## Abstract

We present a perfect simulation algorithm for stationary processes indexed by  $\mathbb{Z}$ , with summable memory decay. Depending on the decay, we construct the process on finite or semi-infinite intervals, explicitly from an i.i.d. uniform sequence. Even though the process has infinite memory, its value at time 0 depends only on a finite, but random, number of these uniform variables. The algorithm is based on a recent regenerative construction of these measures by Ferrari, Maass, Martnez and Ney. As applications, we discuss the perfect simulation of binary autoregressions and Markov chains on the unit interval.

Short Title. Long Memory and Perfect Simulation

Key words and phrases. Perfect simulation. Regeneration. Chains with complete connections. Binary autoregressions.

# 1 Introduction

In this paper we consider processes with transition probabilities that depend on the whole past history, i.e. processes with long memory. When this dependence decays fast enough with time, we exhibit a regenerative construction which, besides yielding an explicit proof of existence and uniqueness of the process, can be transcribed into a perfect simulation scheme.

Processes with long memory have a long history. They were first studied by Onicescu and Mihoc (1935) under the label chains with complete connections (*chaînes à liaisons complètes*). Harris (1955) proposed the somehow less used name of chains of infinite order. Doeblin and Fortet (1937) proved the first results on speed of convergence towards the invariant measure. Harris (1955) called these processes chains of infinite order, and extended results on existence and uniqueness. The chains appeared also as part of the formalism introduced by Keane (1971 and 1976) to study of subshifts of finite type (or covering transformations). In this theory the transition probabilities are called  $g$ -functions and the invariant measures  $g$ -measures.

The theory of long-memory processes has found applications in the study of urn schemes (Onicescu and Mihoc, 1935b), continued-fraction expansions (Doeblin, 1940; Iosifescu 1978 and references therein), learning processes (see, for instance, Iosifescu and Theodorescu, 1969; Norman, 1972 and 1974), models of gene population (Norman, 1975), in age coding (Bamsley, Demko, Elton and Gerinomo, 1988), automata theory (Herkenrath and Theodorescu, 1978), partially observed or "grouped" random chains (Harris, 1955; Blackwell, 1957; Kaijser, 1975; Pruscha and Theodorescu, 1977; Elton and Piccioni, 1992) and products of random matrices (Kaijser, 1981). For further references we refer the reader to Kaijser (1981 and 1994) [from which most of the material of the previous review paragraphs is taken] and to Iosifescu and Grigorescu (1990).

It is clear that these applications should benefit from the construction and perfect-simulation scheme presented here. As an illustration, we discuss in Sections 3 and 9 applications to binary autoregressions and to the Markov processes on the interval  $[0;1]$  defined by Harris (1955) by mapping chains with complete connection into  $D$ -ary expansions.

In this paper we rely on a regenerative construction of the chain, which generalizes, in some direction, those existing in the literature. This type of construction has been first introduced by Doeblin (1938) for Markov chains with countable alphabet. Schemes for more general state spaces came much later (Athreya and Ney, 1978; Nummelin, 1978). The first regenerative structures for chains with complete connections were proposed by Lalley (1986, 2000) and Berbee (1987) for chains with summable continuity rates. An explicit regenerative construction was put forward by Ferrari, Massart, Martinez and Ney (2000) in the spirit of Berbee's approach.

In the present paper we take up the scheme of Ferrari, Massazza, Martinez and Ney (2000), extend it to part of the Harris uniqueness regime and transcribe it as a perfect simulation algorithm. Basically, the construction used here can be interpreted as a simultaneous coupling of all histories, built in such a way that at each instant  $i$  there is a (random) number  $k_i \geq 0$  such that the distribution of the move  $i+1$  is the same for all histories agreeing the  $k_i$  preceding instants. This independence from the  $k_i$ -remote past yields the times such that preceding histories are irrelevant for future moves. These are the regeneration times, defined by the conditions  $k_i = i$  for all  $i$ . Both Berbee's and Lalley's constructions rely on the regeneration probability being positive, a fact that seems to hold only for summable continuity rates. In contrast, our construction extends to cases where (global) regeneration may have probability zero. Non-summable but still not too slowly decreasing rates inside the Harris uniqueness regime yield local regeneration times, that is, regenerations for finite time intervals (windows). In ergodic-theory terms, our construction is in fact a unitary coding of a process of i.i.d. uniform variables in the interval  $[0;1]$ .

Perfect simulation became popular after Propp and Wilson (1996) introduced the coupling from the past algorithm to simulate invariant measures of Markov chains. Wilson's page <http://dimacs.rutgers.edu/~dbwilson/exact> provides updated and extensive references on perfect simulation. Foss and Tweedie (1998) and Corcoran and Tweedie (1999) proposed a general framework based on regeneration schemes for Markov chains and the so-called "stochastic recursive sequences". These are processes defined by  $X_{n+1} = f(X_n; \eta_n)$ , where  $\eta$  is a stationary process. In the Markovian case  $\eta_i$  are i.i.d.; in the non-Markovian case, it remains the matter of how to construct/simulate the sequence  $\eta_i$ . Our algorithm applies to a wide variety of non-Markovian processes and, through the formalism of random system with complete connections, it can be used to simulate Markov processes with state space of large cardinality (e.g. the unit interval). Section 9 presents an example along these lines.

Our main result is an explicit construction, as a deterministic function of a sequence of i.i.d. random variables uniformly distributed in  $[0;1]$ , of realizations of the stationary chain with finite memory. As corollaries we get: (i) an alternative proof of the existence and uniqueness of the stationary process, and (ii) a perfect simulation algorithm and a regeneration scheme for this process. These results are summarized in Theorem 4.3 and Corollaries 4.12, 4.14 and 4.18. In Section 2 we introduce the basic definitions and in Section 3 we illustrate the simulation on a concrete example, which is continued in Section 9. The results of Section 4 are proved in Sections 5-6 and 8, though the perfect simulation algorithm is described in Section 7 in its general version.

## 2 Definitions

We denote by  $G$  our alphabet,  $N = N \cup \{0\}$  and  $\mathbb{N} = \{i : i \in \mathbb{N}\}$ . In what follows  $G$  can be finite or countable, though in the latter case conditions (4.4) and (4.9) below impose severe limitations. The set  $G^{\mathbb{N}}$  is the space of histories; we write  $w_a^b = (w_b; w_{b-1}; \dots; w_a)$  for  $1 \leq a \leq b+1$ . For shortness we write  $\underline{w} = w_1^1$ . Let  $P : G \times G^{\mathbb{N}} \rightarrow [0;1]$  be a probability transition kernel; that is,  $P(g; w_1^1) \geq 0$  for all  $g$  and

$$\sum_{g \in G} P(g; w_1^1) = 1 : \quad (2.1)$$

for each  $w_1^1 \in G^{\mathbb{N}}$ . The kernel  $P$  defines, by telescopic products, what in statistical mechanics is called a specification. A specification is a consistent system of conditional probabilities, where consistency is required for all histories  $w_1^1$ . In standard probabilistic treatments, such requirements are made only almost surely with respect to some pre-established appropriate measure. But in the present setting the determination of the appropriate measure is part of the problem, and stronger requirements are a priori necessary.

