A bstract

Starting from a precise two{nucleon potential, we use the method of unitary transform ations to construct an elective potential that involves only momentaless than a given maximal value. We describe this method for an S{wave potential of the Maliet{T jon type. It is demonstrated that the bound and scattering state spectrum calculated within the elective theory agrees exactly with the one based on the original potential. This might open an avenue for the construction of elective chiral few {nucleon forces and for a system atic treatment of relativistic elects in few {body system s.

1. Chiral perturbation theory for two and more nucleons became a subject of a great research interest in the past few years, see e.g. the pioneering work in [1, 2]. One hopes to be able to clarify the structure of nuclear forces in this way. However, only the low {momentum matrix elements of nuclear forces may be systematically treated in this approach since it is based on a consistent power counting of sm allm om enta and pion m asses com pared to the typical hadronic scale of had' 1 GeV (for some recent work along these lines see e.g. refs. [3, 4]). A natural problem arises due to the appearance of shallow nuclear bound states indicating a breakdown of perturbation theory. Furtherm ore, solving the Lippm ann {Schwinger equation for constructing the deuteron necessarily involves m om enta \dot{p}_{j} had. For such m om enta, the chiral e ective potential constructed according to the conventional power counting rules is no longer applicable. This is witnessed by the fact that in the calculations for the two{nucleon system in [2], an additional ad hoc cut{o to tame the high {m om entum com ponents had to be introduced. To be more precise, this cut{o function is not commensurate with the underlying chiral power counting since it introduces an in nite string of local operators with increasing dimension. One m ight therefore question the validity or usefulness of such an approach alltogether. For recent discussions of this subject see [5] and a di erent power counting scheme has been presented in [6]. A similar problem arises in standard few { and many { body calculations based on realistic nucleon (NN) forces. The potentials, if derived from meson (exchange diagrams, are generally based on a non{relativistic expansion in powers of momenta over the nucleon mass and are then used in various types of bound state equations. These usually involve integrations over a much larger range of momenta as used in the construction of the NN potentials. The same is of course also true for the various phenom enological NN forces, which are chosen more or less ad hoc (with the exception of the pion tail). This a ects in a non{trivial way the calculation of observables, such as masses, levels or electrom agnetic response functions. For a recent discussion, see e.g. ref.[7]. In this general context the question of the existence and the properties of a low {m om entum e ective theory for nucleons are thus of great in portance. We show here that it is indeed possible to construct an e ective two{nucleon potential from a given realistic potential which involves only low momenta, i.e. momenta below a chosen momentum cut{o, but which gives exactly the same results for bound and scattering states. The cut{o scale introduced in our approach should be considered a physical quantity since it de nes the Hilbert space in which the theory operates. This is dierent from the cut(o in a form factor or vertex function. It is important to stress that our approach diers from the treatment of the Schrödinger equation in an elective eld theory framework proposed by Lepage [8]. In his approach, an elective eld theory for nucleons only is constructed for very low momenta and eventually pions are added. While that is certainly a valid fram ework, we intend to stay closer to the already existing nuclear physics know ledge in that our approach will eventually allow to m atch the low {m om entum theory in a well{de ned way to the highly successful meson {exchange pictures of the nucleon (nucleon force. The results presented here should therefore be considered as a rst step in a bigger program . Finally, we remark that while it seems to be known that such an exact momentum space projection can be done, to our know ledge this program has never been carried out before.

2. To be specic, we consider a momentum {space H am iltonian for the two{nucleon system of the form

H (
$$\mathbf{p}; \mathbf{p}^{0}$$
) = H₀ (\mathbf{p}) ($\mathbf{p} = \mathbf{p}^{0}$) + V ($\mathbf{p}; \mathbf{p}^{0}$); (1)

where H_0 stands for the kinetic energy and the explicit form of the NN potential will be specified later. For illustrative purposes we stick here to a simple S{wave potential. Note, however, that the inclusion of spin and isospin dependent potentials can be handled along the lines outlined here. Our aim is to decouple the low and high momentum components of this two{nucleon potential using the method of unitary transformation [9, 10]. For achieving that, we introduce the projection operators

$$= d^{3}p j p ihp j; j p j;$$

$$= d^{3}p j p ihp j; j p j ;$$
(2)

where is a momentum cut{o whose value will be specified later and () is a projection operator onto low (high) momentum states with 2 = 2, 2 = 2

