Abstract

In elective supergravity theories following from the superstring, a modulus eld can quite naturally set the neccessary initial conditions for successful cosmological in ation to be driven by a hidden sector scalar eld. The leading term in the scalar potential is cubic hence the spectrum of scalar density perturbations neccessarily deviates from scale-invariance, while the generation of gravitational waves is negligible. The grow th of large-scale structure is then consistent with observational data assuming a critical density cold dark matter universe, with no need for a component of hot dark matter. The model can be tested thorough measurements of cosmic microwave background anisotropy on small angular scales.

I. IN TRODUCTION

It is well known that a su ciently long period of accelerated, non-adiabatic expansion in the early universe, driven by the false vacuum energy of a scalar eld, successfully solves the horizon and atness problem s of the standard B ig B ang m odel, as well as the cosm ological monopole problem of grand uni ed theories [2]. In the hew ' in ationary model [3], a single bubble of the true vacuum expands su ciently in the vacuum energy dom inated D e Sitter epoch, so as to contain the entire universe visible today and drive it to the critical density; the vacuum energy is then converted to radiation, 'reheating' the universe and starting o the standard Friedm ann-R obertson-W alker evolution. Furtherm ore, the density perturbations generated by quantum uctuations of the scalar eld driving in ation have a (nearly) scale-invariant spectrum, as is required by observations [3]. However it was observed over a decade ago that in order to respect the observational limit on the perturbation amplitude deduced from the isotropy of the 2.73K cosm ic microw are background (CMB), the scalar potential has to be extrem ely at and protected against radiative corrections. It became e evident that the only plausible candidates for the 'in aton' are gauge singlet elds in supersymmeteric theories [4], which were recognized already as being the most probable extension of physics beyond the Standard SU (3)_c SU (2)_t U (1)_t M odel [5].

However all such models [4] were found to be plagued with various phenom enological problem s, in particular the production during reheating of massive unstable particles such as gravitinos whose late decays can disrupt the standard cosm ology [6] as well as the excitation during in ation of weakly coupled scalar elds associated with supersymmetry breaking, which too release their energy rather late generating an unacceptable amount of entropy [7]. (The latter problem is particularly acute for the at directions (or moduli) of string theories [8,9].) It was also established that therm all ects in the early universe cannot localize the in atom eld at the origin as is required to ensure a su ciently long period of in ation [4]. However given random initial conditions, as is appropriate for a weakly coupled eld, successful in ation was shown to be possible if the in atom has its global m inimum at the origin and evolves towards it from an initial vacuum expectation value (vev) beyond the P lanck scale. Such a 'chaotic' in ation model [3] accom odates a wide variety of potentials (albeit with arbitrary ne tuning) hence attention drifted away from the speci c problem s encountered by supersymmetric in ationary models.

Subsequently, precision accelerator data [10] have con med that them ost likely solution to the hierarchy' problem posed by a fundam ental Higgs boson in the Standard M odel is indeed (broken) supersymm etry just above the electroweak scale. Moreover, this enables successful uni cation of the strong and electroweak gauge couplings at a scale of 2 $1\dot{\theta}^6$ G eV as well as providing an elegant mechanism for electroweak symmetry breaking and an understanding of the pattern of ferm ion m asses [11]. The superpartners of the known particles should have m asses no higher than a few TeV so can be directly created at the forthcoming LHC or possibly even at LEP 2. The lightest supersymmetric particle is typically the neutralino, a neutral weakly interacting mixture of the superpartners of the gauge and Higgs bosons. It naturally has a relic abundance of order the critical density [12] and is therefore an excellent candidate for the cold dark matter (CDM) [13] which is required in all viable models of large-scale structure form ation [14]. This provides strong m otivation to reexam ine the problem s connected with in ation in supersymmetric theories, speci cally N = 1 supergravity, the phenom enologically successful e ective eld theory below the Planck scale [5]. We focus on models where supersymmetry breaking occurs in a hidden' sector and is communicated to the visible sector through gravitational interactions.