Denoting by  $(i); i \in \mathbb{Z}$ ; the coordinate mappings on  $G^{\mathbb{Z}}$ , we say that a (non-necessarily stationary) probability measure  $\mu$  on  $G^{\mathbb{Z}}$  or a process with distribution  $\mu$  is compatible with the specification  $P$  if the latter is a version of the one-sided conditional probabilities of the former:

$$\mu((i) = g \mid (i+j) = w_j; j \in \mathbb{N}) = P(g; w_1^1) \quad (2.2)$$

for all  $i \in \mathbb{Z}$ ,  $g \in G$  and  $\mu$ -a.e.  $w_1^1 \in G^{\mathbb{N}}$ . Then the identities

$$\mu((i+k) = g_k; k \in [0;n] \mid (i+j) = w_j; j \in \mathbb{N}) = \prod_{k=0}^n P(g_k; w_{k-1}^1; \dots; g_0; w_1^1); \quad (2.3)$$

hold for  $\mu$ -a.e.  $w_1^1$ , where the concatenation is defined by

$$(w_k; w_{k-1}; \dots; w_{-i}; z_1^1) = (w_k; w_{k-1}; \dots; w_{-i}; z_{-1}^1; z_{-2}^1; \dots) :$$

The regenerative construction of this paper is based on the functions

$$\begin{aligned} a_0(g) &= \inf_{z_1^1 \in G^{\mathbb{N}}} \sum_{n=0}^{\infty} P(g; z_1^1) : z_1^1 \in G^{\mathbb{N}} \\ a_k(g; w_1^1) &= \inf_{z_1^1 \in G^{\mathbb{N}}} \sum_{n=0}^{\infty} P(g; w_1^1; \dots; w_{-k}; z_1^1) : z_1^1 \in G^{\mathbb{N}}; \quad k \geq 1; \end{aligned} \quad (2.4)$$

defined for  $k \in \mathbb{N}$ ,  $g; w_1^1; \dots; w_{-k} \in G$ . [These functions are denoted  $g(i_0; i_{-1}; \dots; i_{-k})$  by Berbee (1987)]. The numbers

$$a_k = \inf_{w_{-k}^1 \in G^{\mathbb{N}}} \sum_{g \in G} a_k(g; w_{-k}^1); \quad (2.5)$$

$k \geq N$ , determine a probabilistic threshold for memories limited to  $k$  preceding instants. The sequences  $a_k(jw_k^{-1})$  and  $a_k$  are non-decreasing in  $k$  and contained in  $[0;1]$ .

For our construction we shall use a sequence  $\underline{U} = (U_i : i \geq 1)$  of independent random variables with uniform distribution in  $[0;1]$ , constructed on the corresponding canonical probability space  $(\Omega; \mathcal{F}; P)$ . We denote  $E$  the expectation with respect to  $P$ .

### 3 An example: binary autoregressive processes

To motivate the method, we present an example that shows how to construct and perfect simulate a process with infinite memory. Let us consider binary autoregressive processes. Such a process is the binary version of autoregressive (long memory) processes used in statistics and econometrics. It describes binary responses when covariates are historical values of the process (McCullagh and Nelder, 1989, Sect. 4.3).

Let the state space be  $G = \{0, 1\}$ ,  $q_0$  a real number and  $(w_k; k \geq 1)$  a summable real sequence. Let  $q : \mathbb{R} \rightarrow [0;1]$  be strictly increasing and continuously differentiable. Assume that

$$P(jw_k^{-1}) \text{ is the Bernoulli law on } \{0, 1\} \text{ with parameter } q_0 + \sum_{m=k}^{\infty} w_m; \quad (3.1)$$

$$\text{i.e., } P(1 - jw_k^{-1}) = q_0 + \sum_{m=k-1}^{\infty} w_m = 1 - P(jw_k^{-1}).$$

By compactness there exists at least one process compatible with (3.1); the conditions for uniqueness are well known. The question is how to simulate (construct) such a stationary process. To do that we construct a family of partitions of the interval  $[0;1]$  indexed by  $k$  and  $w_k^{-1}$  using  $a_k(jw_k^{-1})$  and  $a_k$  defined in the previous section. Letting

$$r_k = \sum_{m > k} w_m$$

we have

$$\begin{aligned} a_k(jw_k^{-1}) &= q_0 + \sum_{m=k}^{\infty} w_m jw_m^{-1} r_k A \\ a_k(1 - jw_k^{-1}) &= 1 - q_0 + \sum_{m=k}^{\infty} w_m (1 - jw_m^{-1}) r_k A \end{aligned} \quad (3.2)$$

and

$$a_k = 1 - \sup_{w_k^{-1} \leq \cdot} q_0 + \sum_{m=k}^{\infty} w_m + r_k A \leq q_0 + \sum_{m=k}^{\infty} w_m + r_k A = 1; \quad (3.3)$$

For each  $k$  and  $w_k^{-1}$ , let  $B_k(gjw_k^{-1})$  be intervals of length  $a_k(gjw_k^{-1}) - a_{k-1}(gjw_{k+1}^{-1})$  placed consecutively in lexicographic order in  $k$  and  $g$ , starting at the origin. Use the convention  $a_0(gjw_0^{-1}) = a_0(g)$  and  $a_{-1} = 0$ . These intervals form a partition of the interval  $[0;1[$ .

Let  $(U_i : i \geq 0)$  be the sequence of i.i.d. random variables uniformly distributed in  $[0;1[$  defined at the end of Section 2. For  $n \geq 0$  define the random variable

$$K_n := \sum_{k=0}^n \mathbf{1}_{U_n \in [a_{k-1}; a_k)} g : \quad (3.4)$$

In our construction the variable  $K_n := K_n(\underline{U})$  indicates how many sites in the past are needed to compute the state at time  $n$ . To each  $n$  associate an arrow going from  $n$  to  $n - K_n$ . The state at site  $n$  will be independent of the states at sites if no arrow starting at  $n$  points to the left of  $n$ . Let  $\tau_n := \tau_n(\underline{U})$  be the maximum of such  $s$ :

$$\begin{aligned} \tau_n &:= \max_{s \leq n} s : U_j < a_{j-s} ; j \in [s; n] \\ &= \max_{s \leq n} s : K_j \leq s ; j \in [s; n] \end{aligned} \quad (3.5)$$

Notice that  $\tau_n$  is a stopping time for the sequence  $(U_n : n \geq 0)$ . We show in Theorem 4.3 that the condition

$$\sum_{k=0}^{\infty} \tau_k < \infty \quad (3.6)$$

is sufficient to guarantee  $P(\tau_n < \infty) = 1$  which, in turn, is an equivalent condition to the feasibility of the following construction.

Simulation (construction) of the stationary measure

1. Generate successively i.i.d. uniform random variables  $U_n, U_{n-1}, \dots$ . Stop when  $U_{\tau_n}$  is generated. Using (3.4), the values  $K_n, K_{n-1}, \dots, K_{\tau_n}$  are simultaneously obtained.
2. Use the  $U_{\tau_n}, \dots, U_n$  and  $K_{\tau_n}, \dots, K_n$  generated in the previous step to define

$$X_j = g \quad \text{if} \quad U_j \in \bigcup_{k=0}^{K_j} B(gjw_k^{-1}) ; \quad (3.7)$$

recursively from  $j = \tau_n$  to  $j = n$ .

3. Return  $X_n$ . The algorithm has also constructed  $X_{\tau_n}, \dots, X_{n-1}$ .

The expression (3.7) is well defined because by the definition of  $\tau_n$ ,  $j - K_j \leq \tau_n$ ,  $U_j \in [0; a_{K_j}] \subset \bigcup_{k=0}^{K_j} B(gjw_k^{-1})$  and the set in (3.7) depends at most on  $X_{j-K_j}, \dots, X_{j-1}$ . This

is discussed in detail in Section 6; see (6.3). We show in Theorem 4.3 that the above algorithm constructs a realization  $X_n$  of a random variable which has the one-coordinate marginal of the unique measure compatible with the specification. To construct a realization of the measure in a finite window, just repeat the algorithm for other  $n$  reusing always previously generated  $U_j$ . The algorithm induces a function  $\mu : [0; 1]^{\mathbb{Z}} \rightarrow [0; 1]$ . Given the event  $f_n = \{X_n = k\}$ , the  $n$ th coordinate of  $(U_1, \dots)$  depends only on  $U_k, \dots, U_n$ . (To be rigorous, one should give the definition of  $\mu$  when  $f_n = \emptyset$  for some  $n$ ; this is an arbitrary but irrelevant choice as this set has probability zero under our hypotheses.)

