#### Abstract

W e describe a new com plex system model of an evolving production econom $y$. This model is the sim plest we can envisage which inconporates the new observation that the rate of an econom ic production process depends only on the m inim um of its supplies of inputs. W e describe how this condition gives rise to a new type of com plex multiple tim escale dynam ical evolution through a novel type of bifurcation we call a trapping bifurcation, which is also show $n$ to be one cause of nonequilibrium econom ic behaviour. Such dynam ics is an exam ple of m eta-level coupling which may also arise in other elds such as cellular organization as a netw ork of $m$ olecular $m$ achines.

PACS num bers: $89.65 .-\mathrm{s}, 89.65 \mathrm{Gh}, 89.75 \mathrm{Fb}, 05.45 .-\mathrm{a}, 82 \mathrm{~m}$. $\mathrm{Rt}, 05.45 \mathrm{Xt}$

Introduction. Recently physicists have been devoting a great deal of attention to econom ic and nancial phenom ena[1]. E conom ic dynam ics is easily observed to be far from equilibrium where periodic recessions, unem ploym ent and unstable prices occur persistently. A n understanding of the origins of this behaviour from the view point ofcom plex dynam icalsystem stheory w ould be very valuable. O urm odel[2], which we hope takes a step in this direction, is based on von N eum ann's[3] neoclassicalm odelofeconom ic production and catalytic chem ical reaction netw ork dynam ics [4].

The originalvon $N$ eum ann $m$ odel (VNM) of econom ic production assum es that each good is produced jointly w ith certain others, in an analogousw ay to a chem icalreaction. A production process is the operation which converts one bundle of goods, including capital equipm ent, into anotherbundle of goods, including the capitalequip$m$ ent. C apital goods therefore function approxim ately like catalysts in chem icalreactions, reform ed at the end of the reaction in am ounts conserved in the reaction. C onsum ption of goods is assum ed to take place only through production processes, including life necessities consum ed by workers, and all income is reinvested in production. Therefore the VNM is de ned by a xed input $m$ atrix and a xed output $m$ atrix, representing, the xed stochiom etric ratios of input products and output products for each process. A n exam ple of such an econom ic network is show $n$ in $F$ ig 1. E ach process is assum ed to have unit tim e duration, longer processes being broken down into several processes w ith interm ediate products. T he VNM is de ned as a static equilibrium $m$ odel describing relationships betw een the variables which $m$ ust hold at equilibrium . Equilibrium is a state of balanced grow th' where prices are constant. T here are no dynam ics de ned by the $m$ odelw hich $m$ ight describe out of equilibrium or approach to equilibrium behaviour.

H ow ever it is rarely the case that econom ic processes are in equilibrium . For exam ple consider a sim ple bakery w ith input: (dough, baker, oven) and output: (bread,

E lectronic address: adam@ com plex.c.u-tokyo.ac.jp

FIG. 1: An Economy. Red lines are production ow S , blue lines ow sto and from the environm ent (including other countries) and green lines are catalytic e ects. Som e processes are autocatalytic.
baker, oven), so that the baker and the oven are catalysts. W e observe that the rate of bread production, and econom ic processes in general, depends on the quantity of the $m$ inim um of its input supplies and not on the quantities of its other supplies. I.e. the baker working at fiull pace can only $l l$ ovens at a certain rate. Sim ilarly em ploying $m$ ore bakers $w$ ill not increase bread production if the ovens are already fill. This is in direct contrast w ith a chem ical reaction obeying the law ofm ass action, where an increase in concentration of any of its input species w ill increase the rate of reaction.

This minimum condition leads directly to multiple tim escales [5]. C onsider a factory assem bling bicycles from wheels and fram es at a given rate. Suppose for som e reason the rate of supply ofw heels increases so that their prioe drops. Tom axim isee ciency the factory $w$ ill try to use all its finds to expand production, buying the extra $w$ heels and dem anding $m$ ore fram es. A factory $w$ th large fundsm ay dem and fram es so strongly that the the fram e$m$ akers respond to it and increase their supply rate. In this way the wheel-m akers and fram em akers production rates $m$ ay becom e synchronised. A factory $w$ ith $s m$ all funds on the other hand $m$ ay only weakly in uence the fram e supply rate. Its bicycle production rate w ill be determ ined by the supply rate of whichever is the m ost expensive, and $m$ ay sw itch betw een the rates as price levels change. The factory w ill have ine cient periods w ith surpluses of fram es or wheels, but to avoid this by not using all its funds would still not be $m$ axim ally $e$ cient.