M eanwhile on the cosm ological front, the discovery by COBE of temperature uctuations in the CMB on angular scales larger than the causal horizon at (re)combination has provided strong indirect support for in ation. The power spectrum of the uctuations is consistent with a scaleinvariant prim ordial perturbation, and the statistics with a random G aussian eld, both as predicted by in ation [15]. Thus the spectrum of scalar density perturbations can be norm alized directly to COBE (taking into account any gravitational wave component which would also contribute to the CMB anisotropy). The prim ordial spectrum is modiled on scales smaller than the horizon size at matter-radiation equality by a transfer function' characteristic of the matter content of the universe [14]. The power spectrum inferred from observations of the clustering and motions of galaxies [16] can then be compared with the theory. Of particular interest is whether the problem of excessive small-scale power in a CDM universe (assuming scale-invariant prim ordial uctuations) [17] can be resolved by the spectral tilt' expected from supersymmetric in ation [9,18], rather than by invoking a component of hot dark matter. Ongoing and future observations of the CMB anisotropy on small angular scales [19] will provide an independent test of this possibility.

II. REQUIREMENTS OF THE INFLATIONARY POTENTIAL

The main theoretical problem in constructing an in ationary model based on supergravity is that the large cosm ological constant during in ation breaks global supersymmetry, giving all scalar elds a 'soff' mass of order the Hubble parameter [20]. In the simplest models, the in aton potential thus acquires a curvature too large to allow in ation to proceed for the required number of e-folds. The problem is characteristic of the scalar potential (along a F- at direction) of a singlet eld in the hidden sector having minimal kinetic terms, hence various solutions have been proposed which modify one or the other of these assumptions, e.g. introduction of non-minimal kinetic terms, or speci c interactions of the in aton with gauge elds, or identication of the in aton as a D- (rather than F-) at direction or even as a modulus eld [21]. Here, I would like to discuss a new mechanism leading to successful in ation in the low-energy elds so f such theories, the equations of motion have an infra-red xed point at which successful in ation can occur, even for minimal kinetic terms, along a F- at direction.

First, let us brie y review the necessary ingredients for successful in ation with a scalar potential V (). Essentially all model generating an exponential increase of the cosm ological scale-factor a satisfy the 'slow-roll' conditions [22]

$$-' \frac{V^{0}}{3H}; \frac{M^{2}}{2} \frac{V^{0}}{V}^{2} 1; j j M^{2} \frac{V^{\infty}}{V} 1;$$
(1)

where H $'_{p}^{p} \overline{V=3M^{2}}$ is the Hubble parameter during in ation, and the normalized Planck mass M $M_{Pl}=\frac{p}{8}$ '2:44 10⁸ GeV. In ation ends (i.e. a drops through zero) when ;j j' 1. The spectrum of adiabatic scalar perturbations is [22]

$${}^{2}_{H}(\mathbf{k}) = \frac{1}{150^{-2}} \frac{V_{2}}{M^{-4}} \frac{1}{2};$$
 (2)

where ? denotes the epoch at which a scale of wavenum ber k crosses the horizon' H 1 (m ore correctly, Hubble radius) during in ation, i.e. when aH = k. The CMB anisotropy measured by

COBE [15] allows a determ ination of the uctuation amplitude at the scale, k_{COBE}^{1} H_0^{1} , 3000 h⁻¹ M pc, corresponding roughly to the size of the presently observable universe, where h $H_0=100 \text{ km} \sec^{-1} \text{ M pc}^{-1}$ is the present H ubble parameter. The number of e-folds before the end of in ation when this scale crosses the H ubble radius is

$$N_{COBE} = N_{?} (k_{COBE})' 51 + \ln \frac{k_{COBE}^{1}}{3000h^{1} Mpc} + \ln \frac{V_{?}}{3 \ 10^{4} GeV} + \ln \frac{V_{?}}{V_{end}}$$

$$\frac{1}{3} \ln \frac{V_{end}}{3 \ 10^{4} GeV} + \frac{1}{3} \ln \frac{T_{reheat}}{10^{5} GeV} ; \qquad (3)$$

where we have indicated the numerical values anticipated for the various energy scales in our model. (Note that N_{COBE} is smaller than the usually quoted [22] value of 62 because the reheat temperature must be low enough to suppress the production of unstable gravitinos which can disrupt primordial nucleosynthesis [6].) The COBE observations sample CMB multipoles upto