This construction exploits a well known fact. The existence of a renovating event gives rise to a perfect simulation algorithm and a regenerative structure. In our case there is a regeneration at times  $s$  if  $j \leq K_j \leq s$  for all  $j \leq s$  (no arrow passes over  $s$ ). However for the construction of the measure in site  $n$  we use a weaker condition: it suffices that no arrow passes from  $j$  to the left of  $s$  for  $j \leq [s; n]$ .

While in some cases one may have explicit expressions for  $a_k$ , in general, this will not be the case (see (3.3)). An useful aspect of our construction is that in these cases we can work with lower bounds  $a_k$ . We shall discuss this issue in Section 9.

## 4 Results

The existence of our regeneration scheme depends on the non-increasing sequence

$$\mu_n := \sum_{k=0}^n a_k; \quad (4.1)$$

with  $a_k$  defined in (2.5), and a necessary (but not sufficient) condition is  $\lim_{k \rightarrow \infty} a_k = 1$ . The regeneration time for a window  $[s; t]$ , for  $1 \leq s < t$  and  $s \leq t$ , is the random variable

$$[s; t] := \max_{n \leq t} \{n : U_k < a_{k-n}; k \geq [n; t]\} \quad (4.2)$$

which may be  $\infty$ . Notice that  $[s; t] = \min_{n \leq t} \{n : U_k < a_{k-n}; k \geq [n; t]\}$  and that it is a stopping time for  $(U_k : k \geq 0)$ , in the sense that  $f_{[s; t]} \in \mathcal{F}(U_i : i \geq [j; t])$  for  $j \leq s$ , where  $\mathcal{F}(U_i : i \geq [j; t])$  is the sigma field generated by  $(U_i : i \geq [j; t])$ .

Our main result is:

Theorem 4.3 If

$$\sum_{m=0}^{\infty} \mu_m = 1 \quad (4.4)$$

then

- (i) For each finite  $[s; t] \subset \mathbb{Z}$ ,  $P([s; t] > 1) = 1$ , where  $[s; t]$  is defined in (4.2).
- (ii) There exists a measurable function  $\gamma : [0; 1]^{\mathbb{Z}} \rightarrow G^{\mathbb{Z}}$  described in Section 6 such that

$$\mu = P(\gamma(U)) \quad (4.5)$$

the law of  $\gamma(U)$ , is compatible with  $P$ . Moreover, the distribution  $\mu$  is stationary.

- (iii) In addition, the function  $\gamma$  has the property that for each finite interval  $[s; t] \subset \mathbb{Z}$ , its restriction  $\gamma(U)|_{[s; t]}$  depends only on the values of  $U_i$  in the interval  $[s; t; t]$ . More precisely, for  $i \in [s; t]$ ,

$$\gamma(U)(i) = (\dots; v_{-2}; v_{-1}; U_i; \dots; U_t; v_{t+1}; \dots)(i) \quad (4.6)$$

for any sequence  $\underline{v} \in [0; 1]^{\mathbb{Z}}$  (we abbreviated  $[s; t]$  as  $\gamma$ ).

- (iv) The law of  $\gamma$  satisfies the following bound:

$$P([s; t] > m) \leq \sum_{i=0}^{\infty} \gamma_m^s \quad (4.7)$$

where  $\gamma_m$  is the probability of return to the origin at epoch  $m$  of the Markov chain on  $\mathbb{N}$  starting at time zero at the origin with transition probabilities

$$\begin{aligned} p(x; x+1) &= a_x \\ p(x; 0) &= (1 - a_x) \end{aligned} \quad (4.8)$$

and  $p(x; y) = 0$  otherwise. In particular, if  $(1 - a_k)$  decreases exponentially fast with  $k$ , then so does  $\gamma_k$ . If  $(1 - a_k) \sim k^{-\alpha}$  with  $\alpha > 1$  then  $\gamma_k$  decreases with the same power.

- (v) If

$$\lim_{m \rightarrow \infty} \gamma_m > 0 \quad (4.9)$$

then items (i), (iii) and (iv) above hold also for  $t = 1$ .

This theorem is proven in Sections 5 and 6. More detailed bounds on the parameters  $\gamma_m$  are given in Proposition 5.13. Conditions (4.4) and (4.9) require  $a_0 > 0$  as in Harris (1955). Both conditions are noticeable weaker than those imposed by Lalley (1986), Berbee (1987) and Bressaud, Fernandez and Galves (1999b), as well as those corresponding to the g-measure approach (Ledrappier, 1974) and to Gibbsian specifications (Kozlov, 1974).

Remark 4.10 The construction can be performed replacing the  $a_k$ 's with lower bounds, that is, considering a sequence  $a_k$  in  $]0;1[$ , such that

$$a_k \leq a_k \quad \text{for } k \geq 0 : \quad (4.11)$$

The theorem is valid replacing the unstarred  $a_k$  by starred ones, and using the corresponding starred versions of  $\mu_m$ ,  $\nu_m$  and  $\mu_m^*$ . While the actual  $a_k$ 's give shorter regeneration times, they could be hard to estimate. Suitable choices of  $a_k$  could provide a reasonable compromise between shorter regeneration times and feasible calculational efforts (Section 9).

Our first corollary is the uniqueness of the measure compatible with  $P$ .

Corollary 4.12 (Loss of memory and uniqueness)

- (i) Every measure compatible with the specification  $P$  has the following loss-of-memory property: If  $f$  is a function depending on the interval  $[s;t]$  and  $i \leq s$ ,

$$f(i) = w_j; j < i \quad f(i) = v_j; j < i \quad 2kf k_1 \sum_{j=0}^{\infty} \mu_{s+j-i} \quad (4.13)$$

for every  $w, v \in G^{\mathbb{Z}}$ . Here we use the notation  $f \approx^R (d)f(\cdot)$ .

- (ii) If  $\mu_{m,0,m}^P = 1$  the measure defined in (4.5) is the unique measure compatible with  $P$ .

The uniqueness result is not new. Under the more restrictive condition (4.9) it was already obtained by Doeblin and Fortet (1937). Harris (1955) [see also Section 5.5 of Iosifescu and Grigorescu (1990) and references therein] extended this uniqueness to a region that coincides with (4.4) for two-symbol alphabets but it is larger for larger alphabets. Other uniqueness results, in smaller regions, were obtained by Ledrappier (1974) and Berbee (1987) in different ways. Results on loss of memory were also obtained by Doeblin and Fortet (1937) (see also Iosifescu, 1992), under the summability condition (4.9). Bressaud, Fernandez and Galves (1999b) extended those to a region defined by a condition slightly stronger than (4.4). The rates of loss of memory obtained in this last references strengthen those of Doeblin, Fortet and Iosifescu, but are weaker than ours.

A corollary of (ii) and (iii) of the theorem is a perfect simulation scheme:

Corollary 4.14 (Perfect simulation) Let  $P$  be a specification with  $\mu_{m,0,m}^P = 1$  and the unique measure compatible with  $P$ . For each finite window  $[s;t]$  there exist a family  $(e_{m,t}; m \leq s)$  of functions  $e_{m,t} : [0;1]^{[m,t]} \rightarrow G^{[m,t]}$  such that

$$(i) = g_i; i \in [s;t] = P \cup : e_{m,t}(U; \dots; U_t) (i) = g_i; i \in [s;t] \quad (4.15)$$

where  $\tau = [s;t]$  is the stopping time defined in (4.2).

