses are self-consistently determined by the gap equations in the mean field approximation. The covariant cutoff is introduced to regularize the divergent integrals. The pseudoscalar channel quark-antiquark scattering amplitudes are then calculated in the ladder approximation. From the pole positions of the scattering amplitudes, the pseudoscalar meson masses are determined. We define the effective meson-quark coupling constants g_{qq} and $g_{qq'}$ by introducing additional vertex lagrangians,

$$L_{qq} = g_{qq} \bar{\psi} \gamma_5 \psi \phi ; \quad (5)$$

$$L_{qq'} = g_{qq'} \bar{\psi} \gamma_5 \psi \phi' ; \quad (6)$$

with $\phi = \cos \theta \phi^8 + \sin \theta \phi^0$. Here ϕ is an auxiliary meson field introduced for convenience and the effective meson-quark coupling constants are calculated from the residues of the qq -scattering amplitudes at the corresponding meson poles. Because of the $SU(3)$ symmetry breaking, the flavor 8 and 0 components mix with each other. Thus we solve the coupled-channel qq scattering problem for the meson. The mixing angle θ is obtained by diagonalization of the qq -scattering

Table 1: The parameters and π^0 decay widths for each G_D^e

amplitude at the π -meson pole. The meson decay constant f_M ($M = \pi; K; \eta$) is determined by calculating the quark-antiquark one-loop graph. The explicit expressions are found in [1].

The parameters of the model are the current quark masses $m_u = m_d; m_s$, the four-quark coupling constant G_S , the six-quark determinant coupling constant G_D and the covariant cutoff Λ . We take G_D as a free parameter and study meson properties as functions of G_D . We use the light current quark masses $m_u = m_d = 8.0$ MeV (same as in [1]). Other parameters, $m_s; G_S$, and Λ , are determined so as to reproduce the isospin averaged observed masses, $m_\pi; m_K$, and f_π .

We obtain $m_s = 193$ MeV, $\Lambda = 783$ MeV, the constituent $u; d$ -quark mass $M_{u;d} = 325$ MeV and $g_{qq} = 3.44$, which are almost independent of G_D .

Table 1 summarizes the fitted results of the model parameters and the quantities necessary for calculating the $\eta' \rightarrow \pi^0$ decay width which depend on G_D . We define dimensionless parameters $G_D^e = G_D / (2)^4 N_c^2$ and $G_S^e = G_S / (2)^2 N_c$. When G_D^e is zero, our lagrangian does not cause the flavor mixing and therefore the ideal mixing is achieved. The η' is purely $u\bar{u} + d\bar{d}$ and is degenerate to the pion in this limit.

It is found in [1] that the $\eta' \rightarrow \pi^0$ decay width is reproduced at about $G_D^e = 0.7$. At this value the ratio $G_D^e / G_S^e = 0.44$ indicates that the contribution from L_6 to the dynamical mass of the up and down quarks is 44% of that from L_4 . The mixing angle at $G_D^e = 0.7$ is $\theta = 1.3$ and that indicates a strong OZI violation and a large (u,d) -mixing. This disagrees with the "standard" value $\theta' \approx 20^\circ$ obtained in ChPT [3]. This is due to the stronger $U_A(1)$ breaking in the present calculation. The difference mainly comes from the fact that the mixing angle in the NJL model depends on q^2 of the $\bar{q}q$ state and thus reflects the internal structure of the meson. On the contrary the analyses of ChPT [3] assume an energy-independent mixing angle, i.e., $(M^2) = (M^2_0)$.

We are now in a position to study whether the $\eta' \rightarrow \pi^0$ decay rate is consistent with our picture of η' with a large OZI mixing.

The experimental value of the $\eta' \rightarrow \pi^0$ decay width is [4]

$$\Gamma_{\eta' \rightarrow \pi^0}^{\text{exp}} = 0.85 \pm 0.19 \text{ eV} ; \quad (7)$$

We evaluate the quark-box diagram given in Fig 1. We follow the evaluation of the box-diagram performed in [5]. Other possible contributions will be discussed later.

The $\eta' \rightarrow \pi^0$ decay amplitude is given by

$$\langle \pi^0(p) | (k_1; 1) (k_2; 2) | \eta'(p) \rangle = i(2)^{4-4} (p + k_1 + k_2 - p)_{12} T ; \quad (8)$$