Here we show how such multiple tim escales arise endogenously' in a new model of an econom y of coupled processeswhich is di erent from the VNM in that we explicitly take into account the w ay a process' production rate depends on the $m$ inim um of its input supplies.

M odel. A lthough our $m$ odel ignores $m$ any details, we believe it captures the essential characteristics of a evolving production-m arketing network, in the sim plest way possible. The system is de ned by a xed number of processes $K_{I}$ and products $K_{J}$ w ith input stochiom etric ratios $a_{i j}$ and ouput stochiom etric ratios $b_{i j}$, where i labels the processes and $j$ the products. E ach process has supplies of its products $S_{i j}(t)$, it also has a dynam ical
tness called finds $F_{i}(t)$, $m$ easured in dollars, which represents the size' or 'intensity' of the process. Them odel can be conveniently broken down into four sim ple parts.
(i) P rocessing. H ere all processes sim ultaneously $m$ anufacture goods so that their supplies after processing, denoted w ith ' ', are given by,

$$
\begin{equation*}
S_{i j}(t)=S_{i j}(t)+\left(b_{i j} \quad a_{i j}\right) M \quad i n_{k}\left(S_{i k}(t)=a_{i k}\right) \tag{1}
\end{equation*}
$$

where the processing rate is given by $M \quad \mathrm{in}_{\mathrm{k}}\left(\mathrm{S}_{\mathrm{ik}}(\mathrm{t})=\mathrm{a}_{\mathrm{ik}}\right)$ where $M \mathrm{in}_{\mathrm{k}}\left(\mathrm{x}_{\mathrm{k}}\right)$ denotes the m in im um over $\mathrm{x}_{\mathrm{k}}$.
(ii) $P$ roduct revaluation. T he value, or price $p_{j}(t)$, of a product is recalculated after processing and depends on the overall supply available in the whole econom $y$ and on how much all the processes want it. To m easure how much the processes want the product we consider how much they will pay for it and each process therefore divides its funds $F_{i}(t)$ into dem ands $D_{i j}(t)$ for its input products. The new product value $\mathrm{p}_{j}(t)$ is then given by

$$
\begin{equation*}
p_{j}(t)=\frac{T \text { otalD em and }}{T \text { otal } S \text { upply }}=\frac{P}{{ }_{i} D_{i j}(t)+D_{j}^{e}}{ }_{i} S_{i j}(t)+S_{j}^{e} ; \tag{2}
\end{equation*}
$$

where $S_{j}^{e}$ and $D_{j}^{e}$ are possible extemal supplies and de$m$ ands com ing from, say, another country.
$T$ here are $m$ any ways a process $m$ ay allocate its fiunds into dem ands. If we consider a feedback from the price the fiunds should be divided according to $a_{i j} p_{j}(t \quad 1)$ since this is process i's best estim ate of the per unit cost of input $j$ depending on the $m$ ost recent know $n$ price $p_{j}$ (t 1). A ltematively the processm ay sim ply divide its funds according to the ratios $\mathrm{a}_{\mathrm{ij}}$. H ere we w ill consider,

$$
\begin{equation*}
D_{i j}(t)=F_{i}(t)\left(\frac{a_{i j} p_{j}(t \quad 1)}{{ }_{j} a_{i j} p_{j}(t \quad 1)}+(1 \quad) a_{i j}\right) \tag{3}
\end{equation*}
$$

where the param eter $0 \ll 1$ quanti es the feedback from the price. In fact we will show that the interesting behaviour is found independently of , the im portant points being $D_{i j}(t) / F_{i}(t) 8 j$ and ${ }_{j} D_{i j}(t)=F_{i}(t)$.
(iii) $P$ roduct resharing. P rocesses obtain new supplies for processing sim ply according to

$$
\begin{equation*}
S_{i j}(t+1)=D_{i j}(t)=P_{j}(t) \tag{4}
\end{equation*}
$$

so that processes w ith relatively large funds obtain larger proportions of the available supply.

FIG . 2: Three exam ples of multi-tim escale tim e series produced from 15 process, 10 product netw orks, ( $=0: 9$ ).
(iv) P rocess revaluation. The new process funds are,

$$
F_{i}(t+1)={ }_{j}^{X} S_{i j}(t) p_{j}(t)
$$

so that processes $w$ ith larger $m$ anufactured supplies obtain greater proportions of the available funds, and in this way the system becom es an evolving netw ork.