Expression (4.15) is our perfect simulation scheme for  $\mathbb{P}$ . Possible implementations are discussed in Section 7. Roughly speaking the algorithm goes as follows:

1. Produce a realization of  $U_t; \dots; U_s; U_{s-1}; \dots; U_{[s;t]}$ ;
2. Compute  $e_{[s;t],t}(U_{[s;t]}; \dots; U_t)$ .
3. Return the configuration  $(e_{[s;t],t}(U_{[s;t]}; \dots; U_t)(i) : i \in \mathbb{Z}_{[s;t]})$ . Its law is the projection of  $\mathbb{P}$  in the window  $[s;t]$ .

Our algorithm shares two features with the famous Coupling From The Past (CFTP) algorithm for Markov chains, introduced by Propp and Wilson (1996): (1) The r.v.  $U_i$  are generated sequentially backwards in time, until the stopping time  $[s;t]$  is discovered. (2) The algorithm is based on a coupled realization of the chain for all possible initial conditions ensuring the coalescence of the different trajectories before the observation window. Restricted to the Markovian case, our renewal times are, in principle, larger than the coalescence times of well designed CFTP algorithms. Nevertheless, our approach, besides extending to non-Markovian processes, yields coupling times that depend only on the numbers  $a_k$  defined in (2.5) [see (4.16)], and hence that are only indirectly related to the cardinality of the alphabet.

The bounds in (iv) of Theorem 4.3 can be used to control the user-impatience bias. This picturesque name proposed by Fill (1998) relates to the bias caused by practical constraints such as time limitation or computer storage capacity which force the user to stop a (long and unlucky) run before it reaches perfect equilibrium. Indeed, suppose that while sampling window  $[s;t]$  we decide to abort runs with regeneration times  $[s;t] > M$  for some large  $M > 0$ , causing our algorithm to produce a biased distribution  $b_{[s;t]}^M$ . Applying Lemma 6.1 of Fill (1998) and (4.7), we obtain:

$$\sup_{A \in \mathcal{G}_{[s;t]}} \left( \mathbb{P}(A) - b_{[s;t]}^M(A) \right) = \frac{\sum_{i=0}^{M-1} \mathbb{P}_s^{M+i}(A)}{\sum_{i=0}^{M-1} \mathbb{P}_s^{M+i}(\Omega)} : \quad (4.16)$$

In regime (v), Theorem 4.3 yields the following regeneration scheme. Let  $N \in \mathcal{F}_0; \mathbb{P}^Z$  be the random counting measure defined by

$$N(j) = 1 \text{ if } [j;1] = jg : \quad (4.17)$$

Let  $(T_\cdot : \cdot \in \mathbb{Z})$  be the ordered time events of  $N$  defined by  $N(i) = 1$  if and only if  $i = T_\cdot$  for some  $\cdot$ ,  $T_\cdot < T_{\cdot+1}$  and  $T_0 = 0 < T_1$ .

Corollary 4.18 (Regeneration scheme) If  $\lambda > 0$ , then the process  $N$  defined in (4.17) is a stationary renewal process with renewal distribution

$$P(T_{n+1} - T_n = m) = \mu_m \quad (4.19)$$

for  $m > 0$  and  $\lambda \neq 0$ . Furthermore, the random vectors  $\mathbf{U}_n \in \mathbb{R}^n$ ,  $\mathbf{U}_n \in \mathbb{Z}^n$ , defined by

$$\mathbf{U}_n = (U_n(T_1), \dots, U_n(T_{n+1} - 1)) \quad (4.20)$$

are mutually independent and  $(U_n(t) : t \geq 0)$  are identically distributed.

## 5 Distribution of $[s; t]$ and $[s; 1]$

In this section we prove items (i) and (iv) [and the corresponding parts in (v)] of the theorem.

We fix an increasing sequence of numbers  $(a_k)$  such that

$$a_k \rightarrow 1 \text{ as } k \rightarrow \infty \quad (5.1)$$

and define the following house of cards family of chains  $(W_n^m : n \geq m) : m \in \mathbb{Z}$  by  $W_m^m = 0$  and for  $n > m$ :

$$W_n^m = (W_{n-1}^m + 1) \mathbf{1}_{\{U_n < a_{W_{n-1}^m}\}} \quad (5.2)$$

where  $U_n$  are the uniform random variables introduced in the previous section. Notation alert: Here  $W_n^m$  is not a vector of length  $n - m$ , but the position at time  $n$  of a chain starting at time  $m$  at the origin. Alternatively,  $P(W_n^m = y | W_{n-1}^m = x) = p(x; y)$ , where the latter are the transition probabilities defined in item (iv) of Theorem 4.3. Notice that

$$p_k = P(W_{m+k}^m = 0) \quad (5.3)$$

for all  $m \in \mathbb{Z}$  and  $k \in \mathbb{N}$ . The monotonicity of the  $a_k$ 's implies that

$$W_n^m \leq W_n^k \text{ for all } m < k \leq n : \quad (5.4)$$

Hence,  $W_n^m = 0$  implies that  $W_n^k = 0$  for  $m < k \leq n$ , and the chains coalesce at time  $n$ :

$$W_n^m = 0 \Rightarrow W_t^m = W_t^k; m \leq k \leq n \leq t \quad (5.5)$$

(furthermore,  $W_t^m > W_t^k$  for  $t$  smaller than the smallest such  $n$ ).

By the definition (4.2) of  $\rho_j$ , we have for  $j \leq s$

$$\begin{aligned} \rho_j[s;t] &< j \quad ( ) \quad \lim_{n \rightarrow \infty} \rho_j[s;t] = 0 \\ ( ) \quad \lim_{n \rightarrow \infty} \rho_j[s;t] &= 0 \\ ( ) \quad \max_{m \leq s} \lim_{n \rightarrow \infty} \rho_j[s;t] &> 0 \text{ if } j > 1 \\ ( ) \quad \lim_{n \rightarrow \infty} \rho_j[s;t] &= 0 \end{aligned} \quad (5.6)$$

where the second line follows from the coalescing property (5.5), and the last line is a consequence of the second one and the monotonicity (5.4). From the third line we get

$$\rho_j[s;t] = 1 + \max_{m \leq s} \lim_{n \rightarrow \infty} \rho_j[s;t] \quad (5.7)$$

Lemma 5.8

a) Condition  $\sum_{k=1}^{\infty} a_k = 1$  is equivalent to any of the two following properties:

(a.1) The chain  $(W_n^m : n \geq m)$  is non positive-recurrent for each  $m$ .

(a.2) For each  $1 < s < t < \infty$ ,  $\rho_j[s;t] > 1$  a.s..

b) Condition  $\sum_{k=1}^{\infty} a_k > 0$  is equivalent to any of the two following properties:

(b.1)  $(W_n^m : n \geq m)$  is transient

(b.2) For each  $1 < s, [s; \infty] > 1$  a.s..

In both cases, inequality (4.7) holds.

