#### Abstract

W e study the production of spin $3=2$ particles in hom ogeneous scalar and gravitationalbackgrounds using the $m$ ode-m ixing Bogolyubov m ethod. C onsidering only the helicity 3=2 states, we can reduce the problem to a standard D irac ferm ion calculation and apply the standard techn iques in a straightforw ard way. As an exam ple we consider a speci c supergravity in ationary model and calculate the spectrum of gravitinos created during preheating at the end of in ation.

The quantization of elds in the presence of external classicalbackgrounds leads to interesting phenom ena such as the production of particles via the am pli cation ofvacuum uctuations. Thise ect hasbeen $m$ ainly studied in bosonic models, for exam ple production of scalars or gravitons in scalar or gravitational backgrounds. In addition, this $m$ echanism for the creation of particles is believed to be responsible for the generation of m ost of the particles that constitute the present universe [in] and in fact it plays a key role in the m odem theories of preheating after in ation. In those models, the energy of the in aton eld is resonantly converted into particles during the period of coherent oscillations after in ation. $T$ his param etric resonance phenom enon $m$ akes the occupation num ber of the new ly created bosons grow exponentially fast and causes their spectra to be characterized by resonance bands. R ecently, the resonant generation of spin $1=2$ particles has also been considered in the literature [ lim it on the occupation num ber im posed by P auliexclusion principle is saturated and thus the non-perturbative results deviate considerably from what is expected in a perturbative approach.

In this work we are interested in the creation of spin $3=2$ particles through the am pli cation of vacuum uctuations. The generation of such particles in the early universe has traditionally been treated by_considering the perturbative decay of other particles [ [3n in ' $1_{1}^{\prime}$ ], but not using the non-perturbative approach based on the B ogolyubov transform ations technique. Som e estim ations of the gravitino production during in ation, based on the analogy w ith D irac ferm ions can be found in [5]1]. The spin $1=2$ case suggests that both approaches can give rise to quite di erent results. This could be of the utm ost im portance in the so-called gravitino problem: in supergravity m odels, the supenpartner of the graviton eld (gravitino) is described by a spin $3=2$ particle. If such particles are created after in ation by som em echanism (particle collision, vacuum uctuations) they could disnupt prim ordial nucleosynthesis if they do not decay fast enough,
or if they are stable particles and their $m$ asses are high, they could overclose the universe. In the perturbative approach, these facts im pose stringent constraints on both the reheating tem perature and the gravitino $m$ ass $[\underline{[6]}]$.

The calculation of spin 3=2 particle production from vacuum uctuations is plagued w th consistency problem sthat ham per the quantization of such elds in the presence of extemalbackgrounds. It has been known for a long tim e $[\underline{1} 11$, that a spin $3=2$ particle in scalar, electrom agnetic or gravitational backgrounds can give rise, apart from algebraic inconsistencies, to faster than light propagation $m$ odes. $T$ his fact com pletely prevents a consistent quantization in such cases [8]. The only theory in which these problem s seem to be absent is supergravity, provided the background elds satisfy the corresponding equations of $m$ otion $\left[\frac{9}{9}\right]$. H ow ever, the com plicated form of the R arita-Schw inger equation $m$ akes it very di cult to extract explicit results even in sim ple backgrounds. In this paper we w ill show that when we consider helicity $3=2$ states (which dom inate the high-energy interactions of gravitinos [3, [1] propagating in arbitrary ho$m$ ogeneous (and isotropic) scalar or gravitational backgrounds, the equations can be reduced to a D irac-like equation. T he quantization can be done along the sam e lines as for D irac spinors and therefore the standard Bogolyubov technique [1d] can be used to calculate the particle production. We will also show explicitly, within a previously considered supergravity in ationary model, that the expected am pli cation does take place.
$T$ he $m$ assive spin $3=2$ dynam ics in at space-tim e is described by the $R$ arita-Schw inger equation. W ew ill include the scalar eld coupling by modifying the $m$ ass term, (follow ing the notation in [ill ):

$$
\begin{equation*}
5 @+\frac{1}{2}\left(m_{3=2}\right)[\quad ; \quad]=0: \tag{1}
\end{equation*}
$$

