A lthough behavioral econom ics has dem onstrated that there are m any situations where rational choice is a poor em pirical model, it has so far failed to provide quantitative models of economic problems such as price formation. We make a step in this direction by developing em piricalm odels that capture behavioral regularities in trading order placem ent and cancellation using data from the London Stock Exchange. For order placem entwe show that the probability of placing an order at a given price is well approxim ated by a Student distribution with less than two degrees of freedom, centered on the best quoted price. This result is surprising because it in plies that trading order placement is symmetric, independent of the bid-ask spread, and the same for buying and selling. We also develop a crude but simple cancellation m odel that depends on the position of an order relative to the best price and the in balance between buying and selling orders in the limit order book. These results are com bined to construct a stochastic representative agent model, in which the orders and cancellations are described in terms of conditional probability distributions. This m odel is used to simulate price form ation and the results are compared to real data from the London Stock Exchange. W ithout adjusting any param eters based on price data, the model produces good predictions for the magnitude and functional form of the distribution of returns and the bid-ask spread.

R eferences and N otes

I. IN TRODUCTION

In the last two decades the eld of behavioral nance has presented an increasingly large number of examples where equilibrium rational choice models are a poor description of real econom ic behavior¹ (Hirschleifer 2001, Barberis and Thaler 2003, Camerer 2003, Thaler 2005). While this evidence may be compelling, so far behavioral nance has largely been a negative science. It illustrates problems with the mainstream paradigm, but it fails to provide a positive alternative with quantitative predictive power². There are many e orts underway to build a better foundation for econom ics based on psychological evidence, but this imposes a di cult hurdle for building quantitative theories. The hum an brain is a complex and subtle instrum ent, and the distance from psychology to prices is large.

In this study we take advantage of the fact that electronic markets provide a superb laboratory for studying patterns in hum an behavior. Market participants make decisions in an extrem ely complex environment, but in the end these decisions are reduced to the simple actions of placing and canceling trading orders. The data that we study here contains hundreds of millions of records of both trading orders and prices, allowing us to reconstruct the state of the market at any instant in time.

Our goal here is to capture behavioral regularities in order placem ent and cancellation, and to exploit these regularities to achieve a better understanding of price form ation. The practical component of this goal is to understand statistical properties of prices, such as the distribution of price returns and the bid-ask spread. Serious interest in the distribution of prices began with M andelbrot's (1963) study of cotton prices, in which he showed that logarithm ic price returns are far from norm al, and suggested that they m ight be drawn from a Levy distribution. There have been many studies since then, most of which indicate that the cum ulative distribution of logarithm ic price changes has tails that asymptotically scale for large \dot{r} jasa power law of the form \dot{r} j, where $r(t) = \log p(t)$ p(t) is the logarithm ic return at time ton time scale and p is the price (Fam a 1965, 0 cer 1972, Akgiray, Booth and Loist11989, Koedik, Schafgans and de Vries 1990, Loretan 1994, Mantegna and Stanley 1995, Longin 1996, Lux 1996, Muller, Dacorogna and Pictet 1998, Plerou et al. 1999, Rachev and M ittnik 2000, G oldstein, M orris and Y en 2004). The exponent , which takes on typical values in the range 2 << 4, is called the tail exponent. It is important because it characterizes the risk of extrem e price movem ents and corresponds to the threshold above which the moments of the distribution become in nite. Having a good characterization of price returns has in portant practical consequences for risk control and option pricing.

From a theoretical point of view, the heavy tails of price returns excite interest among

24

24

¹ This may be partly because of other strong assumptions that typically accompany such models, such as complete markets. Until we have predictive models that drop these assumptions, however, we will not know whether more realistic assumptions in rational choice models are su cient to solve these problems.

 $^{^{2}}$ There are several examples of models that make qualitative predictions, such as in the popular book by Schleifer (2000).

physicists because they suggest nonequilibrium behavior. A fundam ental result in statistical mechanics is that, except for unusual situations such as phase transitions, equilibrium distributions are either exponential or norm al distributions³. The fact that price returns have tails that are heavier than this suggests that markets are not at equilibrium. A lthough the notion of equilibrium as it is used in physics is very di erent from that in econom ics, the two have enough in common to make this at least an intriguing possibility. M any models have been proposed that attempt to explain the heavy tails of price returns (A rthur et al. 1997, Bak, Pacuski and Shubik 1997, Brock and Hommes 1999, Lux and M archesi 1999, Chang, Stau er and Pandey 2002, LeBaron 2003, G iardina and Bouchaud 2003, G abaix et al. 2003, Challet, M arsiliand Zhang 2005). These models have a wide range in the specie city of their predictions, from those that simply demonstrate heavy tails to those that make a more quantitative prediction for example about the tail exponent . How ever, none of the full return distribution.

