yasuda@phys.metro-u.ac.jp

Abstract

Superkamiookande atmospheric neutrino data for 414 days are analyzed in the framework of three flavor oscillations with mass hierarchy. It is shown that the best fit point is very close to the pure maximal δ case and $m^2 \approx 7 \times 10^{-3}$ eV². The allowed region at 90 % CL is given and the implications to the long baseline experiments are briefly discussed. It is also shown that the threefold mixing model fits to the data of atmospheric neutrinos and the reactor experiments for $m^2 = 1 \times 10^{-3}$ eV².

1. Introduction

Recent atmospheric neutrino data of the Superkamiookande experiment^{11,12,17} provide very strong evidence for neutrino oscillations. The original analysis by the Superkamiookande group is based on the two flavor framework. Despite the constraints from the reactor experiments^{27;1,2}, there can be small mixing between

μ and τ in the atmospheric neutrinos. To estimate the oscillation probability of $\mu \rightarrow e$ or $\mu \rightarrow \tau$ in the long baseline experiments^{23,21,16,25,26}, therefore, it is important to know the allowed region of the mixing parameters at a certain confidence level. In this talk I present a three flavor analysis of the Superkamiookande atmospheric neutrino data for 414 days¹¹. Some of the contents of this presentation overlaps with Lisi's talk^{18;7}.

2. Three flavor analysis of the Superkamikande atmospheric neutrino data

To evaluate the number of events, we integrate numerically the Schrödinger equation

$$i \frac{d}{dx} \begin{pmatrix} 0 & e(x) \\ \bar{\nu}_e(x) & A(x) \end{pmatrix} = \frac{\hbar^2}{U} \text{diag}(0; E_{21}; E_{31}) U^{-1} + \text{diag}(A; 0; 0) \begin{pmatrix} 0 & e(x) \\ \bar{\nu}_e(x) & A(x) \end{pmatrix}; \quad (1)$$

where

$$U = \begin{pmatrix} 0 & U_{e1} & U_{e2} & U_{e3} \\ \bar{\nu}_e & U_1 & U_2 & U_3 \\ 0 & U_1 & U_2 & U_3 \end{pmatrix}$$

$\bar{\nu}_e$ is the MNS mixing matrix¹⁹, E is the neutrino energy, A is $\frac{p}{2G_F N_e(x)}$ stands for the matter effect^{20,28} in the Earth, $E_{ij} = m_{ij}^2/2E$, $m_{ij}^2 = m_i^2 - m_j^2$. We assume without loss of generality that m_{21}^2 has the smallest absolute value of the mass squared difference. To account for the solar neutrino deficit³ we assume that m_{21}^2 is of order 10^{-5} eV^2 or $10^{-10} - 10^{-9} \text{ eV}^2$. On the other hand, the zenith angle dependence in the atmospheric neutrino anomaly requires that the larger mass squared difference be of order $10^{-3} - 10^{-2} \text{ eV}^2$. So the pattern of the mass squared differences has hierarchy and can be classified into two cases which are depicted in Fig. 1.

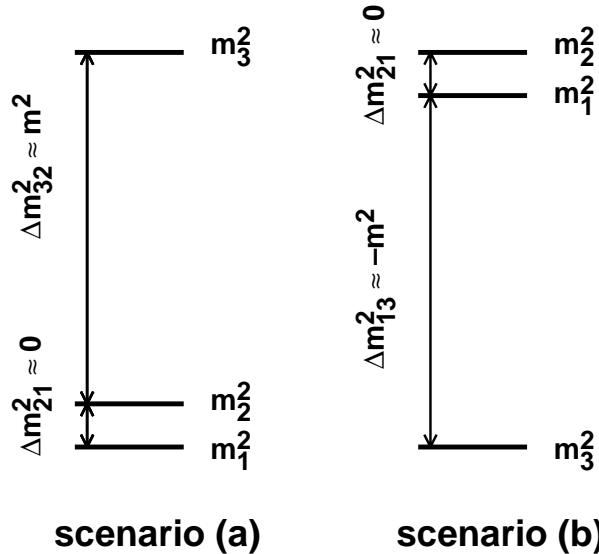

Fig. 1 The hierarchical neutrino mass squared differences. The scenarios (a) and (b) are related by exchanging $m^2 \leftrightarrow -m^2$. They are equivalent in vacuum but physically inequivalent in matter.

