# $\mathrm{V}_{4}$ : A sm all, but sensitive observable for heavy ion collisions 

Peter F.K olb<br>D epartm ent of P hysics and A stronom y, SU N Y, Stony B rook, N ew Y ork, 11794-3800, U SA<br>(Septem ber 23, 2003)

#### Abstract

H igher order Fourier coe cients of the azim uthally dependent single particle spectra resulting from noncentral heavy ion collisions are investigated. F or interm ediate to large transverse m om enta, these an isotropies are expected to becom e as large as $5 \%$, and should be clearly $m$ easurable. T he physics content of these observables is discussed from tw o di erent extrem e but com plem entary view points, hydrodynam ics and the geom etric lim it w ith extrem e energy loss.

C ollisions of large nuclei at nonzero im pact param eter exhibit the special feature of a strongly deform ed overlap region. T he subsequent dynam ical evolution of the collision zone converts the in itial spatialeccentricity into an azim uthal anisotropy of the nal state observables. In particular anisotropies in m om entum space [1] have been analyzed experim entally in great detail in recent years, as they have been shown to be generated during the earliest and hottest stages of the reaction [2]. A smom entum anisotropies are generated, the eccentricity in coordinate space is sm oothed out, bringing further generation of m om entum anisotropies to a stall, a process that occurs w thin about the rst $5 \mathrm{fm} / \mathrm{c}$ of the total $15 \mathrm{fm} / \mathrm{c}$ lifetim e of the reball [2\{4]. In Au+Au collisions at RH IC (the R elativistic H eavy Ion C ollider at B rookhaven N ational Laboratory), those anisotropies have been found [5] to be as large as predicted by hydrodynam ic calculations that assum e a short equilibration time equ $1 \mathrm{fm} / \mathrm{c}[4,6]$. Further theoretical investigation has revealed the sensitivity of anisotropic ow on the equation ofstate of the expanding $m$ edium [79], indicating the necessity of a hard phase at high tem peratures w ith a soft transition region ofw idth e $1 \mathrm{GeV} / \mathrm{fm}^{3}$ to low er tem peratures in order to describe the data in $m$ ore detail. For these reasons anisotropic ow becam e one of the $m$ ost attractive tools to study the nuclear equation of state of the $m$ atter created in the collision by utilizing the m ost abundant particles, altematively to study statistically disadvantaged rare probes w th which one tries to infer the properties of the bulk by m odeling theirm utual interaction $w$ ith the $m$ edium they traverse. O ther predictions from hydrodynam ic concepts such as centrally and m ass dependence ofm om entum anisotropies [8] have subsequently been con m ed to be in qualitative and quantitative agreem ent w ith experim ents $[10,11]$, as long as the applicability of hydrodynam ics is not overstretched, i.e. for im pact param eters not larger than b 7 fm and transversem om enta not to exceed $p_{T} \quad 1: 5 \mathrm{G} \mathrm{eV}$. Beyond these values clear deviations from the hydrodynam ic predictions start to occur. This is expected as the sm aller system sdo not su ciently equilibrate and them ost rapid particles escape the reballw ithout fully participating in the collective dynam ics.

To date, anisotropies at m idrapidity are generally only characterized in term $s$ of the second coe cient $v_{2}$ of the Fourier decom position of the azim uthally sensitive mo-
$m$ entum spectrum. W ith the $z$ direction given by the beam axis and the x direction de ned by the direction of the im pact param eter (and y perpendicular to both), the general expression for the Fourier decom position $w$ ith respect to the azim uthalangle ${ }^{\prime}=\arctan (y=x)$ is
$\frac{d N}{d p_{T} d y d^{\prime}}=\frac{1}{2} \frac{d N}{d p_{T} d y} 1+{ }_{n ; \text { even }}^{X} 2 v_{n}\left(p_{T}\right) \cos \left(n^{\prime}\right) ;$
where no sine term $s$ appear due to the sym $m$ etry $w$ ith respect to the reaction plane, and allodd ham onics van ish at $m$ idrapidity due to the sym $m$ etry ${ }^{\prime} \$ \quad+\quad$. (N ote that the latter is not true for noncentral $d-A u$ collisions, where $v_{1}, v_{3}, \ldots$ should be useful quantities to classify and study the $m$ easured spectra \{ even at $m$ idrapidity). In the follow ing we will elaborate on the centrality and m om entum dependence of higher anisotropy coe cients, which tum out to exhibit interesting features that, with the currently available data from RHIC's run in 2002, m ight already be accessible.