As usual in supergravity models we will consider M ajorana spinors satisfying $=C{ }^{T}$ with $C=i^{2} 0$ the charge conjugation $m$ atrix. Contracting this equation with @ and we get:

$$
\begin{gather*}
\theta+\infty \\
+\frac{1}{2}\left(m_{3=2} \quad\right)(\theta \quad \theta \quad)=0 ; \tag{2}
\end{gather*}
$$

and
2i(@

$$
\begin{equation*}
\text { (e) })+\left(m_{3=2}\right)( \tag{3}
\end{equation*}
$$

$$
+2 \quad)=0:
$$

Finally contracting this last equation with we get:

$$
\begin{equation*}
i(@)+3\left(m_{3=2}\right) \quad=0 \text { : } \tag{4}
\end{equation*}
$$

W hen $=0$ the three equations ( $\overline{2} \overline{2}$, ( $\overline{3}$ ) and ( $\overline{4} \overline{4}$ ) can be w ritten as the D irac equation plus two constraints, ie:

$$
\text { (i@ } \begin{align*}
\left.\mathrm{m}_{3=2}\right) & =0 ;  \tag{5}\\
& =0 ;  \tag{6}\\
\text { @ } & =0: \tag{7}
\end{align*}
$$

The generalsolution of these equations can be expanded in helicity $l=s=2+m$ odes:
w ith $J_{s m}$ the C lebsch-G ordan coe cients $\frac{w}{}$ hose values are: $J_{\mathrm{p}} \frac{1}{2=3} \mathrm{~J}_{11}=1, \mathrm{~J}_{11}=\mathrm{J}_{1} 1=1=\overline{3}$ and $\mathrm{J}_{10}=$ $J_{10}=\overline{2=3}$. Here $u(\rho ; s)$ are spinors $w$ th de nite helicity $s=1$ and nom alized as $u(p ; r) u(\rho ; s)=r s$. If we set $p=(!; p \sin c o s ; p \sin \sin ; p \cos ) w$ th $p p=m{ }_{3=2}^{2}$ and $p=j \dot{p} j$ then the three spin 1 polarization vectors are given by:

$$
\begin{align*}
(p ; 1)= & \frac{1}{P_{\overline{2}}}(0 ; \cos \cos \\
& i \sin ; \cos \sin +i \cos ; \sin ) ;  \tag{9}\\
(p ; 0)= & \frac{1}{m_{3=2}(p ; \quad \sin \cos ;} \\
& !\sin \sin ;!\cos ) ;  \tag{10}\\
(p ; 1)= & \frac{1}{p_{2}}(0 ; \cos \cos \\
+ & i \sin ; \cos \sin i \cos ; \sin ): \tag{11}
\end{align*}
$$

The nomalization is $(\rho ; \mathrm{m})(\rho ; \mathrm{n})=\mathrm{mn}$, $\mathrm{p} \quad(\rho ; \mathrm{m})=\mathrm{p} \quad(\rho ; \mathrm{m})=0$. The corresponding quantization details can be found elsew here $[\underline{[4]}]$.
$N$ ow we tum to the 0 case. The expression in ( $\overline{\mathrm{p}}$ ) is no longer a solution of the equations ofm otion. Let us now concentrate on hom ogeneous scalar elds, only dependent on the tim ecoordinate ( t ). W e look for general hom ogeneous solutions of the R arita-Schw inger equation of the form:

These elds satisfy the condition $\quad=0$, since they di er from ( $\bar{l}_{1}^{\prime}$ ) in just a scalar factor. Now if we restrict ourselves to the helicily $l=3=2$ states, they satisfy $\quad{ }_{0}^{p} \quad 3=2$ and, since the spatial derivatives of the
scalar eld vanish $\left(@_{i}=0\right)$, then ( $\overline{2}$ ) and ( $\overline{1} 1$ are autom atically satis ed provided @ ${ }^{i}{ }_{i}=0$. From (12) this last condition is equivalent to $\mathrm{p}^{\mathrm{i}}{ }_{i}=0$ which holds from the condition $\mathrm{p} \quad(p ; m)=0$. A ccordingly, for helicity
$3=2$ states propagating in an hom ogeneous scalar background, the R arita-Schw inger equation reduces again to the $D$ irac form :