The eigenvalues of the Schrodinger equation (1) are given by⁴

$$\begin{aligned} \lambda_1 &= 3 + (2\pi)^2 \frac{p^2}{3} \cos(\theta = 3) \\ \lambda_2 &= 3 - (2\pi)^2 \frac{p^2}{3} \cos((\theta - \pi) = 3) \\ \lambda_3 &= 3 - (2\pi)^2 \frac{p^2}{3} \cos((\theta + \pi) = 3); \end{aligned} \quad (2)$$

where

$$\begin{aligned} p^2 &= \frac{2^3 - 9 + 27}{2(2^2 - 3)} \\ E_{31} + E_{21} + A_h &= E_{31} + E_{21} + A_h (1 - jU_{e3}) + E_{21} (1 - jU_{e2})^i \\ E_{31} E_{21} A_h jU_{e1}^2 & \end{aligned}$$

Under our assumption that $m^2 < 10^5 \text{ eV}^2$, in the contained atmospheric neutrino events ($0.1 \text{ GeV} \leq E \leq 100 \text{ GeV}$) we have $|E_{21}L| \ll 1$ for downward going events (L is the neutrino path length and $L < 500 \text{ km}$), and $|E_{31}| \approx |E_{32}| \approx |E_{21}|$ for upward going events. Thus the eigenvalues in (2) with $m_{21}^2 \ll 10^5 \text{ eV}^2$ or 10^{10} eV^2 are almost the same as those with $m_{21}^2 = 0$ to good precision, i.e., the matter effects are much more important than the smaller mass squared difference $m_{21}^2 < 10^5 \text{ eV}^2$ in the atmospheric neutrino problem. Hence we can safely ignore m_{21}^2 in the following discussions. In the limit $m_{21}^2 = 0$ the mass matrix on the right hand side of (1) becomes

$$D^h U (U^{-1} = 0) \text{diag}(0; 0; E_{31}) U^{-1} (U^{-1} = 0) + \text{diag}(A; 0; 0) D^{-1}; \quad (3)$$

where $D = \text{diag}(e^{i\alpha}; 1; 1)$, we have used the standard parametrization²⁴ of the MNS mixing matrix¹⁹

$$U = e^{i\alpha} \text{diag}(e^{i\beta}; 1; e^{i\gamma}) e^{i\delta} \text{diag}(e^{i\epsilon}; 1; e^{i\zeta}) e^{i\eta} \text{diag}(e^{i\phi}; 1; e^{i\psi})$$

and

$$U = \begin{pmatrix} 0 & 1 & 0 \\ \frac{B}{C} & 0 & i \\ \frac{B}{C} & i & 0 \end{pmatrix}; \quad U^{-1} = \begin{pmatrix} 0 & 0 & 1 \\ \frac{B}{C} & 0 & 1 \\ \frac{B}{C} & 0 & 0 \end{pmatrix}; \quad U^{-1} = \begin{pmatrix} 0 & 1 & 0 \\ \frac{B}{C} & 0 & 0 \\ \frac{B}{C} & 0 & i \end{pmatrix};$$

are the Gell-Mann matrices. As we see in (3), U^{-1} drops out and so does A , as appears only in the overall phase of the oscillation amplitude $A (e^{i\phi})$. Putting $m^2 = m_{31}^2$, therefore, we are left with the three parameters $(m^2; \epsilon; \eta)$.

The way to obtain the numbers of events is exactly the same as in Foot et al.⁸, and we refer to Foot et al.⁸ for details. In Foot et al.⁸ two quantities have been introduced to perform a χ^2 analysis. One is the double ratio^{15;10}

$$R = \frac{(N_e - N_{e\text{osc}})_{\text{obs}}}{(N_e + N_{e\text{osc}})_{\text{obs}}}$$

where the quantities N_e are the numbers of e-like and -like events. The numerator denotes numbers with oscillation probability obtained by (1), while the denominator the numbers expected with oscillations switched off. The other one is the quantity on up-down flux asymmetries for -like ($= e, \bar{\nu}_e$) events and is defined by

$$Y = \frac{(N^{0.2} - N^{+0.2})_{\text{obs}}}{(N^{0.2} + N^{+0.2})_{\text{obs}}};$$

where N^- denotes the number of -like events produced in the detector with zenith angle $\cos < 0$, while N^+ denotes the analogous quantity for $\cos > 0$, where is defined to be positive. Superkamiookande divides the $(-1;+1)$ interval in $\cos \theta$ into five equal bins, so we choose $\Delta\theta = 0.2$ in order to use all the data in the other four bins. Thus χ^2 for atmospheric neutrinos is defined by

$$\chi^2_{\text{atm}} = \sum_{E=1}^2 \frac{R^{\text{SK}} - R^{\text{th}}}{R^{\text{SK}}}^2 + \frac{Y^{\text{SK}} - Y^{\text{th}}}{Y^{\text{SK}}}^2 + \frac{Y_e^{\text{SK}} - Y_e^{\text{th}}}{Y_e^{\text{SK}}}^2;$$

where the sum is over the sub-G eV and multi-G eV cases, the measured Superkamiookande values and errors are denoted by the superscript "SK" and the theoretical predictions for the quantities are labeled by "th". In Foot et al.⁸ a χ^2 analysis has been performed using the quantities R and Y 's, or using Y 's only. Throughout this paper we use the quantities R and Y 's to get narrower allowed regions for the parameters. We have to incorporate also the results of the reactor experiments. We define the following χ^2 :