Results. These equations have the novel property that they sw itch their form depending on which product is the $m$ inim um at any time. Synergetic e ects then appear because the dynam ics itself selects the equations which determ ine its own future evolution. W e will show that this strong non-linearity leads to the new type of very com plex multi-tim escale dynam ics ilhustrated in F ig 2 , focusing on $=0$ since the analysis is $m u c h ~ s i m p l e r . ~$

We rst show that even the sim plest single process, in a xed environm ent, will, under general conditions, oscillate periodically due to a novelsw itching $m$ echanism and furtherm ore this has interesting econom ic relevance.
$T$ his $K_{I}=1, K_{J}=3$ system has one input product $I_{\text {, }}$ one catalyst C , and one output product O , reacting w ith non-zero stoch iom etric ratios $a_{I}=a_{C}=b_{C}=b_{0}=1=2$ w th $=0$. It has 3 variables, its input supplies $S_{I}(t)$, catalyst supplies $S_{C}$ ( $t$ ) and funds $F$ ( $(t)$, where we drop the process label i. There are two phases: ( X ) excess input, $S_{I}(t)>S_{C}(t)$ and ( $Y$ ) excess catalyst, $S_{I}(t)<$ $S_{C}(t)$, such that Eq4 $4, S_{I}(t+1)=1=2 F(t)=P_{I}(t)$ and $S_{C}(t+1)=1=2 F(t)=p_{C}(t)$ becom es,

$$
\begin{array}{r}
\text { (X) } \quad S_{I}(t+1)=\frac{1=2 F(t)\left(S_{I}(t) S_{C}(t)+S_{I}^{e}\right)}{1=2 F(t)+D_{I}^{e}} \\
(Y) \quad S_{I}(t+1)=\frac{1=2 F(t) S_{I}^{e}}{1=2 F(t)+D_{I}^{e}} \\
(X ; Y) \quad S_{C}(t+1)=\frac{1=2 F(t)\left(S_{C}(t)+S_{C}^{e}\right)}{1=2 F(t)+D_{C}^{e}} \tag{8}
\end{array}
$$

where we have om itted the ( X ) and ( Y ) F ( t ) equations for sim plicity and where $S_{I}^{e} ; S_{C}^{e} ; S_{o}^{e}$ and $D{ }_{I}^{e} ; D_{C}^{e} ; D{ }_{o}^{e}$ are xed extemalsupplies and dem ands of the three products respectively. H ere, since $=0$ and $a_{I}=a_{C},(X)$ and $(Y)$ sw itch whenever the prices $p_{I}(t)$ and $p_{C}(t)$ cross.

To understand the noveldynam ical features of th is system it is su cient to consider the interaction of the phase ( X ) and phase ( $Y$ ) xed points. Denoting these two xed points by superscript ${ }^{\text {siy }}$ 'we nd that, although the xed point positions are di erent, the xed point prices in both phases are the sam e and given by,

$$
\begin{equation*}
p_{I}^{x i y}=p_{o}^{x i y}=\frac{D_{I}^{e}+D_{o}^{e}}{S_{I}^{e}+S_{O}^{e}} ; \quad p_{C}^{x i y}=\frac{D_{C}^{e}}{S_{C}^{e}}: \tag{9}
\end{equation*}
$$

Therefore a process in equilibrium acts to m ake its input and output product prices equal[6]. This interesting non-trivial relationship has the observable consequence that for exam ple scaling both $D_{0}^{e}$ and $S_{o}^{e}$ by the sam $e$ constant factor will change the prioe of both $O$ and $I$, although one would naively expect that such a scaling should leave the prioes unchanged. (7]

H ow ever as shown in F ig ${ }^{3}(\mathrm{a})$, which show $s$ a typical tim e series variation in the $S_{I}(t), S_{C}(t)$ plane, the proœess w ill not in generalbe at a xed point, but oscillates periodically. A though nether phase ( $X$ ) nor ( $Y$ ) has a periodic attractor on 斗s ow n , a lim it cycle is created by a novel trapped sw itching $m$ echanism which arises due to the $m$ inim um dynam ics as explained in $F$ ig ${ }^{3}(a)$. A s show $n$ the ratio of the xed point values $=\left(P_{C}^{x i y}=P_{I}^{x i y}\right)$ acts as a trapping bifurcation param eter since when $>1$ the sw itching state is obtained but when $<1$ the system rem ains at the node w ithout oscillating.