Figure 1: The quark-box diagram for $e^+e^- \rightarrow \gamma\gamma \rightarrow e^+e^-$

where ϵ_1 and ϵ_2 are the polarization vectors of the photons. T is given by a straightforward evaluation of the Feynman diagrams. After calculating traces in color and flavor spaces, we obtain

$$T = \frac{1}{i\pi^3} (\cos^2 \theta - \frac{p^2}{2} \sin^2 \theta) e^2 g_{qq} g_{q\bar{q}} \int \frac{d^4 q}{(2\pi)^4} \sum_{i=1}^Z U^i; \quad (9)$$

with

$$U^1 = \text{Tr}^{(D)} \left(\frac{1}{\not{q} \not{M} + i} \frac{1}{\not{q} + \not{p} \not{k}_1 \not{k}_2 \not{M} + i} \frac{1}{\not{q} + \not{p} \not{k}_1 \not{M} + i} \frac{1}{\not{q} + \not{p} \not{M} + i} \right); \quad (10)$$

$$U^2 = \text{Tr}^{(D)} \left(\frac{1}{\not{q} \not{M} + i} \frac{1}{\not{q} + \not{k}_2 \not{M} + i} \frac{1}{\not{q} + \not{p} \not{k}_1 \not{M} + i} \frac{1}{\not{q} + \not{p} \not{M} + i} \right); \quad (11)$$

$$U^3 = \text{Tr}^{(D)} \left(\frac{1}{\not{q} \not{M} + i} \frac{1}{\not{q} + \not{k}_2 \not{M} + i} \frac{1}{\not{q} + \not{k}_1 + \not{k}_2 \not{M} + i} \frac{1}{\not{q} + \not{p} \not{M} + i} \right); \quad (12)$$

$$U^4 = U^1(k_1 \otimes k_2); \quad (13)$$

$$U^5 = U^2(k_1 \otimes k_2); \quad (14)$$

$$U^6 = U^3(k_1 \otimes k_2); \quad (15)$$

Here $\text{Tr}^{(D)}$ means trace in the Dirac indices and M is the constituent u,d-quark mass. Because the loop integration in (9) is not divergent, we do not introduce the UV cutoff. Then the gauge invariance is preserved. The inclusion of the cutoff that is consistent with the gap equation will break the gauge invariance and make the present calculation too complicated. Note that the strange quark does not contribute to the loop.

On the other hand the amplitude T has a general form required by the gauge invariance [6]

$$T = A(x_1; x_2) (k_1 k_2 - k_1 \cdot k_2 g^{\mu\nu}) + B(x_1; x_2) M^2 x_1 x_2 g^{\mu\nu} - \frac{k_1^\mu k_2^\nu}{M^2} p^\mu p^\nu + x_1 k_2^\mu p^\nu + x_2 p^\mu k_1^\nu; \quad (16)$$

with

$$x_i = \frac{p \cdot k_i}{M^2}; \quad (17)$$

and M is the meson mass. With A and B , the differential decay rate with respect to the energies of the two photons is given by

$$\frac{d^2}{dx_1 dx_2} = \frac{M^5}{256} \left[A + \frac{1}{2} B \right] 2(x_1 + x_2) + \frac{M^2}{M^2} + \frac{1}{4} B^2 4x_1 x_2 - 2(x_1 + x_2) + \frac{M^2}{M^2}; \quad (18)$$

where M is the ϕ meson mass. Though the mass of ϕ as a $q\bar{q}$ bound state depends on G_D^e , we use the experimental value $M = 547 \text{ MeV}$ in evaluating (18). The Dalitz boundary is given by two conditions:

$$\frac{1}{2} \leq \frac{M^2}{M^2} \leq x_1 + x_2 \leq 1 - \frac{M^2}{M^2}; \quad (19)$$

and

$$x_1 + x_2 = 2x_1x_2 + \frac{1}{2} \left(1 - \frac{M^2}{M^2} \right) ; \quad (20)$$

In evaluating (10)–(15), one only has to identify the coefficients of $p \cdot p$ and g . Details of the calculation are given in [5]. Defining A and B by

$$\int \frac{d^4q}{(2\pi)^4} x^6 U_i = i A g + B \frac{p \cdot p}{M^2} + \dots ; \quad (21)$$

we find A and B as

$$A = \frac{1}{3} (\cos \frac{p}{2} \sin \frac{p}{2})^2 g_{qq} g_{qq} \frac{2}{M^2} A + 2x_1x_2 \frac{B}{M^2} ; \quad (22)$$

$$B = \frac{1}{3} (\cos \frac{p}{2} \sin \frac{p}{2})^2 g_{qq} g_{qq} \frac{2}{M^2} B ; \quad (23)$$

with

$$= \frac{(k_1 + k_2)^2}{M^2} = 2(x_1 + x_2) + \frac{M^2}{M^2} = 1 ; \quad (24)$$

We evaluate A and B numerically and further integrate (18) to obtain the π^0 decay rate. The results are given in the last column of Table 1 and shown in Fig 2.

Our result is $(\pi^0 \rightarrow \pi^0) = 0.92 \text{ eV}$ at $G_D^e = 0.70$ where the π^0 decay width is reproduced [1]. At $G_D^e = 1.40$ which reproduces the experimental meson mass, $(\pi^0 \rightarrow \pi^0) = 0.58 \text{ eV}$. Both are in reasonable agreement with (7).

In ChPT [7], there is no lowest order $O(p^2)$ contribution to the $\pi^0 \rightarrow \pi^0$ process because the involved mesons are neutral. Likewise the next order $O(p^4)$ tree diagrams do not exist. Thus the $O(p^4)$ one-loop diagrams give the leading term in this process, but the contribution is two orders of magnitude smaller than the experimental value (7). This is because the pion loop violates the G -parity invariance and the kaon loop is also suppressed by the large kaon mass.