$$\chi^2_{\text{reactor}} = \sum_{j=1,12}^{\text{CHOOZ}} \frac{x_j - y_j}{x_j}^2 + \sum_{j=1,60}^{\text{Bugey}} \frac{x_j - y_j}{x_j}^2 + \sum_{j=1,8}^{\text{Krasnoyarsk}} \frac{x_j - y_j}{x_j}^2;$$

where x_i are experimental values and y_i are the corresponding theoretical predictions, and the sum is over 12, 60, 8 energy bins of data of CHOOZ², Bugey¹ and Krasnoyarsk²⁷, respectively. There are 6 atmospheric and 80 reactor pieces of data in χ^2_{atm} + χ^2_{reactor} and 3 adjustable parameters, m^2 , $\tan^2 \theta_{13}$ and $\tan^2 \theta_{23}$, leaving 83 degrees of freedom.

The best fit is obtained for $(m^2; \tan^2 \theta_{13}; \tan^2 \theta_{23}; \chi^2) = (7 \times 10^{-3} \text{ eV}^2, 1.1 \times 10^{-2}, 0.93, 71.8)$ for $m^2 > 0$ and $(7 \times 10^{-3} \text{ eV}^2, 1.5 \times 10^{-2}, 1.1, 71.4)$

for $m^2 < 0$, respectively. $\chi^2_{\text{min}} = (\chi^2_{\text{atm}})_{\text{min}} + (\chi^2_{\text{reactor}})_{\text{min}} = 4.2 + 67.2 = 71.4$ indicates that a fit to data is good for 83 degrees of freedom at the best fit point. The allowed region for m^2 with θ_{13}, θ_{23} unconstrained is given in Fig. 2, where $\chi^2_{\text{atm}} + \chi^2_{\text{reactor}} = (\chi^2_{\text{atm}} + \chi^2_{\text{reactor}})_{\text{min}} < 3.5; 6.3; 11.5$ corresponds to 1%, 90% CL and 99% CL, respectively. The allowed region for $|m^2|$ at 99% CL is $4 \times 10^{-4} \text{ eV}^2 < |m^2| < 1.7 \times 10^{-2} \text{ eV}^2$.

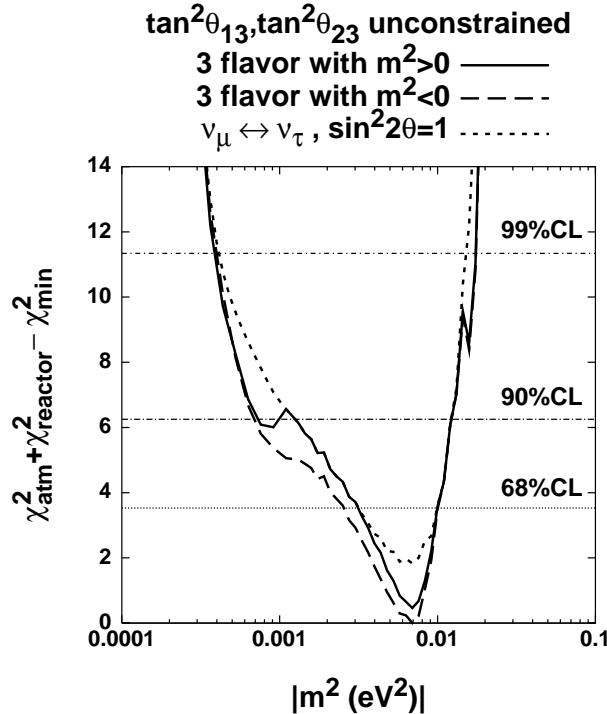

Fig. 2

Value of $\chi^2_{\text{atm}} + \chi^2_{\text{reactor}}$ $= \chi^2_{\text{atm}} + \chi^2_{\text{reactor}} = 71.4$. The solid, dash-dotted, dotted lines represent the scenarios (a), (b) and the two flavor case with mixing, respectively.

Using the same parametrization as that in Fogli et al.⁵, the results for the allowed region of the mixing angles (θ_{13}, θ_{23}) are given for various values of m^2 in Figs. 3 and 4. The results for $m^2 > 0$ (Fig. 3) and $m^2 < 0$ (Fig. 4) are almost the same. Notice that θ_{13} can be large in the region of m^2 where the CHOOZ data² give no constraint on θ_{13} .