The sw itching state is plausible econom ically. In the sw itching state we nd the fund xed points are such that $\mathrm{F}^{\mathrm{X}}=\mathrm{F}^{\mathrm{Y}}>\mathrm{F}^{\mathrm{Y}}$. Therefore when the system is in the excess catalyst phase ( $Y$ ) its funds $F$ ( $(t)$ decrease and it acts to reduce $S_{C}$ (t) (Eq.8). H ow ever the decrease in $S_{C}(t)$, since it is not the $m$ inim um supply, has no e ect on the processing rate, and $S_{I}(t)$ (Eq77) is therefore not a ected by the change in $S_{c}(t)$. In the excess supply phase ( $X$ ) on the other hand, the finds $F(t)$ increase and the process acts to increase $S_{C}$ ( $(\mathrm{t})$ ( Eq (8) which increases the processing rate and decreases $S_{\text {I }}(t)$ (Eq.6) producing the oscillation. Furthem ore as explained in Fig (a) (c) the sw itching frequency decreases as increases. This is to be expected econom ically. The price xed points are determ ined by the extemalenvironm ent. $W$ hen $p_{C}^{x ; y} \gg$ $p_{I}^{x i y}$ the process dem ands $w$ ill have $m$ uch less a ect on $p_{C}(t)$ than $p_{I}(t)$. Therefore in the excess supply phase (X) $S_{C}(t)$, and therefore the processing rate, will only increase slow ly and $S_{I}(t)$ will be reduced only slow ly, producing large am plitude slow oscillations.

W e therefore expect that even a single process in a
xed environm ent will have periodic dynam ics, w ith periods of $(X)$ fullem ploym ent $\left(S_{I}(t)>S_{C}(t)\right)$ interrupted by periods of $(Y)$ unem ploym ent, ( $S_{I}(t)<S_{C}(t)$ ).

Through sim ulations we nd Eq\$9 also seem to hold in the $>0$ case. The sam e sw itching state appears, see

F IG. 3: (a) The switching state; creation of periodic orbit from node and focus. The $S_{I}=S_{C}$ line (see key) divides the $(X)$ and ( $Y$ ) phases, whose xed points are show $n$ labelled. The xed points are such that they lie on the $S_{I}=S_{C}\left(p_{C}^{x ; y}=p_{I}^{x ; y}\right)$ line, (see key). Therefore only one can be com patible $w$ ith its phase. Here, in the sw itching state shown, where $\left.p_{C}^{x i y}=p_{I}^{x i y}\right)>1$ the ( $X$ ) xed point is com patible since $S_{I}^{x}>S_{C}^{x}$, but the (Y) xed point is incom patible since $S_{I}^{Y}>S_{C}^{Y}$. W hen the trajectory is in the ( $Y$ ) phase it is attracted to the stable node $\left(S_{C}^{Y} ; S_{I}^{Y}\right)$, which is incom patible w ith phase ( $Y$ ). Therefore the phase boundary must be crossed and the system switches to an oscillation around the ( $S_{C}^{x} ; S_{I}^{x}$ ) focus. $T$ his then causes the system to be reinjected into the (Y) phase again, producing the clockw ise orbit. Furtherm ore, regardless of initial conditions, the system is alw ays rein jected at the point $R$ thereby producing a lim it cycle. Since $S_{I}^{y}=S_{C}^{x}$, the xed points approach each other as $p_{C}^{x i y}=p_{I}^{x i y}$ approaches 1 from above and therefore the sw itching frequency increases while the am plitude decreases as con-
m ed in (c). (b) T in e series of input supply $\mathrm{S}_{\mathrm{I}}(\mathrm{t})$ (black) and catalyst $S_{C}(t)$ (red) for a single process $w$ ith $=1$. (c) Variation of sw itching frequency $f$ against $=\left(p_{c}^{x i y}=p_{I}^{x i y}\right)$ from Eq. $9 . \quad 0$ (black), $=1$ (red). As increases the bifurcation point decreases and the frequency $f$ increases.

Fig (b) (c), but the exact bifurcation point varies. Furthem ore the equivalence between sw itching and price crossing, seem s to be still approxim ately true. H ow ever the sw itching dynam ics is m ore com plex as shown in $F$ ig 3 (b). This is interesting since one would naively expect that using price inform ation should allow the process to obtain $m$ ore balanced input supplies and processing to occurm ore sm oothly. H ow ever doing so m oves the process nearer the trapping birfiurcation enhancing the sw itching feedback e ects. This can produce quasiperiodic or weakly chaotic dynam ics.