W e now perform a unitary transform ation of the type

$$H ! H^{0} = U^{Y} H U ; (4)$$

so that $H^0 = H^0 = 0$. The corresponding unitary operator U is parametrized in terms of an operator A, following O kubo [9]:

$$U = \begin{pmatrix} 0 & (1 + A^{y}A) & ^{1=2} & A^{y}(1 + AA^{y}) & ^{1=2} \\ A & (1 + A^{y}A) & ^{1=2} & (1 + AA^{y}) & ^{1=2} \end{pmatrix}$$
(5)

and A satis es the condition A = A. The requirement of decoupling the two spaces leads to the following nonlinear integral equation

$$(H [A; H] A H A) = 0$$
(6)

for the operator A. In the context of the nuclear m any{body theory one often introduces a mean eld single particle basis, which de nes a complete set of N {particle states. A low {energy subgroup of states form a model space and one is interested in e ective interactions acting in that m odel space such that the same low energy spectrum results as for the underlying N { body H am iltonian. A way to arrive at that e ective interaction is to decouple by a suitable transform ation the two spaces (m odel space and the rest space), which leads to a decoupling equation of exactly the form Eq.(6). In that context it is often reform ulated into a linear form on a two{body level using the exactly known interacting two{body states (som e references are e.g. [11][12]). This is indeed a feasible way to proceed also in our context, as will be shown in a forthcom ing article. Here, how ever, we solve directly the nonlinear equation (6). If we denote by q (p) a momentum from the (){space, Eq.(6) takes the form # 4

^{# 4}Our notation is such that Q (p;q) stands for the corresponding matrix element hp D jq i for any operator Q.

The quantities $E_{q_{R^2}}$ are the kinetic energies related to the corresponding three {m om enta. This equation can only be solved num erically. This is most easily done by iteration starting with

$$A = \frac{V(p;q)}{E_q E_p} :$$
(8)

A fler four iterations, we then perform an average over the values of the operator A with di erent weight factors. This allows to speed up the convergence considerably (details on this procedure will be published elsewhere). We also provide a regularization scheme for the singularities of the operator A, which arise by solving this equation, i.e. at the cut{o momentum (as becomes obvious from Eq.(8)).^{# 5} To be speci c, we rede not the original potential V ($p; p^{0}$) by multiplying it with some smooth functions f (p) and f (p^{0}) which are zero in some neighborhood of the point $\dot{p} j =$ and one elsewhere. The precise form of this procedure is of no interest for the following and will thus not be discussed in detail here. We only add that the regularization is chosen m ild enough that it has no e ect on the observables, as will be illustrated later on for a speci c example.

3. We now restrict ourselves to the NN S{waves. To be speci c, consider a momentum {space M al iet{T jon [13] potential with an attractive and a repulsive part

$$V_{MT}(\mathbf{g}_{1};\mathbf{g}_{2}) = \frac{1}{2^{2}} \frac{V_{R}}{t + \frac{2}{R}} \frac{V_{A}}{t + \frac{2}{A}}; \qquad (9)$$

with t = $(q_1 q_2)^2$. We choose the parameters as given in [14], $V_R = 7.29$, $V_A = 3.18$, _R = 614 MeV and _A = 306 MeV. From here on, we only consider the S{wave part of this potential which can be obtained analytically. A though this potential is quite simple, it captures essential features of the NN interaction, in particular, it supports exactly one bound state at E = 2.23 MeV. Since we are interested in an elective theory with small momenta only, we set the cut{o} = 400 MeV (or smaller). In Fig. 1, we compare the original potential with the elective one. The latter is de ned via

$$V_{e} = H^{0} H_{0}$$
 : (10)

In the range of the sm allm om enta, the potentials are very sim ilar. How ever, one nds signi cant di erences between the elective and the original potential when the cut{o, above which the nucleonic momenta are integrated out, is chosen very sm all, 200 MeV. This is shown in Fig. 2.