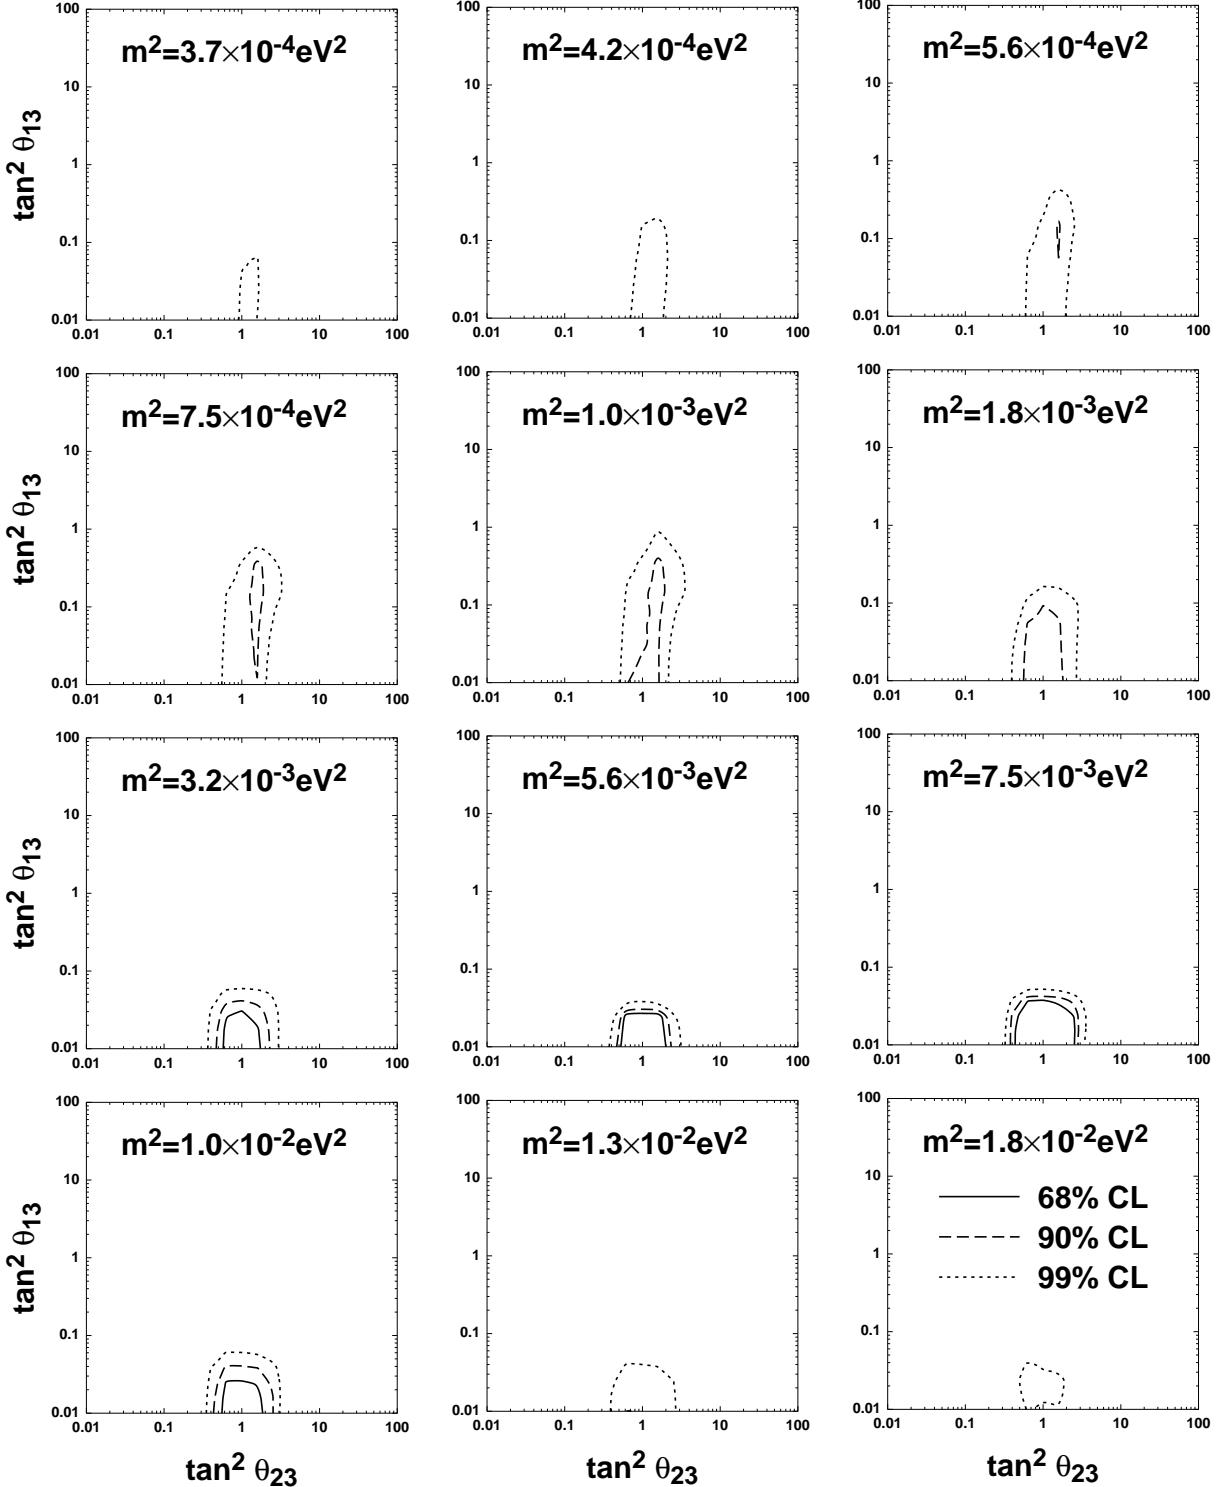

Fig. 3 The solid, dashed, dotted lines represent the allowed region at 68 % CL, 90 % CL, 99 % CL, respectively for scenario (a) in Fig. 1.