Proof. a) It is well known that  $W_n$  is positive-recurrent if and only if  $\sum_{k=1}^{\infty} a_k < 1$ , (for instance Dacunha-Castelle, Du o and Genon-Catalot (1983), p. 62 ex. E.4.1). Also, by (5.6)

$$\lim_{n \rightarrow \infty} \rho_j[s;t] = \lim_{n \rightarrow \infty} \rho_j[s;t] = 0 \quad (5.9)$$

for  $m \leq s$ . By translation invariance, the probability of the right-hand side of (5.9) satisfies

$$\lim_{n \rightarrow \infty} \rho_j[s;t] = \lim_{n \rightarrow \infty} \rho_j[s;t] = 0 \quad (5.10)$$

where the right-hand side is a consequence of the monotonicity property (5.4). As  $m \rightarrow \infty$ , this interval remains bounded away from 0 in the positive-recurrent case, but shrinks to 0

otherwise. Since  $P([s;t] = 1) = \lim_{m \rightarrow \infty} \frac{1}{m} P([s;t] < m)$ , this proves that (a.1) and (a.2) are equivalent.

b) Clearly,

$$P(W_n^m \in [0; 8n - m]) = \sum_{i=0}^m a_i : \quad (5.11)$$

This implies that the product of  $a_k$  is positive if and only if the house-of-cards process is transient. From (5.9) we have that

$$P([s; 1] < m) = P\left[\sum_{i=[s-m+1; 1]} fW_i^0 = 0\right] \quad (5.12)$$

which goes to zero as  $m \rightarrow \infty$  in the transient case only. Therefore (b.1) and (b.2) are equivalent.

Inequality (4.7) follows from (5.9) or (5.12), due to (5.3).  $\square$

The following proposition is due to Bressaud, Fernandez and Galves (1999b).

**Proposition 5.13** Let  $a_k$  be a  $[0;1]$ -sequence increasing to one. Let  $\rho_k$  be the probability of return to the origin at epoch  $k$  of  $(W_n^0 : n \geq 0)$ .

- (i) If  $\sum_{n=0}^{\infty} \rho_n \sum_{k=1}^n a_k = 1$ , then  $\rho_n \rightarrow 0$ .
- (ii) If  $\sum_{k=1}^{\infty} a_k > 0$ , then  $\sum_{n=0}^{\infty} \rho_n < 1$ .
- (iii) If  $(1 - a_n)$  decreases exponentially then so does  $\rho_n$ .
- (iv)

$$\sum_{k=1}^{\infty} a_k > 0 \quad \text{and} \quad \sup_i \limsup_{k \rightarrow \infty} \frac{1 - a_i}{1 - a_{ki}} = 1 \quad \text{imply} \quad \rho_n = O(1 - a_n) \quad (5.14)$$

Item (iv) can be applied, for instance, when  $a_n = 1 - (\log n)^b n^{-\gamma}$  for  $\gamma > 1$ . Items (i) and (ii) are direct transcriptions of (a.1) and (b.2) of the previous lemma.

**Remark 5.15** The results of this section are also monotonic on the choice of sequence  $(a_k)$ : A sequence  $(a_k)$ , satisfying (5.1), with  $a_k \leq a'_k$  for all  $k$ , yields chains  $W_n^m$  with larger probability of visiting 0, and hence with larger regeneration intervals  $s \rightarrow [s;t]$  and larger values of  $\rho_m$ . This is the content of Remark 4.10.

Figure 1: Partition  $\{B_k(g \setminus \frac{1}{k}) : g \in G; k \in \mathbb{N}\}$  of  $[0, 1]$  in the case  $G = \{1, 2, g\}$

## 6 Construction of

In this section we prove results needed to show (ii) and (iii) [and the corresponding part in (v)] of Theorem 4.3. The results hold for any sequence  $(a_k)$  satisfying (4.11), but for notational simplicity we omit the superscript  $\setminus$ . For  $g \in G$  let  $b_0(g) = a_0(g)$ , and for  $k \geq 1$ ,

$$b_k(g \setminus \frac{1}{k}) = a_k(g \setminus \frac{1}{k}) - a_{k-1}(g \setminus \frac{1}{k}):$$

For each  $w \setminus \frac{1}{1} \in G \setminus \mathbb{N}$  let  $\{B_k(g \setminus \frac{1}{k}) : g \in G; k \in \mathbb{N}\}$  be a partition of  $[0, 1]$  with the following properties: (i) for  $g \in G, k \geq 0, B_k(g \setminus \frac{1}{k})$  is an interval closed in the left extreme and open in the right one with Lebesgue measure  $\mathcal{B}_k(g \setminus \frac{1}{k}) = b_k(g \setminus \frac{1}{k})$ ; (ii) these intervals are disposed in increasing lexicographic order with respect to  $g$  and  $k$  in such a way that the left extreme of one interval coincides with the right extreme of the precedent:

$$B_0(g_1); B_0(g_2); \dots; B_1(g_1 \setminus \frac{1}{1}); B_1(g_2 \setminus \frac{1}{1}); \dots; B_2(g_1 \setminus \frac{1}{2}); B_2(g_2 \setminus \frac{1}{2}); \dots$$

is a partition of  $[0, 1]$  into consecutive intervals increasingly arranged. This definition is illustrated in Figure 1 in the case  $G = \{1, 2, g\}$ .

In particular we have

$$\sum_{k=0}^{\infty} \mathcal{B}_k(g \setminus \frac{1}{k}) = \sum_{k=0}^{\infty} b_k(g \setminus \frac{1}{k}) = P(g \setminus \frac{1}{1}) \quad (6.1)$$

and

$$\bigcup_{g \in G, k=0}^{\infty} B_k(gjw_k^{-1}) = [0; 1[ \quad (6.2)$$

where all the unions above are disjoint. For  $k=0$  let

$$B_k(w_k^{-1}) := \bigcup_{g \in G} B_k(gjw_k^{-1});$$

By (2.5) and (4.11), we have

$$[0; a_k[ \bigcup_{v=0}^k B_v(w_v^{-1}) = 40; \sum_{g \in G} a_k(gjw_k^{-1})^4; \quad \text{for all } w_k^{-1} \in G^N : \quad (6.3)$$

As a consequence,

$$[0; a_k[ \setminus B_v(w_v^{-1}) = ; \quad \text{for } v > k; \quad (6.4)$$

a fact that makes the definitions

$$B_{v,k}(w_1^{-1}; \dots; w_k^{-1}) := [0; a_k[ \setminus B_v(w_v^{-1}) \quad (6.5)$$

$$B_{v,k}(gjw_1^{-1}; \dots; w_k^{-1}) := [0; a_k[ \setminus B_v(gjw_v^{-1}) : \quad (6.6)$$

meaningful for all  $v, k \geq 0$ .

Items (ii) and (iii) [and the corresponding part in (v)] of Theorem 4.3 are immediate consequences of the following proposition. Similar to (3.5), define

$$[n](u) := \max_{s \leq n} s : u_j < a_{j-s}; j \in [s; n] :$$

**Proposition 6.7** Let  $g_0$  be an arbitrary point in  $G$ . Define the function  $x : [0; 1[ \rightarrow G^{\mathbb{Z}}; u \mapsto x = (u)$ , recursively from  $j = [n](u)$  to  $j = n$  in the following fashion: write  $x = [n](u)$  and define

$$\begin{aligned} x &= \sum_{g \in G} \sum_{u \in B_0(g)}^n \circ \\ x_{+1} &= \sum_{g \in G} \sum_{u \in B_0(g)}^n [B_{1,1}(gj)] \circ \\ &\vdots \\ x_n &= \sum_{g \in G} \sum_{u \in B_0(g)}^n [B_{j,n}(gj_{n-1}; \dots; x)] \circ \end{aligned} \quad (6.8)$$

if  $[n](u)$  is finite, and  $x_n = g_0$  if  $[n](u) = \infty$ . (Each sum in (6.8) reduces to a single term.) Then:

- (i)  $\underline{u}$  is well defined and measurable.
- (ii) For each  $n \in \mathbb{Z}$ , the component  $\underline{u}(n)$  depends only on the values of  $u_i$  on the interval  $[\lfloor n \rfloor(n); n]$  if  $\lfloor n \rfloor(n) > -1$ , and on  $(u_i : i \leq n)$  otherwise.
- (iii) If  $P(\lfloor n \rfloor(\underline{U}) > -1) = 1$ , for all  $n \in \mathbb{Z}$ , then the law of  $(\underline{U})$  is compatible with  $P$  and is stationary.