4. We now consider observables. P has shifts can be derived from the S {m atrix, or equivalently, from a K {m atrix approach. Symbolically, the relation between the S { and the K {m atrix can be expressed as

$$S = \frac{1 \text{ i } qK}{1 + \text{ i } qK} ; \qquad (11)$$

with q the on{shell relative momentum of the two nucleons corresponding to the laboratory energy being considered. We work in the framework of the latter because the K {m atrix is purely real. This is, however, just a matter of convenience.

The low {energy phase shifts and the bound{state energy are reproduced to a very high precision with the resulting elective potential acting only in the low momentum components. This is shown for the S{wave phase in Fig. 3 for two values of the cut{o} = 200 and 400 M eV,

 $^{^{#5}}$ In contrast, the e ective potential is well{behaved.

respectively. The phase shifts from the original potential are exactly reproduced in the approach based on the elective potential, as long as one stays below the chosen cut{o. This is the reason why the solid and dashed lines in the gure fallon top of each other. The Lippm ann {Schwinger equation in the elective approach involves by construction only momenta below the cut{o and thus the bound state can be calculated completely consistently. We not that the bound state energy is also exactly reproduced. Furthermore, the deuteron state evaluated in the elective theory is of course unitarily transformed. Matrix{elements of an arbitrary operator 0 remain unchanged under this unitary transform ation,

$$h_{D} \mathcal{D} j_{D} i = h_{D}^{0} \mathcal{D}^{0} j_{D}^{0} i; \qquad (12)$$

with $O^0 = U^y O U$, $j_D^0 i = U^y j_D i$ and $D(p) = hp j_D i$ denotes the deuteron wave function in momentum space. For illustration, we compare in Fig. 4 the original and the unitarily transformed deuteron momentum {space wave functions for $= 200 \text{ MeV} \cdot \text{N}$ ote that due to the regularization, the spike close to the cut{o is infact a smooth function and does not introduce any singular derivatives. For a larger cut $\{0 \text{ value, say} = 400 \text{ MeV}, \text{ the two curves} \}$ fall onto of each other apart from a small interval in the vicinity of the cut{o. We thus do not show that case here. Note, however, that the unprojected deuteron wave function is still not negligible at momenta of about 800 MeV.As an illustration, we consider the expectation value of the modulus of the momentum operator in the S{wave deuteron, h_{D} (p) \dot{p} j (p) i, with $p = p_j$. The results are listed in table 1 for the two cut{o values = 200;400 M eV. Of course, for the full M T { potential we do not need the regularization. However, to illustrate its in uence, we have also performed a calculation with a M T {potential subject to the same regularization as used for the elective potential (labelled \regularized" in the table). For the lower cut{o, the few permille deviation between the exact result and the one based on the regularized potential is simply due to the fact that we did not optim ize the num erical solution of the integral equation Eq.(7) to determ ine the operator A. If needed, one can in prove these num bers to agree to arbitrary precision (which is not of relevance here).

	= 200M eV	= 400 M eV
Exact Potential, not regularized	80.23	80,2308
Exact Potential, regularized	79.90	80,2303
E ective Potentail, regularized	79 . 90	80,2304

Table 1: Expectation value of j p j M eV] in the S{wave deuteron based on the exact and the e ective M T {potential. For the exact case, we show the results with and without regularization at the singularity j p j =.

5. In sum mary, we have shown how to construct an elective low energy theory for nucleons based on the method of unitary transformations. For a simple S {wave potential, we have shown that the theory projected onto the subspace of momenta below a given cut{oreproduces exactly the features of the original one. We hope that this study might be useful for derivation of NN { forces based on chiral Lagrangians in the low {momentum regime. It should also provide new insights into a consistent and convergent treatment of relativistic elects in few { and many{nucleon system s.