$$
\text { (i © } \quad m_{3=2}+\text { (t)) } \quad 3=2=0
$$

As far as these m odes satisfy a D irac-like equation, it appears that all the di culties in the quantization w ould concem just the helicity $1=2 \mathrm{~m}$ odes in this case. In fact the above ansatz (1-1) is not a solution for the helicity $1=2 \mathrm{~m}$ odes even for hom ogeneous backgrounds.
Let us include the e ect of curved space-time. We w ill concentrate on spatially at Friedm ann-R obertsonW alker ( $F$ RW) m etrics, and we will introduce it by m inim al coupling as done in supergravity, ie, $\mathrm{D}=$ ( $@^{+} \frac{i}{2}^{a b} \mathrm{ab}$ ) $w$ ith ${ }^{a b}$ the spin-connection coefcients and $a b=\frac{i}{4}[a ; b]$. The rem oves the C hristo el sym bols contribution in the covariant derivative. W e will continue considering ( $t$ ) to be a function of tim e alone. W e will only consider the linearized equation in $1=\mathrm{M}$ (where $\mathrm{M}_{\mathrm{P}}^{2}=8 \mathrm{M}^{2}$ ) for supergravity [1] $\left.{ }_{1}^{1}\right]$, i.e, we will ignore the torsion contribution to the spinconnection which is of $O\left(M^{2}\right)$. In this case the equations of $m$ otion for the gravitino read:

$$
\begin{equation*}
5 \mathrm{D} \quad+\frac{1}{2}\left(\mathrm{~m}_{3=2} \quad[\quad ; \quad]=0:\right. \tag{14}
\end{equation*}
$$

C ontracting w ith D , taking into account that $\mathrm{D}=$ 0 and $\mathbb{D} ; D]=\quad \frac{i}{2} R^{a b} \quad$ ab (the vector part cancels because of the term ), we get:

$$
\begin{array}{llll}
\frac{i}{4} & 5 R^{\mathrm{ab}} \mathrm{ab} & (\sqrt{6}) & +(\mathbb{D}) \\
& +\frac{1}{2}\left(m_{3=2}\right. & )(\sqrt{6} & \text { (6) })=0: \tag{15}
\end{array}
$$

Follow ing the sam e steps as in at space-tim e we obtain (3i) and (4) but replacing ordinary derivatives by covariant ones. For FRW $m$ etrics and helicity $3=2$ states, i.e., $0=0$, it is possible to show that due to the form of the $R$ iem ann tensor, the rst term in (115) is proportional to and accordingly we get:

$$
\begin{align*}
\left(i \sqrt{6} \quad m_{3=2}+\quad\right) & =0 ;  \tag{16}\\
& =0 ;  \tag{17}\\
D & =0: \tag{18}
\end{align*}
$$

H ere again we can use the standard form ulae for particle production obtained for the spin $1=2$ cases to study the creation of helicity $3=2$ states in a FRW background. W ith that purpose we have to reduce equation (1G) to a second order equation. Let us rst write the equation in conform altim e de ned as dt=a( )d :

$$
\begin{equation*}
i^{1} \text { a }{ }^{a} @ \quad m_{3=2}++i \frac{3}{2} \frac{a}{a^{2}} 0 \quad=0 ; \tag{19}
\end{equation*}
$$

where $\underline{a}=d a=d$. W e will adopt the follow ing ansatz for the helicity $l=3=2$ solutions:

$$
\begin{equation*}
\mathrm{pl}^{1}(\mathrm{x})=a^{3=2}() e^{\mathrm{iP}} \mathrm{U}^{\mathrm{pl}}() ; \tag{20}
\end{equation*}
$$

w ith

$$
\begin{align*}
& U^{\mathrm{Pl}}()=Q \frac{1}{!+\mathrm{m}_{3=2}^{0}} \mathrm{i}^{0} \varrho_{0} \quad \mathrm{P} \quad \sim \\
& +a()\left(m_{3=2} \quad() f_{p l}() u(p ; s)^{a} a(\rho ; m) ;\right. \tag{21}
\end{align*}
$$

and the norm alization $U^{p l y}(0) U_{p 1}(0)=2$ ! and $m_{3=2}^{0}=$ $a(0) m_{3=2}$. O ne_can check that this ansatz autom atically satis es (17) and (18) . An appropriate form for the spinor $u(p ; s)$ and polarization vectors a $(\rho ; m)$ can be obtained ifwe choose the D irac representation for the gam m a m atrices and we take (w thout loss of generality) the $z$-axis to be along the $p$ direction. In this case $u(p ; 1)^{T}=(1 ; 0 ; 0 ; 0), u(\rho ; 1)^{T}=(0 ; 1 ; 0 ; 0)$, a $(\rho ; 1)=$ $\mathrm{P}^{1} \overline{2}(0 ; 1 ; 1 ; 0)$ and $a(\rho ; 1)=\frac{1}{1}(0 ; 1 ; \quad i ; 0)$. W ith this choice, $u(\rho ; 1)$ are eigenstates of ${ }^{0} w$ th eigenvalues +1 . Then equation (19) reduces to the well-known form:

$$
\begin{align*}
\frac{d^{2}}{d^{2}} & +p^{2} \quad \frac{d}{d} a()\left(m_{3=2}\right. \\
& +a^{2}()\left(m_{3=2} \quad()\right)^{2} f_{p 1}()=0: \tag{22}
\end{align*}
$$