Proof. Let

$$A_n = \{ \underline{u} \in [0; 1]^{\mathbb{Z}} : \lfloor n \rfloor(\underline{u}) > -1 \} \quad (6.9)$$

(i) On the set  $A_n$ , the consistency of the definition 6.8 follows from two facts: (1) By definition,  $\lfloor n \rfloor = \lfloor j \rfloor$  for  $j \in [\lfloor n \rfloor(n); n]$ , and (2) (6.3) shows that if the event  $\{U_n < a_k\}$  holds, then we only need to look at  $x_{n-1}; \dots; x_{n-k}$  to obtain the value of  $x_n$ . These facts imply that for every  $k \in [\lfloor n \rfloor(n); n]$ , the value of  $x_k$  computed using (6.8) with  $k$  in place of  $n$  yields the same value as the one obtained as part of the recursive calculation (6.8) for  $x_n$ . The  $F(U_i : i \leq n)$ -measurability of  $x_n$  follows, then, from definition (6.8). As the sets  $A_n$  are  $F(U_i : i \leq n)$ -measurable, see (4.2), the maps  $x_n$  remain measurable after gluing. We conclude that  $\underline{u} = (x_n; n \in \mathbb{Z})$  is well defined and measurable.

(ii) Immediate from the definition (now known to be consistent).

(iii) When  $A_n$  is true, (6.4) implies that Definition 6.8 amounts to

$$x_n = \bigoplus_{g \in G} \bigoplus_{k=0}^n [B_k(g \cdot \bigoplus_{j=0}^{n-1} x_{n-j}^k)] \quad (6.10)$$

which implies

$$P(\underline{U}(n) = g \mid U_i : i < n; A_n) = P(U_n \in [B_k(g \cdot [\underline{U}]_n^{n-1}) \mid U_i : i < n; A_n) \quad (6.11)$$

Since each  $\underline{U}(j)$  is  $F(U_i : i \leq j)$ -measurable, and each  $U_n$  is independent of  $F(U_i : i < n)$ , if  $A_n$  has full measure, then (6.11) equals

$$\bigoplus_{k=0} [B_k(g \cdot [\underline{U}]_n^{n-1})] = \bigoplus_{k=0} B_k(g \cdot [\underline{U}]_n^{n-1}) = P(g \cdot [\underline{U}]_1^{n-1}) \quad (6.12)$$

by (6.1). In other words,

$$P(\underline{U}(n) = g \mid U_i : i < n) = P(g \cdot (\underline{U}(i) : i < n)) \quad (6.13)$$

As the right-hand side depends only on  $(\underline{U}(i) : i < n)$ , so does the left-hand side. Hence the law of  $\underline{U}(n)$  given  $(\underline{U}(i) : i < n)$  itself is still given by  $P$ . Therefore the distribution of  $\underline{U}$  is compatible with  $P$  in the sense of (2.2). It is stationary by construction.  $\square$

Remark 6.14 The previous argument shows, in particular, that if  $a_k \geq a_k$  for all  $k \geq 0$ , and  $[s;t](u)$  is finite (in which case  $[s;t] < [s;t]$  is finite, see Remark 5.15), then  $(u)(j) = (u)(j)$  for all  $j \geq [s;t]$ . (Each  $(u)(j)$  depends on a larger number  $j$  of preceding  $U^0$ s.) If Condition (4.4) holds for the coefficients  $m = \sum_{k=0}^{\infty} a_k$ , both  $\mu$  and  $\nu$  have laws compatible with  $P$ .

Proof of Corollary 4.12. We represent the one-sided conditioned measure through a family of functions  $(\underline{w}; i) : [0; 1]^{\mathbb{Z}} \rightarrow \mathbb{G}^{\mathbb{Z}}$  corresponding to a history  $\underline{w} \in \mathbb{G}^{\mathbb{Z}}$  frozen for times smaller than  $i \in \mathbb{Z}$ . Writing, for shortness,  $y_j = (\underline{w}; i)(j)$ , we set  $y_j = w_j$  for  $j < i$  and successively for  $n = i, i+1, \dots$ ,

$$y_n = \sum_{g \in G} \sum_{k=0}^n [B_k g y_{n-1}; \dots; y_i; w_{i-1}; \dots; w_{n-k}; \dots] : \quad (6.15)$$

Let  $\mu$  be any probability measure on  $\mathbb{G}^{\mathbb{Z}}$  compatible with  $P$ . From (2.3) and (6.1) we see that the law of  $(\underline{w}; i)$  is a regular version of  $\mu$  given  $i-1 = i-1; i-2 = i-2; \dots$ . That is,

$$f((j) = w_j; j < i) = E[f((\underline{w}; i)) \mid \mathcal{F}_{i-1}] \quad (6.16)$$

for any continuous  $f$ . We now follow the classical arguments.

Proof of (i): Let  $f$  be as stated. By (6.16)

$$f((j) = w_j; j < i) = f((j) = v_j; j < i) = E[f((\underline{w}; i)) \mid \mathcal{F}_{i-1}] = E[f((\underline{v}; i)) \mid \mathcal{F}_{i-1}] : \quad (6.17)$$

Since

$$\sum_{n=1}^{\infty} |(\underline{w}; i)(n) - (\underline{v}; i)(n)| \leq \sum_{n=1}^{\infty} |f(n)| \quad (6.18)$$

the absolute value of both terms in (6.20) is bounded above by

$$2kf_1 P([s;t] < i) : \quad (6.19)$$

To conclude, we use the bound (4.7).

Proof of (ii): If  $\mu$  and  $\nu$  are two measures on  $\mathbb{G}^{\mathbb{Z}}$  compatible with  $P$ ,

$$\begin{aligned} \int f d\mu - \int f d\nu &= \int \sum_{j=1}^{\infty} (dw_j - dv_j) f((j) = w_j; j < i) - \int \sum_{j=1}^{\infty} (dw_j - dv_j) f((j) = v_j; j < i) \\ &= \int \sum_{j=1}^{\infty} (dw_j - dv_j) f((j) = w_j; j < i) - \int \sum_{j=1}^{\infty} (dw_j - dv_j) f((j) = v_j; j < i) ; \end{aligned} \quad (6.20)$$

which, by part (i), goes to zero as  $i \rightarrow \infty$ .  $\square$

Proof of Theorem 4.3 We finish this section showing how Theorem 4.3 follows from previous results.

Lemma 5.8 proves (i) and (iv) and the corresponding part of (v). The bounds mentioned at the end of (iv) are consequence of Proposition 5.13. Proposition 6.7 proves parts (ii) and (iii) and the corresponding part in (v).

## 7 Perfect simulation

In this section we prove Corollary 4.14. The construction of the function  $e_{\tau}$  relies on an alternative construction of the stopping time  $[s; t]$ . Assume  $s < t$  and define

$$Z[s; t] := \max\{K_n : n + s \leq n \leq [s; t]\} \quad (7.1)$$

where  $K_n = K_n(\underline{U})$  is defined in (3.4).  $Z[s; t]$  is the number of sites to the left of  $s$  we need to know to be able to construct  $\tau$  in the interval  $[s; t]$ . Let  $Y_{-1} := t + 1$ ,  $Y_0 := s$  and for  $n \geq 1$ , inductively

$$Y_n := Y_{n-1} - Z[Y_{n-1}; Y_{n-2} - 1] \quad (7.2)$$

Then it is easy to see that

$$[s; t] = \lim_{n \rightarrow \infty} Y_n = \max\{Y_n : Y_n = Y_{n+1}\} \quad (7.3)$$

with the usual convention  $\max \emptyset = -1$ .