The bid-ask spread s is another in portant m arket property. It can be de ned as s(t) = a(t) = b(t), where a(t) is the logarithm of the best selling price of ered at time t and b(t) is the logarithm of the best buying price. The spread is in portant as a benchm ark for transaction costs. A sm all market order to buy will execute at the best selling price, and an order to sell will execute at the best buying price, so someone who is not buys and then sells in close succession will pay the spread s(t). There is a substantial empirical and theoretical literature on the spread (a sm all sample of examples are D em setz 1968, Stoll 1978, G losten 1988, G losten 1992, E asley and O'H ara 1992, Foucault, K adan and K andel 2001, Sandas 2001), but all this work has a focus that is substantially different from ours here.

The model we develop here is a statistical description of the placem ent and cancellation of trading orders under a continuous double auction, which can be used to understand the statistical properties of price returns and spreads. This model follows in the footsteps of a long list of other m odels that have tried to describe order placem ent as a statistical process (Mendelson 1982, Cohen et al. 1985, Dom ow itz and W ang 1994, Bollerslev, Dom ow itz and W ang 1997, Bak et al. 1997, Eliezer and K ogan 1998, Tang 1999, M aslov 2000, Slanina 2001, Challet and Stinchcombe 2001, Daniels et al. 2003, Chiarella and Iori, 2002, Bouchaud, M ezard and Potters 2002, Sm ith et al. 2003). For a more detailed narrative of the history of this line of work, see Sm ith et al. (2003). We build on the model of Daniels et al. (2003), which assumes that lim it orders, market orders, and cancellations can be described as independent Poisson processes, in which buying and selling have the same parameters. Because it assumes that order placement is random except for a few constraints, it can be regarded as a zero intelligence model of agent behavior. A lthough highly unrealistic in m any respects, the zero intelligence m odel does a reasonable job of capturing the dynam ic feedback and interaction between order placem ent on one hand and price form ation on the other. It predicts scaling laws for the volatility of returns and for the spread, which can be regarded as equations of state relating the properties of order ow s to those of prices. Fam er, P atelli and Zovko (2005) tested these predictions against realdata from the London Stock Exchange and showed that, even though the model does not predict the absolute magnitude of these

³ For example, at equilibrium the distribution of energies is exponentially distributed and the distribution of particle velocities is norm ally distributed. This is violated only at phase transactions, e.g. at the transition between a liquid and a gas.

e ects, it does a good job of capturing how average volatility and spread vary with changes in order ow.

Despite these successes the zero intelligence model is inadequate in many respects. Because of the unrealistic assumptions that order placement and cancellation are uniform along the price axis, to make comparisons with real data it is necessary to introduce an arbitrary interval over which order ow and cancellation densities are measured, and to assume that they vanish outside this interval. This assumption introduces arbitrariness into the scale predictions. In addition it produces price returns with non-white autocorrelations and a thin-tailed distribution, which do not match the data.

The model here has the same basic elements as the zero intelligence model, but each element is modiled based on empirical analysis. In the course of doing this we uncover regularities in order placement and cancellation that are interesting for their own sake. The strategic motivation behind that patterns that we observe is in many cases not obvious { it is not clear whether they are driven by rational equilibrium or irrational behavior. We do not attempt to address this question here. Instead we work in the other direction and construct a model of price formation. The resulting model makes good predictions about the magnitude and the functional form of the distribution of returns and spreads. The predictions are particularly good in the body of the distributions and not quite as good in the tails. The model predicts a power law for the tails, though with tail exponents that are slightly larger than those of the real data. We believe this is due to inadequacies in our cancellation model, which at this stage is still crude.

The paper is organized as follows: Section II discusses the market structure and the data set. In Section III we study the distribution of order placement conditioned on the spread and in Section IV we discuss our approach to modeling the long-memory order signs (whether orders are to buy or to sell). In Section V we develop a model for order cancellation, and in Section V I we develop a simulation based on the models of order ow that allows us to make predictions about returns and spreads. Finally in the last section we summarize and discuss the implications and future directions of this work.

II. THE MARKET AND THE DATA

This study is based on data from the on-book market in the London Stock exchange. These data contain all order placements and cancellations, making it possible to reconstruct the lim it order book at any point in time. In 1997 57% of the transactions in the LSE occurred in the on-book market and by 2002 this rose to 62%. The remaining portion of the trading takes place in the o -book market, where trades are arranged bilaterally by telephone. O -book trades are published, but only after they have been arranged and have e ectively already taken place. Because the on-book market is public and the o -book market is not, it is generally believed that the on-book market plays the dom inant role in price form ation. W e will not use any inform ation from the o -book market here. For a more extensive discussion of the LSE market structure, together with som e com parative analysis of the two markets, see Lilb, M ike and Farm er (2005).