20, where the th multipole probes scales around k¹ 6000h¹ l¹ M pc. The low multipoles, in particular the quadrupole, are entirely due to the SachsW olfe e ect on super-horizon scales (k¹ > k_{dec}¹ / 180h¹ M pc) at CM B decoupling and thus a direct measure of the prim ordial perturbations. However the high multipoles are (increasingly) sensitive to the composition of the dark matter which determ ines how the primordial spectrum is modiled through the growth of the perturbations on scales smaller than the horizon at the epoch of matter-radiation equality, i.e. for k¹ < k_{eq}¹ / 80h¹ M pc. Thus the normalization of the spectrum (2) to the COBE data is sensitive to its k dependence and also on whether there is a contribution from gravitational waves to the CM B anisotropy. The 4-year data is tted by a scale-free spectrum, ${}^2_{\rm H}$ k^{n¹}, n = 12 03, with Q m s = $15.3^{+3.8}_{-2.8}$ K [15]. For a scale-invariant (n = 1) spectrum, Q m s = 18 1.6 K, so assuming that there are no gravitational waves, the amplitude for a = 1 CDM universe is H = (1:94 0:14) 10⁵ [23]. Using eq.(2), the vacuum energy at this epoch is then given by

$$V_{COBE}$$
 ' (6:7 10^{16} GeV)⁴ _{COBE} ; (4)

showing that the in ationary scale is far below the P lanck scale [22]. A similar limit obtains, viz. $V_{COBE} < (4:9 \quad 10^{16} \text{ GeV})^4$, if the observed anisotropy is instead ascribed entirely to gravitational waves, the amplitude of which, in ratio to the scalar perturbations, is just [22]

$$r = 12:4$$
 : (5)

Thus it is legitim ate to study in ation in the context of an elective eld theory. The potential then has the generic form

$$V = {}^{4} [1 + c_n (=M)^{n}]$$
: (6)

In the usual model of chaotic in ation, one has =M 1 so the rst term on the rhs is negligible and and are small because they are proportional to $(=M)^2$. A lternatively may start with a vev much smaller than the P lanck scale during in ation, in which case the smallness of V⁰ and V⁰, and hence and , results from the relative smallness of the second term on the rhs.

To take into account both cases, let us expand the (slow ly varying) potential about the value in in atom eld space at which the observed density uctuations are produced. W riting = $^+$ (in units of M) we have

$$V() = {}^{4} {}^{1}_{1} + c_{1} {}^{2}_{1} + c_{2} {}^{2}_{2} + c_{3} {}^{3}_{3} + c_{4} {}^{4}_{4} + \dots$$
(7)

Here we have factored out the overall scale of in ation , which we have seen must be small relative to the Planck scale M. The constraints on the parameters in the potential following from the slow-roll conditions (1) are therefore

$$c_1$$
 1; c_2 1; c_3^{\sim} 1; $c_4^{\sim 2}$ 1::: (8)

The rst test for an in ationary model is whether these conditions are naturally satis ed. M any complicated models have been proposed which purport to do so [21], although this is not always evident on closer exam ination. We consider here the simplest possibility employing a single in aton eld in minimal supergravity.

III.NATURAL SUPERGRAVITY INFLATION

In supersymmetric theories with a single supersymmetry generator (N = 1), complex scalar elds are the lowest components, ^a, of chiral super elds ^a which contain chiral fermions, ^a, as their other component. (W e will take ^a to be left-handed chiral super elds so that ^a are left-handed fermions.) M asses for elds will be generated by spontaneous symmetry breaking so that the only fundamental mass scale is the P lanck scale, M. (This is aesthetically attractive and also what follows if the underlying theory generating the elective low-energy supergravity theory follows from the superstring.) The N = 1 supergravity theory describing the interaction of the chiral super elds is specified by the K ahler potential

$$G(; Y) = d(; Y) + \ln jf()j^2;$$
 (9)

which yields the scalar potential

$$V = e^{d = M^{2}} F^{A_{Y}}(d_{A}^{B})^{1} F_{B} = 3\frac{jf^{2}}{M^{2}} + D \quad \text{term s};$$
(10)

where

$$F_{A} = \frac{\varrho_{f}}{\varrho_{A}} + \frac{\varrho_{d}}{\varrho_{A}} + \frac{f_{A}}{M^{2}}; \qquad d_{A}^{B} = \frac{1}{\varrho_{A}^{B}} + \frac{\varrho_{A}^{2}}{\varrho_{A}^{A}} + \frac$$