Construction of the perfect-simulation function  $e_{\tau}$

1. Set  $Y_{-1} = t + 1$ ,  $Y_0 = s$  and iterate the following step until  $Y_n = Y_{n-1}$ :

Generate  $U_Y, \dots, U_{Y_{n-1}-1}$ . Use (3.4) to compute  $K_Y, \dots, K_{Y_{n-1}}$  and (7.1) and (7.2) to compute  $Y_{n+1}$ .

2. Let  $\tau = Y_n$

3. Iterate the following procedure from  $k = \tau$  to  $k = t$ :

Define  $x_k$  using (6.8)

4. Return  $(x_j : j \in [s; t]) = e_{\tau}(U, \dots, U_t)(j) : j \in [s; t]$ .

By definition of  $e_{\tau}$ ,  $e_{\tau}(U, \dots, U_t)(j) = (\underline{U})(j)$ ,  $j \in [s; t]$ .  $\square$

Remark 7.4 The algorithm can be applied for any choice of  $(a_k; k \geq 0)$  satisfying (4.11) and, in addition,

$$\sum_{k=0}^{\infty} a_k = 1 \quad (4.12)$$

The smaller the  $a_k$ , the smaller the stopping times  $[s; t]$  of the resulting perfect-simulation scheme. Also the return probabilities  $p_m$  increase if the  $a_k$  increase, worsening the bound (4.16) on the user-impatience bias.

## 8 Regeneration scheme

In this section we prove Corollary 4.18. The stationarity of  $N$  follows immediately from the construction. Let

$$f(j) = P(N(j) = 1 | N(0) = 1) \quad (8.1)$$

for  $j \in \mathbb{Z}$ . To see that  $N$  is a renewal process it is sufficient to show that

$$P(N(s_1) = 1; \dots; N(s_n) = 1) = \prod_{i=1}^{n-1} f(s_{i+1} - s_i) \quad (8.2)$$

for arbitrary integers  $s_1 < \dots < s_n$ . From Poincaré's inclusion-exclusion formula, a measure on  $\{0, 1\}^{\mathbb{Z}}$  is characterized by its value on cylinder sets of the form  $\{s = 1; s_2 \in S; \dots; s_n \in S\}$  for all finite  $S \subset \mathbb{Z}$ . For  $S = \{s_1, \dots, s_n\}$ , a renewal process must satisfy (8.2). For  $j \in \mathbb{Z}$ ,  $j^0 \in \mathbb{Z}$  [1], define

$$H[j; j^0] = \begin{cases} \sum_{k=0}^{\infty} f_{j+k} < a; \dots; j^0 - j; & \text{if } j = j^0 \\ \text{"full event"}; & \text{if } j > j^0 \end{cases} \quad (8.3)$$

With this notation,

$$N(j) = 1 \Leftrightarrow H[j; 1 - j]; \quad j \in \mathbb{Z} \quad (8.4)$$

and

$$P(N(s_1) = 1; \dots; N(s_n) = 1) = \prod_{i=1}^{n-1} H[s_{i+1} - s_i] \quad (8.5)$$

From monotonicity we have for  $j < j^0 < j^0 + 1$ ,

$$H[j; j^0] \setminus H[j^0; j^0] = H[j; j^0 - 1] \setminus H[j^0; j^0]; \quad (8.6)$$

and then, with  $s_{n+1} = 1$  we see that (8.5) equals

$$\prod_{i=1}^n P(H[s_i; s_{i+1} = 1]) ; \quad (8.7)$$

On the other hand,

$$f(j) = P(H[j; 1] | H[0; 1]) = P(H[j; 1]) \quad (8.8)$$

Hence, (8.7) equals the right hand side of (8.2) and we have proved that  $N$  is a renewal process.

On the other hand, by stationarity,

$$P(T_{n+1} - T_n = m) = P([1; 1] < m+1 | [0; 1]) = 0 \quad (8.9)$$

and, hence, by (5.6) and (5.3)

$$P(T_{n+1} - T_n = m) = P(W_1^{m+1} = 0) = 0 ; \quad (8.10)$$

proving (4.19).

The independence of the random vectors  $\mathbf{v}_n$  follows from the definition of  $T_n$  and part (iii) of Theorem 4.3.  $\square$

## 9 Applications

### 9.1 Binary autoregressions, continued

In this subsection we continue the discussion of example (3.1). Recalling the notations of Section 3, we define

$$C^+ = \max_{\mathbf{x} \in [0, 1]^n} q^0(\mathbf{x}) : \sum_{m=0}^{\infty} \prod_{k=0}^m x_k \leq 1 \quad (9.1)$$

$$C = \min_{\mathbf{x} \in [0, 1]^n} q^0(\mathbf{x}) : \sum_{m=0}^{\infty} \prod_{k=0}^m x_k \leq 1 \quad (9.2)$$

From Definition (4.9), a simple computation shows that

$$C > 0 \iff \sum_{k=0}^{\infty} r_k < 1 \iff \sum_{k=0}^{\infty} k^2 j_k < 1 \quad (9.3)$$

and also that for  $j_k \leq C k^{-2}$ , Condition (4.4) is satisfied for  $C < (2C^+)^{-1}$ , but not satisfied for  $C > (2C^+)^{-1}$ . Hence  $\limsup_k k^2 j_k < (2C^+)^{-1}$  is sufficient for being in the Harris regime (4.4), and  $\limsup_k j_k k^2 \ln^2 k < 1$  implies that  $C > 0$ .

Since  $a_k$  given by (3.3) has no simple expression in general, Remark 4.10 could be useful. Indeed,

$$1 - 2C^+ r_k = a_k = 1 - 2C^- r_k : \quad (9.4)$$

Under the extra condition that  $r_k \neq 0$  for infinitely many  $k$ 's, we have in fact  $a_k = 1 - 2C^+ r_k$  as  $k \rightarrow \infty$ .

We can replace the coefficients  $a_k$  with the following lower bounds. We choose first some integer  $k_0$  such that  $2C^+ r_{k_0} < 1$  and define

$$\begin{aligned} a_k &= a_k \wedge (1 - 2C^+ r_{k_0}) \quad \text{for } k < k_0 ; \\ a_k &= 1 - 2C^+ r_k \quad \text{for } k \geq k_0 : \end{aligned} \quad (9.5)$$

We can use the modification of our algorithm at the end of Section 7 with these coefficients  $a_k$ . Note that we only need to compute at most  $k_0$  different  $a_k$ 's.

We now discuss two well-studied choices for  $q$ .

**Sigmoid case:** In addition we assume here that  $q$  is concave on  $\mathbb{R}^+$  with  $q(x) + q(-x) = 1; x \in \mathbb{R}$ . One natural choice is

$$q(x) = \frac{\exp x}{2 \cosh x} = \frac{1}{2(1 + \exp(-2x))} ; \quad (9.6)$$

i.e., the so-called logistic function and logit model (Guyon (1995), Ex. 2.2.4), where the explicative variables are the values of the process in the past. For a general sigmoid  $q$ , the supremum in (3.3) is achieved for  $w_k$  minimizing  $j_0 + \sum_{k=1}^P (1 - a_k) w_k$ .