G enerally, higherm om entum anisotropies are expected to be $s m$ all, and in fact no experim ental data have been published until this day. An early hydrodynam ic calculation [12] predicted the m om entum integrated value of $v_{4}$ not to exceed $0.5 \%$ at SP $S$ energies even in the m ost peripheral collisions, and show s only a slight increase w ith beam energy up to RH IC energies. In another study Teaney and Shuryak [13] calculated 4 , which is the fourth coe cient of the $m$ om entum integrated di erentialparticle spectra w eighted by an additionalm om entum squared (which was applied to enhance the e ects of transverse ow). This quantity is thus strongly biased to larger $p_{T}$. From their hydrodynam ic calculation they obtain $41 \%$; clearly the $m$ om entum integrated value of $\mathrm{v}_{4}$ is still sm aller.

Today, experim ents at RH IC achieve su cient statistics to $m$ easure the elliptic ow coe cienty di erentially in $m$ om entum out to large transverse $m$ om enta up to 10 GeV [14]. In $m$ idcentralcollisions this coe cient is found to saturate starting at $\mathrm{p}_{\mathrm{T}} \quad 2 \mathrm{GeV}$ at a large value of 20 \{ $25 \%$, indicating that three tim es as $m$ any particles are em itted into the reaction plane than out of the reaction plane. Such a large value also $m$ eans that the rst order deform ation ofE q. (1) is not elliptic anym ore, but that a polar plot of the azim uthaldistribution resembles $m$ ore a peanut than an elliptical shape, aligned $w$ ith its
longer axis into the reaction plane, see F ig. 1. W ithout any higher order coe cients, the elliptic deform ation starts to develop such a waist when $\mathrm{v}_{2}$ becom es larger than $10 \%$, which can be shown explicitly by discussing the term $1+\cos 2^{\prime}$ in C artesian coordinates ( $x ; y$ ) around $\mathrm{x}=0$.

F IG . 1. (C olor online) Polar plot of the azim uthal distribution of di erent Fourier expansions. Left, distortion of the unit circle through an elliptic com ponent $\mathrm{v}_{2}$, shown for $10 \%$ (green) and $20 \%$ (red). R ight, fourth com ponent $v_{4}$ for the sam e values.
$T$ his raises the interesting question, whether at high $p_{T}$ Fourier coe cients of higher orderm ight becom e suf-
ciently large to restore the elliptically deform ed shape of the particle distribution. To restore the elliptic shape asm uch as possible only through introduction of a fourth anisotropy coe cient, $\mathrm{v}_{4} \quad \frac{1}{34}\left(10 \mathrm{v}_{2} \quad 1\right)$ is required, as is derived straightforw ardly from Eq. (1). This, in consideration of the large experim ental values for $v_{2}, m$ ight indicate that $\mathrm{v}_{4}$ could reach values around $3\{5 \%$.

To investigate higher ow coe cients in more detail, we rst revisit hydrodynam ic calculations, although they nd their lim itations for pions of transverse $m$ om enta beyond 2 GeV , and for heavier baryons at m om enta $3\{$ 4 GeV (for a recent review see Ref. [15]). Later on we w ill discuss a com plem entary m odel in term s of a sim ple picture for the lim it of very large transverse mom entum. The results presented in the follow ing were achieved by a more modem hydrodynam ic calculation than in Ref. [12], as it becom es im portant at R H IC energies to correctly account for features of chem ical nonequilibrium during the hadronic evolution of the system $[16,17]$, a feature that signi cantly in uences the relation of energy-density and tem perature $[18,19]$. At tem peratures beyond $\mathrm{T}_{\text {crit }}=165 \mathrm{M} \mathrm{eV}$ the underlying equation of state tums into a hard ideal gas equation of state via a strong rst order phase transition in order to $m$ im ic the transition from a gas of interacting resonances