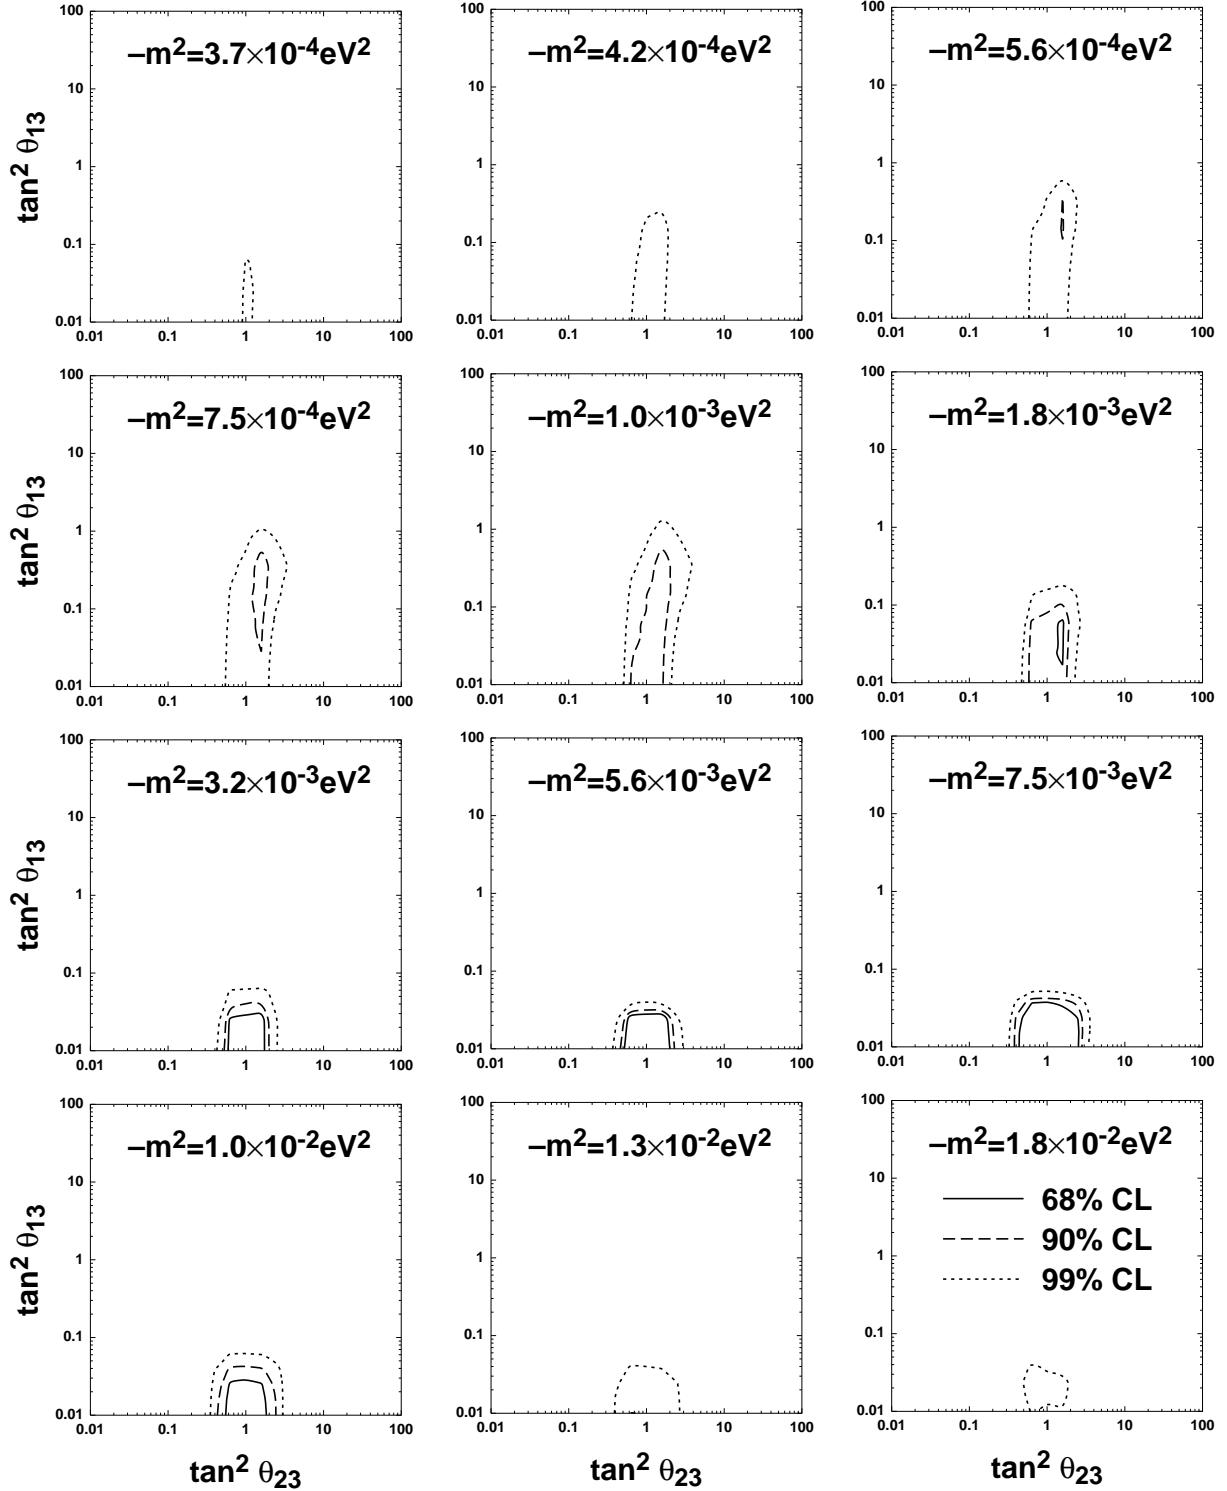

Fig. 4 As in Fig. 3, but the scenario (b) in Fig. 1 is assumed.

3. The implications to the long baseline experiments

In the present case with mass scale hierarchy the oscillation probability $P(\bar{\nu}_\mu \rightarrow \bar{\nu}_e)$ in vacuum is given by

$$P(\bar{\nu}_\mu \rightarrow \bar{\nu}_e) = 4|U_{e3}|^2 |U_{31}|^2 \sin^2 \frac{m^2 L}{4E} = S_{23}^2 \sin^2 2\pi_{13} \sin^2 \frac{m^2 L}{4E};$$

so that we observe that the factor $4|U_{e3}|^2 |U_{31}|^2$ corresponds to $\sin^2 2\pi_{13}$ in the two flavor framework. For each m^2 in Figs. 3 and 4 the maximal allowed values of $4|U_{e3}|^2 |U_{31}|^2$ have been evaluated and are shown in Figs. 5(a) and 5(b) in the two flavor plot ($\sin^2 2\pi_{13}$, m^2), respectively, where the regions which can be probed by K2K²³, MINOS²¹ and KamLAND^{26;25} are also given. The only promising channel for the K2K experiment is $\bar{\nu}_\mu \rightarrow \bar{\nu}_e$ disappearance, while MINOS might have a chance to see $\bar{\nu}_\mu \rightarrow \bar{\nu}_e$ appearance and KamLAND may be also able to observe $\bar{\nu}_e \rightarrow \bar{\nu}_e$ disappearance.