The LSE on-book market is purely electronic. There are no designated market makers (though there is no restriction on simultaneously placing orders to buy and to sell at the same time). Timestamps are accurate to the second and sequencing is more accurate than that, though not always perfect. Because we have a complete record we know whether orders are to buy or to sell, and we also know all transactions in both markets.

W e study data for three stocks, A strazeneca (AZN), Lbyds (LLOY) and BHP B illiton (BLT). The data we analyze are for the period from M ay 2000 – D ecem ber 2002. C ounting an event as either an order placem ent or an order cancellation, there are 4.2 m illion events for AZN, 652 thousand of which are transactions; 3.4 m illion for LLOY, 723 thousand of which are transactions.

During the trading day the LSE is a continuous double auction. Trading begins with an opening auction and ends with a closing auction. To keep things simple we remove these, and also remove the inst hour and last half hour of trading data, i.e. we consider only data from 9.00 am to 4.00 pm. We do this because near the auctions there are transient behaviors, such as the number of orders in the book building up and winding down, caused by the fact that m any traders close out their books and the end of the day. (Even so, this does not seem to be a large elect and does not make a great dill erence in our results). We paste together data from dill erent days by freezing time outside of 9.00 – 4.00 on trading days. In our data analyses we are careful not to include any price movements that span the daily boundaries. This allow s us to treat the data as if it were one continuously running market.

There are several di erent types of possible trading orders in the LSE. The details are not important here. We will simply call any order with a limit price attached a limit order, and any order that generates an unconditional execution a market order. For convenience we will de ne an elective market order as any trading order that generates an immediate transaction, and an elective limit order as any order that does not. The limit order book refers to the queue that holds limit orders waiting to be executed. The priority for executing limit orders depends both on their price and on the time when they are placed, in the obvious way.

III. ORDER PLACEMENT

Even a brief glance at the data makes it clear that the probability for order placem ent depends on the distance from the current best prices. This was studied in the Paris Stock Exchange by Bouchaud, M ezard and Potters (2002) and in the London Stock Exchange by Zovko and Farmer (2002). Both groups studied only orders placed inside the limit order book. They found that the probability for order placem ent drops o asymptotically as a power law of the form x . The value of varies from stock to stock, but is roughly 8:0 in the Paris Stock Exchange and 15 in the London Stock Exchange. This means that in Paris the mean of the distribution does not exist and in London the second moment does not exist. The small values of are surprising because they im ply a non-vanishing probability for order placem ent extrem ely far from the current best prices, where it would seem that the probability of ever making a transaction is exceedingly low. Such orders are often replaced when they expire, which taken together with the fact that they their distribution lies on a continuous scaling curve with orders that are close to the best prices suggests that they are intentional.

Here we add to this earlier work by studying the probability of order placement inside the spread and the frequency of transactions conditional on the spread. We will say that a new order is placed inside the book if its logarithm ic limit price places it within the existing orders, i.e. so that for a buy order $< {}_{\rm b}$ and for a sell order $> {}_{\rm a}$. We will say it is inside the spread if its limit price is between the best price to buy and the best price to sell,

i.e. $_{b} < < _{a}$. Sim ilarly, if it is a buy order it generates a transaction for $_{a}$ and if it is a sell order for $_{b}$. To sim plify nom enclature, when we are speaking of buy orders, we will refer to $_{b}$ as the same best price and $_{a}$ as the opposite best price, and vice versa when we are speaking of sell orders. We will de nex as the logarithm ic distance from the same best price, with $x = _{b}$ for buy orders and $x = _{a}$ for sell orders. Thus by de nition x = 0 for the same best price, x > 0 for aggressive orders placed outside the lim it order book, and x < 0 for less aggressive orders placed inside the lim it order book.

In deciding where to place an order, a trader needs to make a strategic trade o between certainty of execution on one hand and price in provement on the other. One would naturally expect that for strategic reasons the limit prices of orders placed inside the book should have a qualitatively dimension than those placed inside the spread. To see why we say this consider a buy order. If the trader is patient she will choose < b. In this case the order will sit inside the limit book and will not be executed until all buy orders with price greater than have been removed. The proper strategic trade o between certainty of execution and price in provement depends on the position of all the other orders { to gain more price in provement means more other orders have to be executed, which lowers the probability of execution. In the limit where b and there are many orders in the queue the execution probability and price in provement vary in a quasi-continuous manner with .