The de nition of restored ellipticity is am biguous. H ere we chose to nd the value of $v_{4}$ where the second derivative of $y(x)$ vanishes at $x=0$, thus giving rise to a very sm ooth transition across' $=2$.
to a hard plasm a phase. The initial conditions of this calculation w ere determ ined to $t_{p}$ single particle spectra m easured in $\mathrm{Au}+\mathrm{Au}$ collisions at ${ }^{\mathrm{P}} \overline{\mathrm{S}_{\mathrm{N}}}=200 \mathrm{GeV}$. For further details, see Ref. [17].

Figure 2 show sthe m om entum dependence of the Fourier coe cients of pion spectra up to order 8. \Elliptic ow " w dom inates the em ission anisotropy at all m om enta. (To use the sam e vertical scale for all coe cients, the second harm on ic $\mathrm{v}_{2}$ wasdivided by 10.) A s anticipated, $\mathrm{v}_{4}$ increases w th m om entum, reaching a value of about $2.8 \%$ at $p_{T}=2 \mathrm{GeV}$ (thus not quite enough to restore the particle distribution to an elliptic shape, as $\mathrm{v}_{2}\left(\mathrm{p}_{\mathrm{T}}=2 \mathrm{G} \mathrm{eV}\right) 29 \%$ ). A lso $\mathrm{v}_{6}$ still has a sizable negative value of about $12 \%$. Them ass dependence of higher
ow harm onics does not bring any surprises. D ue to their larger m asses, heavy particles pick up larger transverse m om enta when they participate in the established collective ow. As for the spectra and elliptic ow, also the higher anisotropies are shifted out tow ard larger transverse $m$ om enta. Thus at a given transverse $m$ om entum below 2 GeV , the anisotropies of heavy resonances are sm aller than of pions. C om paring hydrodynam ic calculations to experim ental results, it appears how ever that deviations from hydrodynam ic behavior occur later for heavy particles, and therefore an isotropies ofbaryons can eventually surpass an isotropies oflightm esons [20]. From these calculations one can expect a fourth ow com ponent of (anti-)protons of about $7 \%$ at 4 GeV transverse m om entum, a sizable quantity that should be $m$ easur$a b l e$.

F IG .2. (C olor on line) Fourier coe cients of the pion spectra resulting from $\underset{p}{\mathrm{p}}$ hydrodynam ic calculation to describe particle spectra at ${ }^{\mathrm{P}} \overline{\mathrm{S}_{\mathrm{NN}}}=200 \mathrm{GeV}$ at im pact param eter $\mathrm{b}=7 \mathrm{fm} \cdot \mathrm{v}_{2}$ is scaled by a factor 0.1.

Sunprisingly it tums out that $v_{4}$ is highly sensitive to the initial conditions of the calculations: intitializing the calculation $w$ ith a prehydrodynam ic, isotropic radial ow eld as in Ref. [17] does not change the $m$ agnitude of the ow anisotropies by a large am ount. H owever we nd that it com pletely changes the sign of $v_{4}$, while the other coe cients rem ain largely the sam e. C learly $\mathrm{v}_{4}$ at low
and interm ediate $p_{T}$ has therefore a strong potential to constrain $m$ odel calculations and carries valuable infor$m$ ation on the dynam ical evolution of the system. To study how the higher ow anisotropies develop in the course of the hydrodynam ic evolution we calculate $\mathrm{m} \mathrm{o}^{-}$ $m$ ents of the transverse ow eld $\left(\mathrm{y} ; \mathrm{v}_{\mathrm{y}}\right)$ through

$$
\begin{equation*}
\mathrm{n}()=\frac{\mathrm{dxdye}(\mathrm{x} ; \mathrm{y} ;) \mathrm{v}_{\mathrm{T}} \cos \left(\mathrm{n}_{\mathrm{v}}\right)}{\mathrm{dxdye}(\mathrm{x} ; \mathrm{y} ;)} ; \tag{2}
\end{equation*}
$$