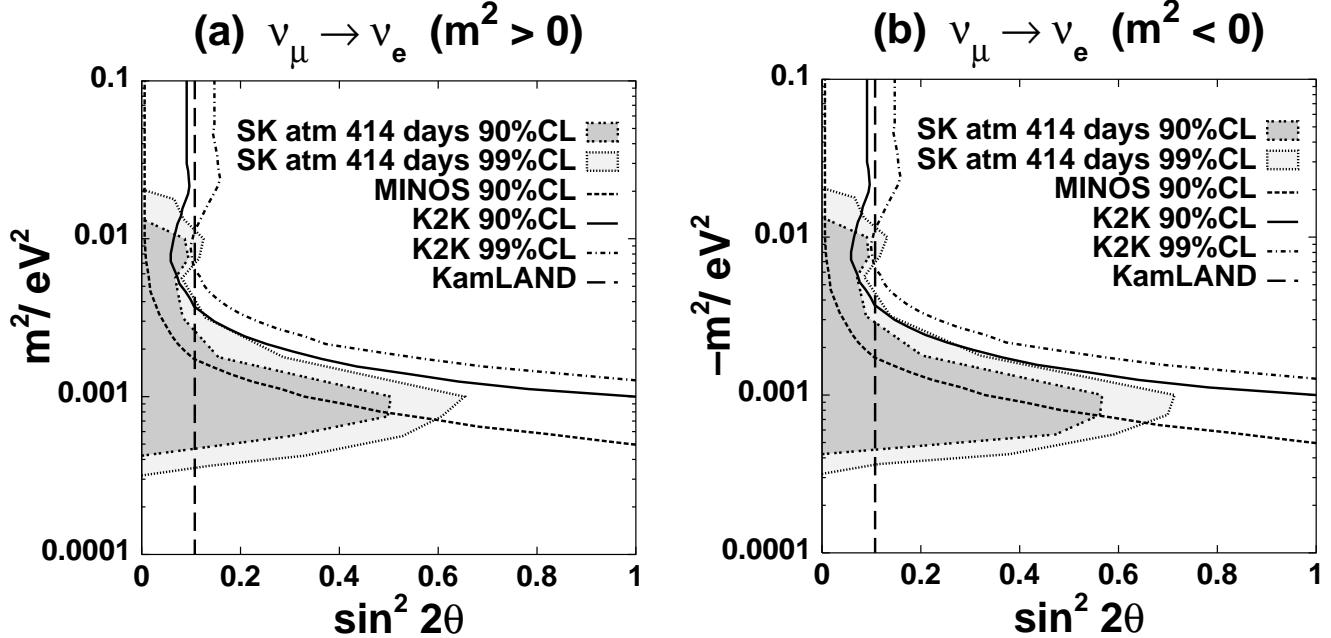

Fig. 5

Shadowed regions are allowed from the Super-Kamiokande atmospheric neutrino data for the scenario (a) (Fig. 5(a)) or (b) (Fig. 5(b)) in Fig. 1, respectively. The region which can be probed by the long baseline experiments (K2K, MINOS, KamLAND) is the right side of each line.

4. The threefold mixing model^{22,14,13}

Using (1) and (3), and redefining e^i we have

$$\begin{aligned}
 & \frac{i}{dx} \begin{pmatrix} 0 & 1 \\ e(x) & C \\ B(x) & A \\ 0 & 0 \end{pmatrix} \\
 = & e^{i_{23} - 7} e^{i_{13} - 5} \text{diag}(0; 0; E_{31}) e^{i_{13} - 5} + \text{diag}(A; 0; 0) e^{i_{23} - 7} \begin{pmatrix} 0 & 1 \\ e(x) & C \\ B(x) & A \\ 0 & 0 \end{pmatrix} \\
 = & e^{i_{23} - 7} e^{i_M - 5} \frac{E_{31} + A}{2} \text{diag}(1; 0; 1) - \frac{B}{2} \text{diag}(1; 0; -1) e^{i_M - 5} e^{i_{23} - 7} \begin{pmatrix} 0 & 1 \\ e(x) & C \\ B(x) & A \\ 0 & 0 \end{pmatrix};
 \end{aligned} \tag{4}$$

where M is the mixing angle in matter given by

$$\tan 2_M = \frac{E_{31} \sin 2_{13}}{E_{31} \cos 2_{13} - A}$$

as in the two flavor case^{20,28}, and

$$B = \frac{q}{(E_{31} \cos 2_{13} - A)^2 + (E_{31} \sin 2_{13})^2};$$

If we assume that the density of the Earth is approximately constant, then (4) can be integrated as

$$\frac{0}{B} \begin{pmatrix} 0 & 1 \\ e(L) & C \\ B(L) & A \\ 0 & 0 \end{pmatrix} = e^{i_{23} - 7} e^{i_M - 5} \text{diag}(e^{i_1}; 1; e^{i_1} e^{i_M - 5} e^{i_{23} - 7} \begin{pmatrix} 0 & 1 \\ e(0) & C \\ B(0) & A \\ 0 & 0 \end{pmatrix});$$

where

$$(L) = \frac{L}{2} (E_{31} + A - B);$$

The oscillation probability is given by

$$\begin{aligned}
 P(e^- \rightarrow e^-) &= 1 - \sin^2 2_M \sin^2 \frac{\Delta m^2}{2} \\
 P(e^- \rightarrow \nu) &= s_{23}^2 \sin^2 2_M \sin^2 \frac{\Delta m^2}{2} \\
 P(\bar{e} \rightarrow \bar{e}) &= 1 - \frac{4}{3} s_{23}^2 \sin^2 2_M \sin^2 \frac{\Delta m^2}{2} - \sin^2 2_{23} s_M^2 \sin^2 \frac{\Delta m^2}{2} + c_M^2 \sin^2 \frac{\Delta m^2}{2}
 \end{aligned} \tag{5}$$