The situation is dimensional for an impatient trader. Such a trader will choose > b. If she is very impatient and is willing to pay a high price she will choose a, which will result in an immediate transaction. If she is of intermediate patience, she will place her order inside the spread. In this case the obvious strategy is to place the order one price tick above b, as this is the best possible price with higher priority than any existing orders. It would seem foolish to place an order anywhere else inside the spread⁴, as this gives a higher price with no improvement in priority of execution. One would therefore naively expect to and that order placement of buy orders inside the spread is highly concentrated one tick above the current best price. This suggests that as one moves away from the same best price, how new trading orders are placed inside the spread should be dimension how they are placed inside the book. The resulting distribution should be asymmetric around b.

To model order placement we seek a good functional form for p(x js), the probability density for x conditioned on the spread. This is complicated by the fact that for an order that generates an immediate transaction the relative price x is not meaningful. Such an order can either be placed as a limit order with x > s or as a market order, which has an e ective price x = 1. In Farmer et al. (2004) we showed that for the LSE it is very rare for a market order to penetrate deeper than the opposite best price. This restriction can be achieved either through the choice of limit price or by the choice of order size. Thus two orders with very di erent limit prices may be equivalent from a functional point of view. We resolve this am biguity by lumping all orders with x > s together and characterizing them by P, the probability that a trading order causes an immediate transaction⁵. We thus restrict our attention to the probability p(x js) only for orders with x < s and the probability P for orders that generate transactions (which can be thought of as all orders with x > s). We

⁴ This reasoning neglects the consequences of time priority; as we will discuss later, when time priority is taken into account other values may be reasonable.

⁵ If only part of an order causes an immediate transaction we will treat it as two orders, one of which causes a transaction and one of which doesn't.

expect P to depend on the spread.

A fler considerable exploratory analysis we have been led to make a simple hypothesis about order placement. Our hypothesis is that

Ρ

$$p(x_{js}) = p(x); \quad 1 < x < s;$$
 (1)

$$(s) = p(x)dx;$$
 (2)

where p(x) is a probability density function that is symmetric about x = 0 and that is well approximated by a Student distribution. Equation (1) describes the prices where limit orders are placed, and equation (2) describes the probability of a transaction. If the relative price x drawn from p(x) satisfies 1 < x < s then it is an elective limit order at price = b + x, and if x is it is an elective market order. Note that the symmetry of the hypothesized functional form contradicts the strategic reasoning given earlier.

The rst hypothesis in plies that p(x;s) = p(x)p(s) on 1 < x < s, i.e. that x and s are independent in this range. We must be careful, however, since the range depends on s, so p(x;s) is not fully independent of s. This makes it useful to rewrite this hypothesis in a form that makes the dependence on s more explicit. As a convenient conceptual device, we can treat any elective market order to buy as if it were a limit order with a limit price $=_0$, where $_0$ is any price that is high enough to guarantee a transaction (i.e. $_0$ is electively 1). We can then rewrite p(x;s) without any restrictions on the range in the form

$$p(x_{js}) = P(s)(x_{0}) + H(x_{s})p(x);$$
 (3)

where H (x) satis es H (x) = 1 for x < 0 and H (x) = 0 for x > 0, and (x) is the D irac delta function, which satis es (x) = 0 for $x \in 0$ and (x) dx = 1 for any range of integration that includes 0.

We can test our hypothesis by assuming it true and then testing whether this is consistent with the data. To do this we can get better statistical convergence by aggregating a semiin nite range of values of the spread by studying p(xjs > s), where s_1 is a threshold that can be varied to test for dependence on the spread. This conditional density contains inform ation about both the right and left tail of the distribution. Since s can be arbitrarily large, $p(xjs > s_1)$ contains limit orders with arbitrarily large values of x. However, the sample distribution will contain a di erent number of points on the left and right sides due to the fact that for $x > s_1$ the probability of x depends on the distribution of the spread. $p(xjs > s_1)$ can be written

$$p(xjs > s_1) = \frac{R_1}{\frac{s_1 R_1}{s_1 R_1}} p(xjs)p(s)ds}{\frac{s_1 R_1}{s_1} p(s)ds}$$
:

From equation 3 this becomes

$$p(xj_{5} > s_{1}) = \frac{(x _{0})_{s_{1}}^{R_{1}} P(s)p(s)ds + p(x)_{s_{1}}^{R_{1}} H(x _{s})p(s)ds}{R_{1}^{R_{1}} p(s)ds};$$
 (4)

There are three ranges of x that must be treated separately.

x < 0 corresponds to limit orders placed inside the book. In this range $p(x; j_s > j_s) = p(x)$. This can be explicitly verified by doing the integral over H (x s) in equation3 over s.