Here the function d sets the form of the kinetic energy term s of the theory

$$L_{kin} = \frac{\theta^2 d}{\theta_A \theta_Y^B} \theta_A \theta_Y^B;$$
(12)

while the superpotential f determ ines the non-gauge interactions of the theory. For canonical kinetic energy term s, $d = \begin{bmatrix} p \\ A \end{bmatrix}_{A}^{Y} \begin{bmatrix} a \\ A \end{bmatrix}_{A}^{A}$, the potential takes the relatively simple form

In order for there to be a period of in ation, it is necessary for at least one of the term s $j_{e_B}^{\underline{e}f}$ jto be non-zero. How ever, these are precisely the order parameters for supersymmetry so this corresponds to supersymmetry breaking during in ation. While there are several possible mechanisms for such breaking, it su ces for the purposes of this discussion to simply assume that one of the term s has nonvanishing value ⁴, where denotes the supersymmetry breaking scale. Now expansion of the exponential in eq.(13) shows that $c_2 = 1$ and $c_4 = 1$ in eq.(7), in conject with the requirement (8) for successful in ation. We see that the problem can be traced to the presence of the overall factor involving the exponential in the scalar potential (13).

In ref. [9] we suggested that in theories with moduli the problem is easily avoided. Moduli are elds in superstring theories which, in the absence of supersymmetry breaking, have no potential. The moduli vevs serve to determ ine the fundam ental couplings of the theory and for the moduli of interest here they appear in the superpotential only in combination with non-moduli elds, serving to determ ine the latter's couplings in term s of their vevs. We argued [9] that the quadratic term s in the potential involving the non-moduli elds such as the in aton would be absent for special values of these vevs and, since the resultant potential would drive in ation, just this desired con guration would come to dominate the nal state of the universe. Subsequently we realized [1] that it is not even necessary to invoke such an anthropic principle' because there is a quasi- xed point in the evolution of the moduli. As we discuss below, this ensures, for initial values in the basin of attraction of the xed point, that the cancellation of the quadratic terms applies, ensuring that condition (8) is satis ed. Now although the moduli have a at potential in the absence of supersymm etry breaking, once supersymmetry is broken they may acquire a potential through the moduli dependence of the d function in the scalar potential (10). This is potentially disastrous because such a potential would drive the moduli vevs away from the value needed to cancel the quadratic in aton term . However the kinetic term often has a larger symmetry than the full Lagrangian; for example the canonical form has an SU (N) symmetry where N is the total number of chiral elds. In this case there will be m any m oduli left m assless even when supersymmetry is broken because they will be (pseudo) Goldstone modes associated with the spontaneous breaking of this symmetry. These moduli can play the role discussed above eliminating the quadratic term in the in aton potential [1].

The mechanism proposed in ref. [1] applies to a large class of models, the only condition being that the kinetic term does indeed have a sym metry leading to pseudo-G oldstone modes. We have given [1] two specic examples to illustrate the idea in detail, one for the case where the kinetic term has a larger sym metry than the full Lagrangian, and another where the potential discussed above follows from a sym metry of the full theory. In both cases the eld potential is of the general form

$$V(j^{*}j') = {}^{4} 1 + j^{*}j' + j^{*}j^{4} + j^{*}j^{4} + \dots$$
(14)

where further terms have been added in the expansion of V. The cubic term may arise from a cubic term in the superpotential [9]; this is allowed if the additional (U (1)) symmetry of the eld in an R-symmetry. (A lternatively there may be another modulus with U (1) charge such that a cubic term can appear in the kinetic function d.) If the cubic term is not present, then the quartic term, which is always allowed in the kinetic term by the SU (2) and U (1) symmetries of the model, will dom inate. Note that the parameters , and are all naturally of order unity.

