PARTICLE DIFFRACTION

AT HIGH ENERGIES

V ladim ir A .P etrov

Institute for High Energy Physics, 142284, Protvino, Russia

D i raction of light was described by Italian physicist G rim aldiin his book published in 1665. One of the rst (and wrong) explanations was given by Newton, who also contributed a lot into the experimental discovery and the study of new di ractive phenomena. Newton's explanation of light di raction was based on a corpuscular theory of light. However, in the beginning of the X IX century the fam ous \Poisson's puzzle" (the prediction of a light spot in the center of the geometric shadow, a consequence of the Fresnel's wave theory of light) and its experimental con rm ation a rm ed wave nature of light for hundred years, until E instein and Stark disovered that light demonstrated particle properties as well.

From the observation of the di ractive pattern one can judge about the size and the shape of the scatterer. At present this eld is a highly developed branch of applied optics, with innum erous uses and applications in technology.

Since a fundamental guess made in 1923 by Louis de Broglie on wave properties of matter, con med experimentally by Stem in Germany and by Davisson and Germer in the USA, this peculiar quantum behaviour has found a lot of applications. The main lesson was that undulatory or corpuscular properties are inherent to all natural phenomena, though one or another aspect may dominate dependent on conditions.

H igh energy physics is usually synonym ous to particle physics". New phenomena in this eld are related either to the discovery of new particles or to some typical particle | like e ects as, say, B jorken scaling in deeply inelastic scattering, or high p_2 jets, or else. In space-time language these regimes mean the probe of small distances.

However there is a eld in high energy physics which even at very high energies is not related to short distances but rather to large (at nuclear scales) distances. Such are phenom ena like small angle hadron scattering (elastic or inclusive). It is well known feature of these processes that the angular probability distribution of the scattered particle shows a typical di ractive pattern with a maximum at zero angle followed by the dip and, in some cases, second maximum .¹ Here we deal with wave properties of hadrons.

From such a distribution one can conclude about the size of the scatterer, or, more properly, the \interaction region".

An interesting feature of these \size m easurem ents" is that the size appears to be energy dependent. This would correspond to dependence of the visible size of a lit object on the frequency (or the wavelength) of falling light.

M odem theory lim its this energy dependence of the transverse (w.r.t. the incident beam (s)) size by a \max axim alradius", R₀ (1=m) log E, where m is the pion m ass (1=m) is the fam ous Yukawa radius), and E is the center-of-m ass energy. Logarithm ic dependence of the strong interaction transverse range was derived by W. Heisenberg in the fram ework of som em odel of high-energy collisions as early as in 1952. Later M. Froissart obtained the sam e lim it on m ore general grounds in 1961, and, nally, A. M artin gave in 1966 a rigorous proof based on the rst principles of quantum eld theory. Low er bounds on the strong interaction radius were given by A. Logunov and N guen Van H ieu [2].

Experiments con m the energy dependence of the transverse interaction range which weakly grows with energy (but is far below the Heisenberg-Froissart-M artin radius R_0).

W hereas one can extract the transverse interaction radius from the differential cross section, what can one say about the longitudinal size of the interaction region or the interaction time?

Theoretically, the problem was addressed in an early paper by W igner in the framework of non-relativistic quantum mechanics [3]. One can also mention papers [4]. In these papers the longitudinal range was related to some derivatives of the phase of the scattering amplitude. Unfortunately this procedure needed the know ledge of the o -m ass-shell amplitude.

A di erent approach was used in Ref. [5], where the e ective longitudinal

¹Interesting discussion of \high energy di raction" is contained in Ref.[1].

size was estimated to grow with energy as fast as $E = m^2$. This is very interesting because at energies of the future Large Hadron Collider the longitudinal interaction range can achieve atom ic scales.

Unfortunately at present no way to extract this size from the measured characteristics is known. Some hopes refer to nuclear targets where more than one nucleons could be involved into interaction with a \long"projectile.

If one in agines that the size and the shape of the interaction region are extracted from a complete enough set of experim ental data, then the problem is to understand the inform ation obtained on the basis of present theoretical fram eworks. Let us consider a high energy collision in the laboratory fram e when one hadron (nucleon, or nucleus in practice) is at rest (\observer") while another one ies on. Energy dependence then m ay be m ainly related to the projectile, which seem s to be longer in the longitudinal direction and larger in the transverse ones.

Is not it in an apparent contradiction with the special relativity which predicts that the longitudinal size should <u>decrease</u> with the growing velocity while the transverse ones remain intact? In fact there is no contradiction. The matter is that a particle is a quantum object which is hardly a rigid sphere as one could in agine in a classical manner. This is a quantum system which uctuates into various virtual states which have their own lifetimes and sizes. The latters are by no means Lorentz invariant. Moreover, the maximal radius, R_0 , refers, in the transverse plane, to distances between the points taken at dimensional times, and this is not the same as the \instantaneous size" of special relativity.

Quantum uctiations have speci c features which should be related to modern view sofm icrostructure of particles. For strongly interacting particles this is quantum chromodynamics, or shortly, QCD.

QCD gave many insights into understanding of phenomena, related to short distances (hard processes").

Unfortunately, QCD is still not very e ective when applied to large distance (\soff" or di ractive) processes. In the fram ework of Regge approach these are some attempts to obtain the leading Regge trajectory perturbatively. In spite of some progress serious problems remain to be resolved. One of these problems is that the method of quantum perturbations, which works nicely at short distances, fails at large distances. This is related to the con nem ent problem, i.e. absence of quarks and gluons in asym ptotic states detected by the measuring apparatus. It m ay well happen that \particle" approach, where quarks and gluons take part in the process of scattering as constituents of colliding hadrons, is not relevant to di ractive phenom ena, which are more adequate to wave aspects. In this case it could be more appropriate to study some (gluon)

eld con gurations which are beyond reach of usual perturbative treatment. That is why projects like TOTEM at LHC should be considered not just as an inevitable price for a precise measurement of lum inosity but rather as a unique source of information about sizes and shape of the hadron interaction region. Explanation and description of these is a form idable task for QCD.

As a conclusion I should like to stress again that the experimental study of di ractive hadron scattering is in portant and interesting because:

1. Energy-dependent shape of the interaction region is interesting both from general quantum and relativistic points of view;

2. The interpretation of data can promote the new development of QCD at large space-time scales. This is de nitely related to the long-standing con nement problem, which, as we see, is in portant not only at low energies.