0 < x < p corresponds to lim it orders placed inside the spread, in which case $p(x \neq s_1)$ is given by equation 6 below.

s x corresponds to trading orders that generate in m ediate transactions, with a probability given by equation 2.

We now compute a simple expression for $p(x j s > s_1)$ for the second bullet above, i.e. the range where $s_1 < x < 0$. By making a change of variables the H eaviside function can be removed and the domain of integration adjusted to include only the non-zero range of the integrand. This gives

$$p(x j_{s} > s_{1}) = p(x) \frac{\mathbb{R}_{1}^{r_{1}} p(s)ds}{\mathbb{R}_{1}^{r_{1}} p(s)ds}$$
 (5)

This gives an easy way to test our hypothesis. Letting N (x > z) be the num ber of lim it orders that satisfy the condition x > z, equation 5 gives an expression for estimating p(x) for $x > s_1$ as B_z .

$$p(x) = p(xj_{s} > s_{1}) \frac{R_{1}^{s_{1}} p(s)ds}{x} + \frac{N(s > s_{1})}{N(s > x)}$$
(6)

Using these results we can reconstruct p(x) for 1 < x < 1 with any spread condition s_1 , by using equation 6 for $x > s_1$ and $p(x j s > s_1)$ otherwise. This is done for two dimensions values of s_1 in Figure 1. The fact that the data collapse onto the same curve even though we use two very dimensions conditions con most that p(x j s) = p(x). This result is surprising for three reasons:

p(x js) is independent of the spread. This is surprising because one would naively expect the strategic considerations of order placem ent to depend on the spread.

The distributions for buying and selling are the same.

The distribution is symmetric. This is most surprising of all, since for reasons that we outlined in the introduction to this section, the strategic considerations for placing orders inside the spread seem quite di erent than those for placing an order inside the book.

We can test equation 2 using the t to the Student distribution from Figure 1. In Figure 2 we plot the fraction of orders that result in transactions as a function of the spread. This gives an excellent t to the data. The probability that an order generates a transaction approaches 1=2 in the limit as the spread goes to zero, and approaches zero in the limit as the spread becom es large.

To test whether this form is exact or is only an approximation, we used the Kolm ogorov-Sm innov (KS) test. In order to test the conjecture for dierent values of the spread, we divided the data set into bins based on the value of the spread, in the ranges shown in Table I. We then drew values from the Student distribution to match the number of points in each bin, and applied a two-sided KS test. The statistics of the test for each bin and

FIG. 1: Reconstruction of the probability density function p(x) describing limit order prices as a function of x, the limit price relative to the same best price. The reconstruction is done both for buy orders (green upward pointing triangles) and sellorders (red downward pointing triangles), and for two dimenstructure of the spread, q = 0, which uses all the data, and $s_1 = 0.0025$, which uses roughly the 10% of the data with the largest spread. The tted blue curve is a Student distribution with 1.3 degrees of freedom. This shows the order placement is roughly symmetric, independent of the spread, and the same for buy and sell orders.

s in units of E [s]	0-0.5	0.5-1	1-1.5	1.5-2	2 –3	3-5	5-10	10 - 20
KS value	0.39	0.89	1.12	0.97	12	1.07	1.32	1.15
p value	0.72	0.2	80.0	0.15	0.05	0.1	0.03	0.07

TABLE I: Results of applying the Kolm ogorov-Sm innov test to the data shown in Figure 1. The rst row contains the range of spreads for each bin in units of the sample mean E [s], the second row contains the values for the test, and the third row contains the corresponding p values.

the corresponding p values are given in Table I. In one case out of eight we get a rejection at the 95% con dence level, and in four cases out of eight we get rejections at the 90% con dence level, suggesting that there are small deviations from the Student distribution hypothesis. However, these rejections are all weak, and it is important to keep in mind that the KS test requires the data to be IID. A close examination of the data makes it clear that this is not true. Zovko and Farm er (2002) studied negative values of x, and found that they have a strong positive autocorrelation in the tail; we also observe that jxjhas signi cant autocorrelations. Considering this the results of the KS test are surprisingly good. In any case it is clear that the Student distribution is a very good approxim ation of

FIG.2: The transaction probability P as a function of the spread. The curve is based on the t to a student distribution for p(x) in Figure 1 and equation 2. This demonstrates that the fraction of orders that result in transactions approaches 1=2 in the lim it as the spread goes to zero and approaches zero in the lim it as the spread becom es large.

the true distribution.