where $e(x ; y ;)$ is the energy density in the transverse plane at time and $v_{T}=\left(v_{\mathrm{x}}^{2}+v_{\mathrm{y}}^{2}\right)^{1=2}$ is the transverse ow velocity at a given point $(x ; y),=\left(\begin{array}{ll}1 & V_{T}^{2}\end{array}\right)^{1=2}$, and ${ }^{\prime}{ }_{v}=\arctan \left(\mathrm{v}_{\mathrm{y}}=\mathrm{v}_{\mathrm{x}}\right)$ is the angle of the local ow velocity w ith respect to the reaction plane. (N ote that for $n=0$ this reduces to the de nition of the $m$ ean radial velocity used in earlier studies [4], but for $\mathrm{n}=2$ it is slightly di erent from the $m$ om entum anisotropy $p$ which is de ned in term s of the di erence in the diagonal elem ents of the energy m om entum tensor.) Figure 3 displays the tim e evolution of the ow coe cients and clearly show sthat radial ow oincreases throughout the lifetim e of the system (which is about $15 \mathrm{fm} / \mathrm{c}$ ), w ith a som ew hat reduced acceleration while $m$ ost of the system is in them ixed phase at around $4 \mathrm{fm} / \mathrm{c}$. Q uite oppositely anisotropy com ponents quickly saturate and rem ain constant, as the initial geom etric deform ation of the source is lost. About $2 / 3$ of the nal value of 4 is generated during the earliest stages of the evolution, where the system is govemed by the hard equation of state of the quark ghon plasm a. 6 quickly achieves sm all negative values of the order of $-0.2 \%$ (as expected from the negative value of $v_{6}$ ). D ue to its sm all values, it is sub ject to num erical uctuations and therefore not shown. It is expected that the ow coe cients arem onotonically related to the anisotropy coe cients in the nal particle spectra. Details of this relation are sub ject to fiuture study.

FIG.3. (C olor online) $T$ im e evolution of the anisotropy coe cients in the transverse velocity eld as given by the hydrodynam ic calculation. o characterizes the radial ow, 2 the elliptic deform ation and 4 the quadrupole deform ation.

In a model com plem entary to the hydrodynam ic description which is constrained to the low m om en-
tum, therm alized part of the spectrum, one can study anisotropies that result from opacity e ects that the deform ed initial geom etry exerts on particles of high mo $m$ enta [21\{23]. A ssum ing extrem e opacity, or extreme jet quenching, particles of large transversem om enta from any part of the surface can only be em itted w ithin 90 of the norm al vector to the surface, which for this exploratory study is assum ed to be given by the overlap of two hard spheres (radius R)! In this picture, the nth Fourier coe cient of the resulting expansion is found to be (for $n$ even)

$$
\begin{equation*}
\mathrm{v}_{\mathrm{n}}=(1)^{\mathrm{n}=2} \frac{1}{1 \mathrm{n}^{2}} \frac{\sin (\mathrm{n})}{\mathrm{n}} ; \tag{3}
\end{equation*}
$$

where $=\arccos (b=2 R)$ characterizes the centrality in term s of the opening angle betw een the line through the center of one nucleus to the intersection point of the two nuclear spheres and the reaction plane. N ote that as $b$ increases from 0 to $2 R$, decreases from $=2$ to 0 . For $n=2, v_{2}=\sin (2)=(6)$, a formula rst given by Voloshin [26]. For $n>2$, Eq. 3 becom es signi cantly $m$ ore interesting (unfortunately, how ever, the size of the expected signal drops with $\mathrm{n}^{3}$ ). N ote rst the oscillating sign of the prefactor which will manifest itself in an oscillation of the coe cients at large b (sm all ). Second, one notioes that for larger $n$ the sine function starts changing sign upon scanning im pact param eters (b\$), whereas for $n=2$, the Fourier coe cient increases linearly w ith im pact param eter from 0 to $1 / 3$, and is thus alw ays positive. In particular for $n=4$ one obserpes a transition from positive to negative values at $b={ }^{2} \mathrm{R}$, reaching the $\lim$ iting value $v_{4}=1=15 \quad 6: 67 \%$ for $\mathrm{b}!2 \mathrm{R}$, again a rather large num ber. T he local m axim um of $\mathrm{v}_{4}$ is at b $0: 865 \mathrm{R}$ w ith $\mathrm{v}_{4} \quad 1: 45 \%$. The centrality dependences of the second to eighth Fourier coe cients are show $n$ in $F$ ig. 4 (as before $v_{2}$ is divided by a factor of 10).