In order to quantize the m odes we will expand an arbitrary solution $w$ th helicity $l=3=2$ as:

$$
\begin{align*}
{ }^{1}(x) & =\frac{Z}{(2)^{3} 2!} a^{3=2}() e^{i p} U^{p l}() a_{Q 1} \\
& +e^{\text {ip } U^{p l C}}\left(\text { ) } a_{Q 1}^{\mathrm{Y}} ;\right. \tag{23}
\end{align*}
$$

where the creation and annhilation operators satisfy the anticom $m$ utation relations $\mathrm{fa}_{\mathrm{pl}} ; \mathrm{a}_{\mathrm{p}^{0} 1^{0}}^{\mathrm{O}} \mathrm{g}=(2)^{3} 2!$ 11 $p^{0}$ ).

In order to see how this works in practice, we will consider a speci c supergravity in ationary model (see [12 $\left.1^{1} 3^{\prime}\right]$ ), in which the in aton eld is taken as the scalar com ponent of a chiral super eld, and its potential is derived from the superpotential $I=\left({ }^{2}=M\right)(M)$.This is the sim plest choice that satis es the conditions that supersym $m$ etry rem ains unbroken in the $m$ inim um of the potential and that the present cosm ological constant is zero. The observed CM B anisotropy xes the in ationary scale around $\quad=\mathrm{M}$ ' $10^{4}$. For the sake of sim plicity, we will consider the case in which the gravitino $m$ ass is $m$ uch sm aller than the ective $m$ ass of the in aton in this $m$ odel, $m_{3=2} \quad \mathrm{~m}, 10{ }^{8} \mathrm{M}$ and since the production w illtake place during a few in aton oscillations, we will neglect the m ass term in the equations. $T$ he scalar eld potential is given by [1] $1_{1}^{1}$ :

$$
\begin{equation*}
V()=e^{j f=M^{2}} \quad \underset{j}{@}+\frac{I}{M^{2}} \mathfrak{J} \quad \frac{3 j \mathcal{J}}{M^{2}}: \tag{24}
\end{equation*}
$$

For the above supenpotential, the im aginary direction is known to be stable and therefore we w ill take for sim plicity a real in aton eld. A long the real direction the potential can be w ritten as [1]

$$
\begin{equation*}
V()={ }^{4} e^{2}(2(\quad 1)+\quad(\quad 1\})^{2} \quad 3(\quad 1) \tag{25}
\end{equation*}
$$

where we are working in units $M=1$. Wewill assum e, as indicated in $[\underline{1}]$ dilaton and $m$ oduli elds are xed during and after ination. This potential has a minimumat $=1$. The coupling of the in aton eld to gravitinos is given by the follow ing m ass term in the supergravity lagrangian [1] $\left.{ }^{1}\right]$ :

$$
\begin{gather*}
L=\frac{1}{4} e^{G=2} \quad[\quad ; \quad] \quad ;  \tag{26}\\
e^{G=2}={ }^{2} e^{2}=2(1)^{2} ; \tag{27}
\end{gather*}
$$

where we have chosen the $m$ inim al form for the $K$ ahler potentialG $\left(;{ }^{y}\right)=y+\log j j^{2}$. The rest of interaction term $s$ in the supergravity lagrangian are not relevant for our purposes. The in aton and Friedm ann equations can be w ritten in conform al tim e as:

$$
\begin{align*}
& +2 \frac{b}{b}-+\frac{b^{2}}{4} \mathrm{~V} ;=0  \tag{28}\\
\frac{\mathrm{~b}^{2}}{\mathrm{~b}^{2}}= & \frac{1}{3} \frac{1}{2} \frac{2}{2}+\frac{\mathrm{b}^{2}}{4} \mathrm{~V} \tag{29}
\end{align*}
$$

where the derivatives are $w$ ith respect to the new tim e coordinate $\sim=a_{0}{ }^{2}$ and the new scale factor is dened as b $(\sim)=a(\sim)=a_{0}$ w ith $a_{0}=a(0)$. The solution of this equation show $s$ that after the in ationary phase, the scalar eld starts oscillating around the $m$ inim um of the potential w ith dam ped am plitude. Substituting in (22) for this particular case we obtain:

$$
\begin{equation*}
\frac{d^{2}}{d \sim^{2}}+{ }^{2}+\frac{i}{2} \frac{d}{d \sim}\left(b e^{G=2}\right)+\frac{b^{2}}{4} e^{G} \quad f_{1}(\sim)=0 ; \tag{30}
\end{equation*}
$$

w th $=\mathrm{p}=\left(\mathrm{a}_{0}{ }^{2}\right)$. From this expression we see that when the scalar interaction is sw itched 0 , there is no particle production, even in the expanding background.

$$
\begin{align*}
& N_{1}\left(T^{\top}\right)=\frac{1}{4} \quad 2+i\left[\mathcal{E}_{1}\left(T^{\top}\right) f_{1}\left(T^{\top}\right) \quad f_{1}\left(T^{\prime}\right) \mathrm{E}_{1}\left(T^{\top}\right)\right] \\
& \left.\frac{2}{2} b e^{G(T)=2} \text { if } l^{(T)} T^{2}\right] \tag{31}
\end{align*}
$$

In order for the particle number to be well de ned, we m ust evaluate it when the interaction is vanishingly sm all, that is, for large values of $T$. Here $f_{1}$ is a solution of equation ( $3 \mathrm{~B}_{\mathrm{O}}^{1}$ ) w th intial conditions $\mathrm{f}_{1}(0)=1$ and $\mathrm{f}_{1}(0)=\quad$ i which corresponds to a plane wave
for ~ 0 . In order to de ne the initial vacuum at $\sim=0$, we have taken the in aton to be at the m inimum of the potential at that m om ent $((0)=1)$, which in plies $e^{G}(=1)=2=0$ and $b(0)=1$. W e have chosen $-(0)=1: 8$ in our num erical com putations which corresponds to an initialam plitude of the in aton oscillations of about $0: 06 \mathrm{M}_{\mathrm{p}}$ and a m axim um value of the coupling $e^{G=2}$ of $10{ }^{10} \mathrm{M}_{\mathrm{p}}$.

The results for the spectra in the expanding background are show $n$ in $F$ ig.1. N ote that we have not considered the backreaction e ects of the produced particles. In the at space calculation, we nd that broad resonance
 pansion is taken into account ( $F$ ig.1), the production is reduced by 3-4 orders ofm agnitude, how ever the num ber of particles produced is not negligible. From Fig. 1, we can estim ate a low er bound to the total num ber density of gravitinos of both helicities as:
$n()=\frac{1}{{ }^{2} a^{3}()}{ }_{0}^{Z_{1}} N_{p 1} p^{2} d p=\frac{a_{0}^{3} \sigma^{Z_{1}}}{2^{3} a^{3}} 0_{0} N_{1}{ }^{2} d$
Comparing $w$ ith the number density of a them al distribution of helicity $1=2$ gravitinos as estim ated in "[1(the helicity $3=2$ could be even less abundant) for a typical value of the scale factor at the end of in ation [ $\left[\bar{T}_{1}\right]$ $a_{0}{ }^{\prime} 10{ }^{26}$, the vacuum uctuation production is suppressed by a factor $10^{10}$. The corresponding cosm ologicalconsequences have been studied in [1] [18]. C om paring w ith the entropy density today we obtain: $n=s \quad 10^{12}$. $T$ his result is 4-5 orders of m agnitude larger than the perturbative production during reheating from direct inaton decay [13] and it could pose com patibility problem s w th the nucleosynthesis bounds $[\underline{[10]}]$ for som e values of the gravitino $m$ ass.

W e have considered the production of helicity $3=2$ gravitinos (which are the relevant states for the current nucleosynthesis bounds) in a particular in ationary
model. The expression ( $\left.\overline{3} \mathbf{z}^{\prime}\right)$ show s that the results are very sensitive to the $m$ odel param eters, but they can be used to discrim inate betw een di erent supergravity inationary m odels. T he com pletion of the picture would require to study other m odels and also include the production ofhelicity $1=2 \mathrm{~m}$ odes; how ever, the B ogolyubov technique appears very involved for this purpose. (A fter the appearance of th is work, the helicity $1=2$ case w as considered in K allosh et al, hep-th/9907124i) A cknow ledgm ents: A L M . acknow ledges support from SEU D R oyal Society and (C IC Y T-A EN 97-1693) (Spain).