This raises the question of whether p(x) can correspond to an econom ic equilibrium. As we have already suggested, the obvious strategy for placing an order inside the spread is to choose a price one tick better than the current same best price. But perhaps this is naive once one considers a nite tick size and the price priority that comes from placing an order nst. W hen the spread is wide it is likely that other lim it orders will arrive soon and cause the in patient trader to move her order again. W hen she places a new order she may forced to a price that is already occupied and thus get lower priority. In this case she would have been better o to quote a more aggressive price to begin with. Under appropriate assumptions such a line of reasoning might result in an econom ic equilibrium. Because the strategic considerations inside and outside the book are so di erent, however, it is hard to believe that such an equilibrium distribution would be symmetric around the best price. This suggests that this result may only be explainable on behavioral grounds. At this stage it is unclear whether we should consult an equilibrium theorist or a psychologist⁶

⁶ A nother alternative is that we should consult an expert in non-equilibrium statistical mechanics. The Student distribution occurs as a standard solution in nonequilibrium statistical mechanics. An alternate explanation might be an equilibrium that is constrained by inattention, e.g. because of time lags between price perception and order placement. Note, though, that in the LSE order placement is essentially instantaneous and time stamps are accurate to within the second.

IV. LONG-MEMORY AND ORDER SIGNS

To model order placement it is necessary to decide whether each new order is to buy or to sell. We arbitrarily designate +1 for buy and 1 for sell. Given that returns are essentially uncorrelated in time, it might seem natural to simply assume that order signs are IID. However, this is not a good approximation for the two markets where this has been studied'. Instead, the signs of orders follow a long-m em ory process (Bouchaud et al. 2004, Lilb and Farmer 2004). Roughly speaking, this means that the autocorrelation of order signs C () is not integrable, and decays as for large 0 < < 1. Here is the time lag between the placement of two orders measured either as the intervening number of transactions or in terms of clock time while the market is open. The coe cients of the sample autocorrelation remain positive at statistically signi cant levels for lags of 10;000 transactions, corresponding to time intervals of several weeks. This is surprising because it in plies a high degree of predictability in order signs { by observing the sign of an order that has just been placed, it is possible to make a statistically signi cant prediction about the sign of an order that will be placed two weeks later. In order to compensate for this and keep price changes uncorrelated, the market must respond by adjusting other properties, such as liquidity, in order to compensate (Lillo and Farm er 2004). As Bouchaud et al. (2004, 2004) have pointed out this also in plies adjustments in subsequent order placement. We nd that the long-m em ory properties of order signs is very in portant for price form ation.

We have o ered a model to explain the long-mem ory of order ow based on strategic order splitting (Lilb, Mike, and Farm er 2005). When an agent wishes to trade a large amount, she does not do so by placing a large trading order, but rather by splitting it into sm aller pieces and executing each piece incrementally according to the available liquidity in the market. We make a model in which we assume hidden orders have an asymptotic power law distribution in their size V of the form P(V > v) = v, with > 0, as observed by G opikrishnan et al. 2000). Our model assumes that hidden orders enter according to an IID process, and that they are executed in constant increments at a fract. We show that the signs of the executed orders are a long-memory process whose autocorrelation function has exponent = 1. This prediction is borne out empirically by comparisons of o -book and on-book data (Lilb, Mike and Farm er, 2005).

The custom ary way to discuss long-memory is in terms of the Hurst exponent, which is related to the exponent of the autocorrelation function as H = 1 =2. For a long-memory process the Hurst exponent is in the range 1=2 < H < 1. For a di usion process with long-memory increments the variance over a period t scales as t^{2H} , and statistical averages converge as $t^{(H-1)}$. This creates problem s for statistical testing, as discussed in Section VI.

For simulating price form ation as we will do in Section VI we have used our model described above, and we have also used a fractional gaussian random process (Beran, 1994) (in the latter case we take the signs of the resulting random numbers). Because the algorithm for the fractional gaussian algorithm is standard and easy to implement, for purposes of reproducibility we use it for the results presented here. The studies cited above exam ined the signs of market orders only, but in our model we use a long-memory process to model the signs of market orders and limit orders. This is justimed by studies that we have done of the signs of limit orders, which we not exhibit long-memory that is essentially equivalent

 $^{^7}$ These studies were for the Paris and London stock m arkets.

V. ORDER CANCELLATION

Cancellation of trading orders plays an important role in price formation. It causes changes in the midprice when the last order at the best price is removed, and can also have important indirect e ects even when it occurs inside the limit order book. It a ects the distribution of orders in the limit order book, which can later a ect price responses to new market orders. Thus it plays an important role in determining liquidity.