For successful hew' in ation, we are interested in initial conditions which lead to $j^{\sim}j$ being sm allbut there is nothing which constrains the initial conditions of '. However since the potential (14) has an infrared xed point with $^{\sim} = ' = 0$, any initial value of $^{\sim}$ and ' will be driven there if they are within the domain of attraction, given (for positive) by

$$\frac{2}{2} \frac{3}{2} \frac{j}{4} 1 + \frac{4}{9} \frac{2}{j} \frac{2}{5} j^{2} j^{2}; \qquad (15)$$

Thus, without any ne tuning of the initial conditions (beyond the condition that the elds lie in this dom ain of attraction), the elds are driven to xed values and the potential becomes a constant, driving a period of in ation. (We have chosen to be positive, while should be negative if it is to lead to an in ationary potential.) Moreover this xed point corresponds to a point of in ection in the potential which is unstable with respect to small perturbations. Thus in ation is naturally term inated by a new mechanism as follows. The equations of motion for ' and j~jare

so while ' is positive, the elds are driven to the xed point and in ation begins. However ' has uctuations of order the Hawking temperature of the De Sitter vacuum, $T_H = H = 2$, so should it uctuate and become negativ, the elds will be driven away from the xed point thus ending in ation. (For negative, the reverse would be the case.) The initial conditions for this stage are ';j~j H; thereafter, as we see from eq.(16), jj will grow more rapidly than ' and the cubic term in the potential will soon dom inate.

There are two distinctive features of the potential (14) which ensure that, after the transition to positive ', there will be an in ationary period yielding density uctuations of the magnitude observed. The rst is that this potential has a very small gradient in the neighbourhood of the origin in eld space so it generates a long period of slow-roll in ation during which quantum uctuations are naturally small. The second feature is that the full potential, including higher order terms, is governed by an overall scale, . The reason is that the potential arises from the d term of eq.(9) which, in the absence of supersymmetry breaking, gives rise to the kinetic term and thus does not contribute to the potential, vanishing when derivatives are set to zero. Thus the potential is proportional to the (fourth power of the) overall supersymmetry breaking scale, . This scale is plausibly of $O(10^{14})$ G eV during in ation [9] and, in conjunction with the small slope, correctly yields the required magnitude of density uctuations.

IV. IM PLICATIONS FOR LARGE-SCALE STRUCTURE AND CMB AN ISOTROPY

The in ationary period following from a potential of the form (14) with no quadratic term (and = 4) has been closely studied earlier [9]. The eld value when perturbations of a given scale cross the Hubble radius is obtained by integrating the equation of motion (16) back from the end of in ation, which occurs at \sim_{end} ' M =6j jwhen = 1. Thus $\sim_{?}$ ' M =3j jN_? (k) + 2] and using eq.(3) we nd a logarithm ic (squared) deviation from scale invariance for the scalar perturbations,

$${}^{2}_{H}(\mathbf{k}) = \frac{9^{2}}{75^{2}} \frac{4}{M^{4}} [N_{2}(\mathbf{k}) + 2]^{4} :$$
(17)

This corresponds to a 'tilted' spectrum , $\frac{2}{H}$ (k) / k^{n 1}, with

$$n(k) = 1 + 2$$
 $6 \frac{N_{2}(k)}{N_{2}(k) + 2};$ (18)

i.e. n ' 0:92 for N₂ = 51 corresponding to the scales probed by COBE [9]. We emphasize that a leading cubic term in the potential gives the maximal departure from scale-invariance. The slope of the potential is tiny, = $1=18^{2} (N_{2} + 2)^{4}$ ' 7:0 10^{9} ², but its curvature is not:

= $2=(N_2 + 2)'$ 0.038. Consequently, although the spectrum is tilted, the gravitational wave background (5) is negligible. Furtherm one the tilt would be greater if N₂ is smaller, for example if there is a second epoch of therm alin ation' when the scale-factor in ates by 20 e-folds [24] so that the value of N₂ appropriate to COBE is 31 rather than 51, and n ' 0.88. We norm alize the spectrum (17) to the CMB anisotropy using the expression for the (ensem ble-averaged) quadrupole,

$$\frac{hQ_{\rm Im\,s}\dot{z}^2}{T_0^2} = \frac{5C_2}{4} = \frac{5}{4} \frac{5^{-2}}{0} \frac{1}{k} \frac{dk}{k} \dot{z}_2^2 - \frac{2k}{H_0} - \frac{2}{H} (k); \qquad (19)$$

where j_2 is the second-order spherical Bessel function. According to the COBE data [15,23], $Q_{ms}' 20 = 2$ K for n' 0.9 which xes the in ationary scale to be

$$\frac{1}{M}$$
 ' 2.8 0.14 10⁴ j j¹⁼² ; (20)

consistent with general theoretical considerations of supersymmetry breaking [9].