C learly, the expected values for higher expansion coefcients from this calculation are sm all. A pplying a m ore realistic m odel does, how ever, not necessarily lead to a further reduction of the signal, but $m$ ight in contrast increase, sim ilarly as observed for calculations of elliptic ow [24]. This is also suggested by the experim entaldata on $v_{2}$ which seem to exceed the lim its given even by the $m$ ost optim istic assum ptions for anisotropies from geom etry and energy loss. In any case, such a distinctive signal as a sign change upon variation of centrality should be preserved when $m$ odelcalculations get re ned and should be accessible w ithin the statistics reached by today's experim ents.

[^0]

FIG.4. (Color online) Centrality dependence of the anisotropy coe cients in the lim it of pure surface em ission from the deform ed overlap region to describe the saturation value of the anisotropies at large transverse $m$ om enta. $v_{2}$ is scaled by a factor of 0.1.

As an aside we would like to discuss a new but nai̇ve experim ental way of $m$ easuring higher order ow coefcients, in particular $V$. A part from the \straightfor$w$ ard" $m$ ethod to determ ine each event's reaction plane and averaging all particles' cos(4') w ith respect to the reaction plane and the $m$ ore recently developed cum ulant technique [27], sim ply m easuring the particle spectra $w$ th respect to the reaction plane $m$ ight be su cient (theoretically). H aving the azim uthally sensitive particle spectra given, Eq. (1) show s directly that [abbreviating $\left.d N=p_{T} d p_{T} d y d^{\prime}\left(p_{T} ;^{\prime}\right)=n\left({ }^{\prime}\right)\right]$

$$
\begin{align*}
& \mathrm{n}(0)+\mathrm{n}(=2) \quad 2 \mathrm{n}(=4)= \\
& \quad=\frac{1}{2} \frac{d N}{\mathrm{p}_{\mathrm{T}} d \mathrm{p}_{\mathrm{T}}}\left[8 \mathrm{v}_{4}\left(\mathrm{p}_{\mathrm{T}}\right)+8 \mathrm{v}_{12}\left(\mathrm{p}_{\mathrm{T}}\right)+:::\right]: \tag{4}
\end{align*}
$$

From the experience gathered so far we expect $v_{12}$ to be negligibly sm all com pared to $\mathrm{v}_{4}$. F inite opening angles for the azim uthally sensitive distribution will reduce the signalagain, how ever, the $\mathrm{v}_{4}$ is in this approach enhanced by a factor of 8 , which $m$ ight still render it $m$ easurable. $W$ e propose this $m$ ethod thus as an interesting independent approach to $m$ easure $v_{4}$ (but also $v_{2}$, by sim ply subtracting spectra in and out of the reaction plane).

In sum $m$ ary, we have show $n$ that $v_{4}\left(p_{T}\right) m$ ight achieve signi cantly large values at interm ediate and large transverse $m$ om enta in noncentral heavy ion collisions and contains im portant physics of heavy ion collisions, a fact largely overlooked in the past. N um erical estim ates for its size were given both in the lim it of full therm alization w th a subsequent hydrodynam ic expansion as well as in the geom etrical lim it of extrem e \jet quenching." For the latter case a strong centrality dependence and a change of the sign of the signal for higher anisotropies $w$ as found. From both approxim ations $w e$ found that $v_{4}$ m ight reach values of the order of $5 \%$, clearly observable with todays equipm ent and statistics. $\mathrm{v}_{4}$ has been found to be highly dependent on the initialcon guration
of the system and its evolution and is thus an im portant new toolto constrain $m$ odelcalculations and analyze details of the system 's history. C onsequently it deserves to be studied in great detailboth experim entally as well as theoretically.