The model that we develop for cancellation in this section is crude and should be regarded as prelim inary. Our reason for presenting our results at this time is that we want to illustrate that the order placement from the previous section plays an important role in price formation. A lthough the analysis leading up to the cancellation model developed here is quick and dirty, it is justimed in the end by the fact that it produces fairly good results. The resulting model is simple and provides a basis for improvement.

The zero intelligence model used the crude assumption that cancellation is a Poisson process. Let be the lifetime of an order measured from when it is placed to when it is cancelled, where time is measured in term softnum ber of trading orders that are placed (either market orders or limit orders). Under the Poisson assumption the distribution of lifetimes is an exponential distribution of the form P() = (1)¹, where is the rate of the Poisson process. This can also be written = 1=E [], where E [] is the expected lifetime. For A ZN, for example, 0:040. A comparison of the exponential to the true distribution, as done in Figure 3, makes it clear that the Poisson process is a poor assumption. The tail of the empirical density function behaves like a power law⁸ of the form ⁽⁺¹⁾, with = 1:1. This is a good approximation over roughly two orders of magnitude. The fact that the tail is a power law implies that the most long-lived orders last an order of magnitude longer than they would under the Poisson hypothesis. Similar results are observed for BLT with

1:55 and LLOY with 1:19.

It is clear that the Poisson process needs to be modiled and by a process whose lifetime distribution has a heavy tail. There are several elects that can cause this. For example, if () is a decreasing function, the longer an order exists without being cancelled, the less likely it is to be cancelled. A lternatively, even if () is constant in time, if it depends on the order i this can generate heavy tails in the lifetime distribution of the whole population. We not three dilerent elects that are important for price form ation. These three factors are position in the order book relative to the best price, imbalance of buy and sell orders in the book, and the total number of orders. We now explore each of these elects in turn.

⁸ We nd that this exponent is not very stable { when we subsample the data its value varies som ew hat in di erent periods.

FIG. 3: The empirical probability density of the lifetime of cancelled orders for the stock Astrazeneca (black). is the number of trading orders placed between the time given order is placed and the time it is cancelled. This is compared to an exponential distribution with = 0.03 (red). A power law ⁽¹⁺⁾ with = 1.1 is shown for comparison. Note that to avoid end of day e ects we exclude orders that are are not cancelled between 9:00 am and 4:00 pm on trading days (but we do include orders that are placed on one day and cancelled on another day).

A. Position in the order book

Strategic considerations dictate that position in the order book should be important in determining the cancellation rate. Someone who places an order with a positive value of x is likely to have a very dimension expected execution time than someone who places an order with a negative value of x. If an order is placed at the best price then this implies that the trader is impatient and more likely to cancel the order quickly if it is not executed. In contrast, no one would place an order deep inside the book unless they are prepared to wait a long time for execution. Dependence on cancellation times with these basic characteristics was observed in the Paris Stock M arket by Potters and Bouchaud (2003).

To study this e ect we will measure the cancellation rate as a function of the distance to the opposite best price. Letting t_i be the time when the order was placed, the distance from the opposite best at time t $t_i > 0$ is $t_i(t, t_i) = t_b(t)$ for sellorders and $t_i(t) = t_a(t)$ for buy orders. (0) is thus the distance to the opposite best when the order is placed, and $t_i(t) = 0$ if and when the order is executed. We compute the sample correlation ((0);),

and nd that 0:23 for AZN, 0:14 for BLT, and 0:18 for LLOY, con m ing the positive association between distance to the opposite best and cancellation time.

Strategic considerations also suggest that cancellation should depend on (t) as well as (0). If (t) (0) then this means that the opposite best price is now much further away than when the order was originally placed, making execution unlikely and making it

FIG.4: The probability of cancellation P (C \dot{y}_i) for AZN conditioned on $y_i(t) = i(t) = i(0)$. The variable yi measures the distance from order i to the opposite best price relative to its value when the order was originally placed. The solid curve is the empirical tK_1 (1 e^x), with K_1 0:012.

more likely that the order will be cancelled. Similarly, if (t) (0) the opposite best price is quite close, execution is very likely and hence cancellation should be less likely. This is con med by fact that for buy cancellations we observe positive correlations with the opposite best price m ovem ents in the range of $20 \quad 25\%$, and for sellorders we observe negative correlations of the same size. In the interest of keeping the model as simple as possible we de ne a variable that encompasses both the dependence on (0) and the dependence on

(t), de ned as their ratio

$$y_{i}(t) = \frac{i(t)}{i(0)}$$
:

By de nition when order i is placed y = 1 and if and when it is executed, $y_i = 0$. A change in y_i(t) indicates a movement in the opposite price in units whose scale is determined by where order i was originally placed.