To understand the behaviour of a m ulti-process econom $y$ and the appearance of com plex $m$ ulti-tim escale dynam ics, shown in Fig 2 , we need to see how individual processes a ect each other and in this respect we need two points. (i) Trapping bifurcation produces extrem ely di erent frequencies. W hen there are several processes each process has its own, now time dependent, trap-

F IG . 4 : H ierarchicalm ultiple tim escale lim it cycle attractor in process chain in xed environm ent. (a) D iagram ofa 3 process 7 product chain. 3 products are catalysts, one in each process each w ith a xed extemal supply $S_{i C}^{e}$ and dem and $D_{i c}^{e}$, de ning an extemal price ${\underset{P}{C}}_{i y}^{y}=D_{1 C}^{e}=S_{1 C}^{e}$ for each catalyst. There is one input product I w th a xed extemal supply $S_{I}^{e}$ and one output product $O \mathrm{w}$ ith xed extemal dem and $D_{0}^{e}$. There are two interm ediate products w ith no extemal supplies and dem ands. (b) T im e series of supplies and detail (c), colours are as depicted in (a). D ue to price equalization Eq. 9 in chains of processes we get $p_{I}^{x i y}=p_{0}^{x i y}=D_{o}^{e}=S_{I}^{e}$ for the input and output prices. H ere we set extemalenvironm ent such that $p_{1 C}^{x ; y} \gg p_{2 C}^{x i y} \gg p_{3 C}^{x ; y}>p_{I}^{x ; y}$ so that the 3 processes are all in the trapped state $w$ ith very di erent sw itching frequencies, and we obtain a m ultiple tim escale lim it cycle. Since the 3 processes are in the sam e chain and they are all in catalyst $m$ in im um state the process 3 brow n catalyst oscillates around the output level of process 2 which is the blue catalyst which oscillates around the the output level of process 1 which is the red catalyst, to give the pleasing (but econom ically undesirable) e ect of sew ing. H ere price feedback $=0: 9$.
ping bifurcation param eter ${ }^{i}(t)=p_{C}^{i}(t)=p_{I}^{i}(t)$ and own sw itching frequency, determ ined by its extemalenviron-
$m$ ent, where the superscript ${ }^{i}$ now refers to each process' ' xed point' prices given by E dg. The sw itching state can be tumed on and $O$ when the xed point prices id ( $t$ ) and $p_{I}^{i}(t)$ cross and as explained above, since the sw itching frequency depends strongly on , not on the com plex eigenvalues of focus in the conventional way, sw itching frequencies can be extrem ely di erent.
(ii) U nequal coupling and transfer of oscillations. We note that this system is an evolving system of com peting coupled oscillators that can have very di erent funds $F_{i}(t)$. They are coupled only through a series of prices (Eqs(25), so that not all processes are directly coupled. Furthem ore the price couplings (EqZ) are ofm ean- eld threshold type, so that each process transfers it oscillations w ith di erent weights' determ ined by their di erent funds $F_{i}(t)$ which control the size of their dem ands $D_{i j}(t)$, (Eq(3). D ue to this the oscillations of a given proœess $m$ ay dom inate its input product price for exam ple but hardly appear in its catalyst price, allow ing $m$ ultiple tim escales and indeed trapping itself to appear.

An example of how these (i) and (ii) combine in a m ulti-process system is the sim ple chain shown in Fig 4.

Sum mary. It is clear that when econom ic processes w th m inim um condition dynam ics are coupled together, price level crossings will induce hierarchical trapping bifurcationsw ith di erentsw itching frequencies in individual processes. These oscillations w ill be transm itted to som e prices but not others and the dynam ics can easily becom e very com plex as illustrated in F ig 2 which was produced from random netw orks sim ilar to that shown in F ig 1 . $T$ his behaviour $m$ ay be the fundam ental origin of persistent cyclic non-equilibrium econom ic dynam ics.

The noveltrapping bifurcation and sw itching state dynam ics introduced here $m$ ay be relevant in other elds w ith m eta-level coupling where real variable dynam ics is synergetically $m$ ixed w ith boolean type logic. E conom ic agents choosing a maxim um utility action, cellular reaction path expression interacting $w$ ith genetic sorting, netw orks of $m$ olecular $m$ achines in a cell and neural decision m aking system s are possible exam ples.

W e thank K Fu fim oto for useful discussions. A P onzi w ishes to thank the Japan Society for P rom otion of Science for support of this w ork.

[6] This relationship is only approxim ate when processes are less than $100 \%$ e cient orpro ttaking occurs. In this case input prices $m$ ust be less than output prices.
[7] In fact each phase ( $x$ ) and ( $y$ ) also has another xed point at the origin, but in each phase only one of the two xed points is stable. In fact in each phase the zero xed point is stable and the interior xed point unstable when ( $\left.\mathrm{D}_{\mathrm{I}}^{e}=\mathrm{S}_{\mathrm{I}}^{e}\right)>\left(\mathrm{D}_{\mathrm{O}}^{e}=\mathrm{S}_{\mathrm{O}}^{e}\right)$ and, as is plausible econom ically, the process goes bankrupt.