The spectrum of the (dimensionless) rm s m ass uctuations after m atter domination (per unit logarithm ic interval of k) is given by [14]

² (k)
$$\frac{k^{3}P(k)}{2^{2}} = {}^{2}_{H}(k) T^{2}(k) \frac{k}{aH}^{4}$$
; (21)

where P(k) is the usual power spectrum and the 'transfer function' T(k) takes into account that linear perturbations grow at di erent rates depending on the relation between their wavelengths, the Jeans length and the Hubble radius. For CDM we use [14],

$$T(k) = {}^{h}_{1} + {}^{n}_{ak} + (k)^{3=2} + (k)^{2} {}^{o i}_{1=}$$
(22)

with a = 6:4 ¹ h ¹ M pc, b = 3 ¹ h ¹ M pc, c = 1:7 ¹ h ¹ M pc and = 1:13, where the Shape parameter' is ' he ² N [25].

The cosm obgical parameters adopted for 'standard' CDM are h = 0.5 and N = 0.05 [14]. However, observational uncertainties still perm it the Hubble parameter to be as low as 0.4 [26]. A loo the nucleon density parameter $_{\rm N}$ may be as high as 0.033 h², taking into account the recent upward revision of the ⁴He mass fraction [27]. We show P (k) for $_{\rm N}$ = 0.05; 0.1 and h = 0.4; 0.5 in gure 1, having taken account of non-linear gravitational e ects at sm all scales using the prescriptions of ref. [25] (PD) and ref. [28] (BG). The tilt in the prim ordial spectrum which increases logarithm ically with decreasing spatial scales allows a good ton scales of 1 100 Mpc to the data points obtained [29] from the angular correlation function of APM galaxies, if the Hubble parameter (nucleon density) are taken to be at the lower (upper) end of the allowed range. (Only 1 statistical errors are shown; at k < 0.05h M pc¹, there are also large system atic errors [29] so the apparent discrepancy here needs further investigation.) Note that the expected characteristic \shoulder" at small scales due to the non-linear evolution is clearly visible in the APM data. Other studies of tilted spectra [30,31] focussed on the linear evolution and/or used a compendium [25] of data from dierent surveys (having dierent system atic biases) rather than one set of high quality data. We conclude that the problem with the excess power on sm all scales in the COBE-norm alized standard CDM model [17] is naturally alleviated in supergravity in ation as anticipated earlier [9,18], with no need for a component of hot dark matter.

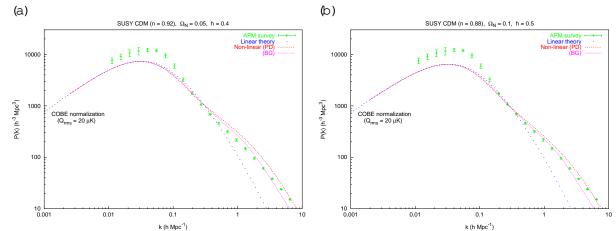

FIG.1. Predicted non-linear power spectra of density uctuations in cold dark matter, normalized to COBE and compared with data inferred from the APM galaxy survey.

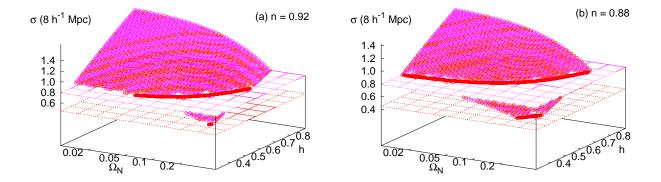

FIG.2. Predicted variance of the density eld sm oothed over a sphere of radius $8 h^{-1} M pc$, compared with observational limits (horizontal planes) inferred from rich clusters of galaxies.