**Linear case:** We take now  $q(x) = (1+x)/2$ , and necessarily  $j_0 + \sum_{k=1}^P (1 - a_k) w_k < 1$ . As we will see, linearity makes the model (3.1) somehow trivial, but also instructive. Writing  $B(p)$  for the Bernoulli distribution with parameter  $p$  and the Dirac measure, we note that the one-sided conditional law (3.1) is given by a convex combination

$$\begin{aligned} P(j_1 = 1) &= B\left(\frac{1 + j_0 + \sum_{k=1}^P (1 - a_k) w_k}{2}\right) = B\left(\frac{1 + j_0 + r_0}{2}\right) + \sum_{k=1}^P (1 - a_k) \frac{\text{sign}(w_k) + 1}{2} A \\ &= (1 - r_0)B\left(\frac{1 + j_0 + r_0}{2}\right) + \sum_{k=1}^P (1 - a_k) \frac{\text{sign}(w_k) + 1}{2} ; \end{aligned} \quad (9.7)$$

since  $B((1-p)/2) = B(p)/2 + (1-p)/2$  for  $p \in [0,1]$ . In this example we have  $a_k(w_k) = 1 - r_k = a_k$  independent of  $w_k$ , and for  $k \geq 1$ ,

$$b_k(j_1 = 1 | w_k) = (w_k + j_k)/2 = \begin{cases} j_k & \text{if } w_k = \text{sign}(w_k) \\ 0 & \text{otherwise} \end{cases} \quad (9.8)$$

Hence one of the two intervals  $B_k(-1/j_k^{1/2})$  is empty, while the other one  $B_k(\text{sign}(w_k)w_k/j_k^{1/2})$  has length  $|j_k|$ . This is in accordance with formula (9.7).

In other respects, the decomposition (9.7) can be directly interpreted in terms of simulation: the value of the process at time  $i = 0$  is chosen according to a "new" coin tossing with probability  $1 - r_0$ , and set to the value  $\text{sign}(w_k)w_k$  with probability  $|j_k|$  ( $k = 1; 2; \dots$ ). In the latter case the value of  $w_k$  is needed, and will be constructed using (9.7) again, etc.: Clearly this recursive construction will eventually stop if and only if  $\sum_{k=0}^{\infty} |j_k| < 1$ . However, our construction in this paper requires the extra condition (4.4), which loosely speaking, amounts to  $\limsup_k k^2 |j_k| < 1$ . The reason for stronger assumptions is that, in order to cover general processes, we need in our general construction to check all intermediate times between 0 and  $[0]$ , though in the special case of  $P$  given by (9.7), it is not necessary to construct all of them following the above lines.

## 9.2 Markov chains defined by D-ary expansions

These are processes having the unit interval as "alphabet",  $I = [0; 1]$ , and defined through another, auxiliary, process with a finite alphabet. Formally, a family of maps is established between sequences of a finite alphabet  $G = \{0; 1; \dots; D-1\}$  and real numbers in  $I$  via D-ary expansions: For each  $n \in \mathbb{Z}$

$$\begin{aligned} X_n : G^{\mathbb{Z}} &\rightarrow I \\ (i : i \in \mathbb{Z}) \mapsto x_n &= \sum_{j=1}^{\infty} \frac{1}{D^j} (i_{-j}) D^{-j} : \end{aligned} \quad (9.9)$$

This map induces a natural map from probability kernels  $P : G^{\mathbb{N}} \rightarrow [0; 1]$  to probability kernels  $F : I \rightarrow [0; 1]$ : For each  $x \in I$ , given an  $w = \sum_{j=1}^{\infty} \frac{1}{D^j} w_j$  with  $x = X_0(w)$

$$F(X_1 = \frac{g+x}{D} \mid X_0 = x) = P(g_j) : \quad (9.10)$$

Interest focuses on the existence and properties of measures on the Borelians of  $I^{\mathbb{Z}}$  compatible with such a (Markov) kernel  $F$ .

Maps (9.9)–(9.10) have been already introduced by Borel (1909) for i.i.d. (i). The general case in which the (i) form a chain with long memory is the object of Harris (1955) seminal paper. They are the prototype of the random systems with complete connections mentioned in the Introduction. Harris determines conditions for the existence and uniqueness of these processes, through the study of long-memory chains: if the finite-alphabet chain satisfies a condition similar to (but weaker than) (4.4), there is a unique process  $M$  on  $I^{\mathbb{Z}}$  compatible with  $F$ . This process  $M$  is of course a (stationary) Markov chain with transition probability

kernel  $F$ . Harris shows that its marginal distribution is continuous, except in the degenerate case with constant  $\rho_i$ 's where it is concentrated on one of the points  $0; 1 = (D-1)/2 = (D-1)/2$ ;  $1$ . Furthermore, if the process is mixing and not degenerate, this marginal is purely singular whenever the variables  $\rho_i$  are not independent uniformly distributed (in which case the marginal is uniform).

Our approach yields, in a straightforward way, a perfect-simulation scheme for the measures  $M$  obtained in this fashion, if the auxiliary process  $\rho_i$  satisfies condition (4.4). Indeed, the map

$$X : G^{\mathbb{N}} \rightarrow I, \quad (9.11)$$

$$w = \frac{1}{D} \quad \tau \quad x = X_0(w = \frac{1}{D})$$

can be made bijective by fixing rules to decide between sequences which are eventually 0 and those that are eventually  $D-1$ . In turns, this map induces a bijection between the sigma algebra  $S$ , formed by unions of intervals with endpoints in multiples of  $D^{-1}$ , and the subsets of  $G^{\mathbb{N}}$ . We conclude that, if  $\rho$  and  $M$  are the processes compatible with the kernels  $P$  and  $F$  related as in (9.10), then the restriction of  $M$  to  $S$  can be perfectly simulated by mapping, via  $X$ , the perfect samples of the measure  $\rho$  on the window  $[0; 1]$ , obtained by the algorithm of Section 7. We point out that the union of the families of  $M$ , uniquely determines the measure  $M$  (it forms a so-called system).

**Conclusion** For Markov chains in general state-space with transition kernel  $P(x; \cdot)$  satisfying the Doob's condition  $P(x; \cdot) \leq \rho(\cdot)$ , for all state  $x$ , some  $\rho > 0$  and a measure  $\rho$  on the state-space, the forward coupling is well known. The corresponding coupling-from-the-past algorithm is illustrated in Example 2 of Foss and Tweedy (1999) and in Corcoran and Tweedie (1999). Notice however that the mere existence of a minorization measure is not sufficient to construct the couplings: one needs to explicitly know  $\rho$  and  $\rho$ . In this section we have discussed an example of a Markov chain with state-space  $[0; 1]$  that can be transcribed as a chain with complete connections and state-space  $\{0; 1; \dots; D-1\}$ . Perfect simulating the latter provides a perfect simulation for the former. Instead of the exhibition of a minorization measure for the Markov chain our method requires the knowledge of  $a_k$  ( $g_j = \frac{1}{D}$ ) and lower bounds of  $a_k$  for the related infinite-memory chain.

## Acknowledgements

RF wants to thank Davide Gabrielli and Jesse Steif for useful discussions. FC acknowledge Xavier Guyon and Alexander Tsybakov for pointing out references relating to Section 9.1.

FC and RF thanks IM E-USP for hospitality. PAF thanks the Laboratoire des Probabilités de l'Université de Paris VII, the Département de Mathématiques de l'Université de Cergy Pontoise and the Laboratory Raphael Salem of the Université de Rouen, for hospitality during the completion of this work.

We thank one of the anonymous referees for his careful reading of the manuscript and for his useful suggestions that improved the paper.