One of the interesting applications is the behaviors of the oscillation probability (5) in the three flavor maximal mixing model^{22;14;13}, which is obtained by putting $\sin^2 \theta_{12} = \sin^2 \theta_{23} = \frac{1}{3}$, $\sin^2 \theta_{13} = \frac{1}{3}$, $\Delta m^2_{31} = 2 \times 10^{-3} \text{ eV}^2$ in the present parameterization. If $|j_E| \gg A$ then we see from (5) that the mixing angle θ_M becomes $\pi/2$, so we get from (5)

$$\begin{aligned} P(e^- \rightarrow e^-) &= 1 \\ P(\bar{\nu}_e \rightarrow \bar{\nu}_e) &= 1 - \sin^2 2\theta_{23} \sin^2 \frac{\Delta m^2_{31} L}{2} = 1 - \sin^2 \frac{\Delta m^2_{31} L}{2}; \end{aligned} \quad (6)$$

where we have used the fact

$$\frac{E_{31}L}{2} (1 + \cos 2\theta_{13}) = c_{13}^2 E_{31}L = \frac{2}{3} E_{31}L;$$

(6) indicates that the mixing becomes pure $\pm i$ with maximal mixing and this is why a fit of this model to the data becomes reasonably good for lower m_{31}^2 . On the other hand, if $|j_E| \ll A$, then θ_M becomes θ_{13} and we find again from (5)

$$\begin{aligned} P(e^- \rightarrow e^-) &= 1 - \frac{1}{2} \sin^2 2\theta_{13} = \frac{5}{9} \\ P(\bar{\nu}_e \rightarrow \bar{\nu}_e) &= 1 - \frac{1}{2} s_{23}^4 \sin^2 2\theta_{13} - \sin^2 2\theta_{23} s_{13}^2 \sin^2 \frac{AL}{3} + \frac{1}{2} c_{13}^2 \\ &= \frac{5}{9} - \frac{1}{3} \sin^2 \frac{AL}{3}; \end{aligned}$$

where we have used

$$\frac{AL}{2} (1 + \cos 2\theta_{13}) = c_{13}^2 AL = \frac{2}{3} AL;$$

Possibility with larger m_{31}^2 is excluded by the CHOOZ result², but a fit of this model to the atmospheric neutrino data themselves is reasonably good because of the factor $\sin^2(AL/3)$ accounts for the zenith angle dependence to some extent^{6;9}. These two behaviors can be confirmed numerically as is shown in Fig. 6 where the value of χ^2_{CHOOZ} is also plotted. Thus we see the analytic formulae for constant density explain the qualitative behaviors of the oscillation probability well. The threefold maximal mixing model fits to the data of atmospheric neutrinos and the CHOOZ experiment for $m^2 \approx 8 \times 10^{-4} \text{ eV}^2$.

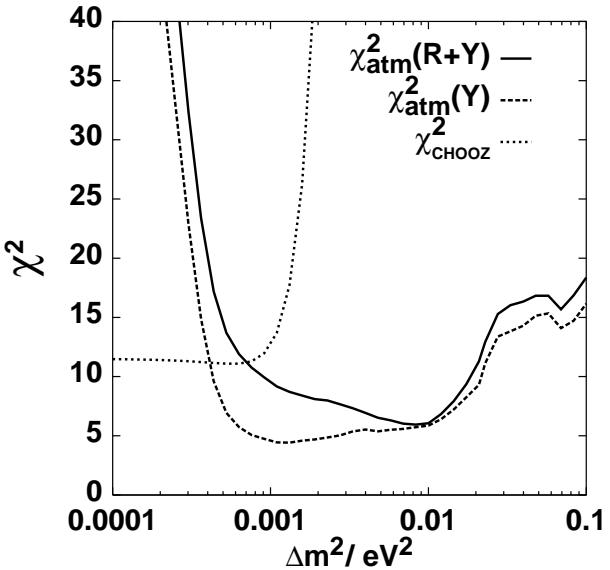

Fig. 6

χ^2 as a function of m^2 to the Superkam iokande atm ospheric data for the threefold m axim al mixing m odel. The solid line includes both R and up-dow n asym metries whereas the dashed line includes only the up-dow n asym metries (# of de- grees of freedom = 6{1= 5 for R + Y and = 4{1= 3 for Y only). The χ^2 for the C H O O Z reac- tor data (dotted line; # of de- grees of freedom = 12{1= 11) is also shown.

5. Conclusions

I have presented a result on the three flavor analysis of the Superkam iokande atm ospheric neutrino data for 414 days. If the mass squared difference is smaller than $1 \times 10^{-3} \text{ eV}^2$ then there can be large mixing between ν_μ and ν_e . It was shown that K2K will be able to see only $\bar{\nu}_\mu \rightarrow \bar{\nu}_e$ disappearance, while there may be a chance for MINOS (KamLAND) to see $\bar{\nu}_\mu \rightarrow \nu_e$ appearance ($\nu_\mu \rightarrow \nu_e$ disappearance), respectively. The threefold mixing model gives a reasonable fit to the atm ospheric neutrino and CHOOZ data for $m^2 < 1 \times 10^{-3} \text{ eV}^2$. It should be emphasized that the matter effects are important in the analysis of atm ospheric neutrinos.