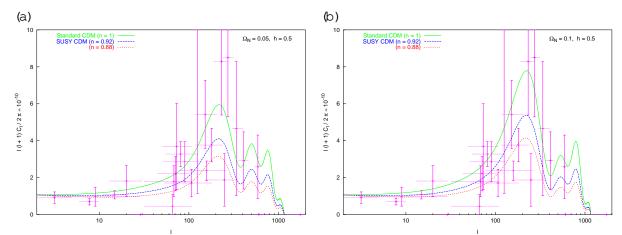

FIG.3. Predicted angular power spectra of CMB anisotropy, normalized to COBE and com – pared with data from current ground-based and balloon experiments.

W e also calculate som e averaged quantities of observational interest. A common measure of large-scale clustering is the variance, (R), of the density eld smoothed over a sphere of radius R, usually taken to be 8 h 1 M pc, given in terms of the matter density spectrum by

$${}^{2}(\mathbf{R}) = \frac{1}{H_{0}^{4}} {}^{\mathbf{Z}_{1}}_{0} W {}^{2}(\mathbf{k}\mathbf{R}) {}^{2}_{H}(\mathbf{k}) T {}^{2}(\mathbf{k}) k^{3} d\mathbf{k};$$
(23)

where a 'top hat' sm oothing function, W (kR) = $3 \frac{\sin (kR)}{(kR)^3} = \frac{\cos (kR)}{(kR)^2} \frac{i}{(kR)^2}$, has been used. As seen from gure 2, the observational value of (8h⁻¹ Mpc) = $0.60^{+0.19}_{-0.15}$ (95% c.l.), inferred from the abundances of rich clusters of galaxies [17,32] favours high tilt, high N and low h.

A nother interesting quantity is the sm oothed peculiar velocity eld or bulk ow',

$$V_{v}^{2}(\mathbf{R}) = \frac{1}{H_{0}^{2}} \int_{0}^{L_{1}} W^{2}(\mathbf{k}\mathbf{R}) e^{(12h^{-1}k)^{2}} \int_{H}^{2} (\mathbf{k}) T^{2}(\mathbf{k}) k dk ; \qquad (24)$$

where, for direct comparison with observations, we have applied an additional gaussian sm oothing on $12h^{1}$ Mpc. For the two models shown in gure 1 we nd,

$$_{v}$$
 (40h ¹ Mpc) = 383 38 km sec¹ (N_{COBE} = 51; _N = 0:05; h = 0:4);
= 320 32 km sec¹ (N_{COBE} = 31; _N = 0:1; h = 0:5): (25)

to be compared with the POTENT III measurement of $_{v}$ (40h ¹ Mpc) = 373 50 km sec¹ [33]. We do not consider constraints coming from the abundances of collapsed objects at high redshift such as Lym an- clouds and quasars [31,35], as this involves many astrophysical uncertainties at present.

A n unam biguous test of the model is the predicted CMB an isotropy. To compute this accurately requires numerical solution of the coupled linearized Boltzm ann, Einstein and uid equations for the perturbation in the photon phase space distribution. We use the COSM ICS computer codes [34] to calculate the angular power spectrum using the primordial scalar uctuation spectrum (17). The rst 1000 multipoles are plotted in gure 3, taking $_{\rm N} = 0.05$; 0.1, along with a compendium of recent observations [19], and the prediction of standard CDM is shown for comparison. The height of the rst Doppler peak' is preferentially boosted for the higher value of $_{\rm N}$ and this is favoured by the CMB observations in conjunction with the large-scale structure data, as has been noted independently [35]. For a given value of $_{\rm N}$ the e ect of the spectral tilt is to suppress the heights of all the peaks. A lthough present ground-based observations are inconclusive, this prediction will be denitively tested by the forthcom ing satellite-borne experiments, MAP and COBRAS/SAMBA.

In sum m ary, in ationary m odel building has received a new impetus as a consequence of the impressive progress in observations of large-scale structure and CMB anisotropy which can discrim in nate between such m odels. It appears quite plausible that within the next decade such astronom ical data will provide a direct window to physics at the uni cation scale.

ACKNOW LEDGM ENTS

I thank Y M. Cho and Jihn K in for the invitation to participate in this stimulating meeting, and Jennifer A dam s and G raham Ross for allowing me to present our joint work.