At $O(p^6)$, there exists contribution coming from tree diagrams, one-loops and two-loops. The loop contributions are smaller than those from the order $O(p^4)$.

Figure 2: Dependence of the ρ^0 decay width on the dimensionless coupling constant G_D^e . The horizontal solid line indicates the experimental value $\Gamma(\rho^0) = 0.85$ eV and the dashed lines indicate its error widths.

At $O(p^8)$, more tree diagrams and a new type of loop corrections appear, but the loop corrections are also small.

In [7], coupling strengths of the tree diagrams are determined assuming saturation by meson resonance poles, such as π ; ρ ; a_0 and a_2 . This gives

$$\Gamma(\rho^0) = 0.42 \pm 0.20 \text{ eV}; \quad (25)$$

where the 0.20 eV is the contribution of a_0 and a_2 , the sign of which is not known. The result is a factor two smaller than the experimental value.

The contributions of other mesons, such as $b_1(1235)$; $h_1(1170)$; $h_1(1380)$ [8] and other tree diagrams [9], are found to be small.

Although these results based on ChPT are not too far from the experimental value, it is noted that the higher order $O(p^6)$ terms in the perturbation expansion are larger than the leading $O(p^4)$ terms and the results contain ambiguous

parameters that cannot be determined well from other processes.

On the other hand in [10] the $O(p^6)$ tree diagrams are evaluated by using the extended NJL (ENJL) model[11]. They calculated three contributions in ENJL, namely, the vector and scalar resonance exchange and the quark-loop contributions. Their result is $(\pi \rightarrow \pi^0 \gamma) = 0.5 \text{ eV}$. They further introduced the $O(p^8)$ chiral corrections as well as the axialvector and tensor meson exchange contributions, and finally obtained $(\pi \rightarrow \pi^0 \gamma) = 0.58 \pm 0.3 \text{ eV}$.

The difference between our approach and that in [10] are as follows. The ENJL model lagrangian has not only the scalar-pseudoscalar four quark interactions but also the vector-axialvector four quark interactions. However, the $U_A(1)$ breaking is not explicitly included in their model and therefore the η' mixing is introduced by hand with the mixing angle $\theta = 20^\circ$. We stress that the introduction of the $U_A(1)$ breaking interaction is important to understand the structure of the meson.

There is another difference. The coupling constants of the chiral effective meson lagrangian predicted in the ENJL model are parameters of the Green function evaluated at zero momenta. On the other hand we evaluate the quantities at the pole position of the mesons.

Calculated spectrum of the photon invariant mass square m^2 for the $\pi \rightarrow \pi^0 \gamma$ decay is shown in Fig 3. As this spectrum is compared with those calculated by ChPT in [9], we find ours to be similar to the one for $d_3 = 4.5 \times 10^{-2} \text{ GeV}^{-2}$ in [9] which involves an additional $O(p^6)$ contribution to the original Lagrangian.

Spectrum of the photon energy E for the $\pi \rightarrow \pi^0 \gamma$ decay is shown in Fig 4, and given in [7] in ChPT. Both are also similar, though there is no experimental result.

In our calculation of the $\pi \rightarrow \pi^0 \gamma$ decay, we evaluate only the quark-box

Figure 3: Spectrum of the photon invariant mass m^2 .

diagram in Fig 1. Since the vector and axialvector four-quark interactions are not included in our model, the only other contribution to this process is the scalar resonance exchange. In the ENJL model the contribution of the scalar resonance exchange is small[10]. We expect that similar result will be obtained in our approach.

If one includes the vector and axialvector four-quark interaction in the NJL model, the pseudoscalar meson properties are affected through the pseudoscalar-axialvector channel mixing and the model parameters with and without the vector and axialvector four-quark interaction are different. We expect that the models with and without the vector-axialvector interaction predict similar results for the processes involving only the pseudoscalar mesons with energies much below the vector meson masses. It is further argued that the contribution of the quark-box

Figure 4: Spectrum of the photon energy E_γ .

diagram to the $\eta' \rightarrow \gamma \gamma$ process, that is similar to $\eta' \rightarrow \gamma \gamma$, is quite close to that of the vector meson exchange in the vector dominance model[12].

In summary, we have studied the $\eta' \rightarrow \gamma \gamma$ decay in the three-flavor NJL model that includes the $U_A(1)$ breaking six-quark determinant interaction. The meson mass, the η' decay width and the $\eta' \rightarrow \gamma \gamma$ decay width are reproduced well with a rather strong $U_A(1)$ breaking interaction, that makes $\theta_1 \approx 8^\circ$ mixing angle $\neq 0$. Since the η' meson is expected to be sensitive to the effects of the $U_A(1)$ anomaly, it is very important to study the η' meson properties. It should be noted, however, that the NJL model does not confine quarks. While the NG bosons, π , K and η , are strongly bound and therefore can be described in the NJL model fairly well, we do not apply our model to the heavy mesons such as η' , η' and η' . Further study of the $U_A(1)$ breaking and the

1 θ mixing will require a calculation including the confinement mechanism.