To measure the conditional probability of cancellation we use Bayes' rule. The probability of cancellation conditioned on yi can be written

$$P (C \dot{y}_{i}) = \frac{P (y_{i} \dot{y}_{i})}{P (y_{i})} P (C);$$
(7)

where C is a variable that is true when a cancellation occurs and false otherwise. The conditional probability P ($y_i t$) can be computed by simply making a histogram of the values of y_i when cancellations occur. Figure 4 shows an empirical estimate of the conditional probability of cancellation for AZN computed in this way. A lthough there are substantial oscillations⁹, as predicted by strategic considerations the cancellation probability tends to increase with y_i . As y_i goes to zero the cancellation probability also goes to zero, and it

⁹ We believe these oscillations are caused by round number e ects in order placement and cancellation.

FIG.5: The probability of cancellation per order, P (C $\dot{n}_{im b}$) for the stock AZN. This is conditioned on the order in balance $n_{im b}$. The dashed curve is a least squares to a linear function, K₂ ($n_{im b}$ + B), with K₂ 0.098 and B 0.20.

increases to a constant value of roughly 3% per unit time as y_i gets large (we are measuring time in units of the number of trading orders that are placed). To approximate this behavior form odeling purposes we empirically ta function of the form K_1 (1 exp(x)). For AZN m inimizing least squares gives K_1 0:012.

The question remains whether the ratio $_{i}(t)=_{i}(0)$ fully captures the cancellation rate, or whether the numerator and denominator have separate e exts that are not well modeled by the ratio. To test this we divided the data into four di erent bins according to $_{i}(0)$ and repeated the measurement of Figure 4 for each of them separately. We do not get a perfect collapse of the data onto a single curve. Nonetheless, each of the four curves has a similar shape, and they are close enough that in the interest of keeping the model simple we have decided not to model these e exts separately.

B. Order book im balance

The imbalance in the order book is another factor that has a signi cante ect on order cancellation. We de nean indicator of order imbalance for buy orders as $n_{m,b} = n_{buy} = (n_{buy} + n_{sell})$ = and for sell orders as $n_{im,b} = n_{sell} = (n_{buy} + n_{sell})$, where n_{buy} is the number of buy orders in the limit order book and n_{sell} is the number of sell orders. In Figure 5 we show an empirical estimate of the conditional distribution P (C $p_{im,b}$), de ned as the probability of cancellation per order. P (C $p_{im,b}$) is less than 1% when $n_{im,b} = 0.1$ and about 4% when $n_{im,b} = 0.95$, increasing by more than a factor of four. This says that it is more likely for an order to be cancelled when it is the dom inant order type on the book, e.g. if the book

FIG. 6: The probability of cancellation per order, P (C j_{tot}), for the stock AZN, conditioned on the total number of orders in the order book, n_{tot} on a log-log plot. The dashed line is the function K $_3$ = n_{tot} , shown for reference, where K $_3$ = 72.2.

has m any m ore buy orders than sell orders, the probability that a given buy order will be cancelled increases (and the probability for a given sell order to be cancelled decreases). Since the functional form appears to be a bit complicated, as a crude approximation we t a linear function of the form $P(C_{jn_{im}b}) = K_2(n_{im b} + B)$. M inimizing least squares gives $K_2 = 0.098$ and b = 0.20 for AZN.

$\ensuremath{\mathsf{C}}$. Number of orders in the order book

Another variable that we nd has an important e ect on cancellation is p_{tt} , the total number of orders in the order book. U sing a procedure similar to those for the other two variables, in F igure 6 we plot the cancellation probability as a function of n_{tot} . Surprisingly, we see that the probability of cancellation decreases as n_{tot} increases, approximately proportional to $1=n_{tot}$. A least squares t of log P (C j_{tot}) vs. b a log n_{tot} gives a slope a = 0.92 0.06 (using one standard deviation error bars). The coe cient a is su ciently close to one that we simply make the approximation in our model that P (C j_{tot}) $1=n_{tot}$. We plot a line of slope 1 in the gure to make the validity of this approximation clear.

This is very surprising, as it indicates that the total cancellation rate is essentially independent of the number of orders in the order book. It raises the question of how the order book can be stable: If the total cancellation rate does not increase as the number of orders in the book increases, what prevents the number of orders in the book from blowing up? A swe discussion in Section V I, we not that the order book dynam ics are stable, even with this term. We believe that this is achieved by the order placement dynam ics illustrated in F igure 2. A s n_{tot} increases, the spread tends to decrease, which stim ulates the submission of

FIG. 7: A comparison of the distribution of lifetimes of simulated cancellations (blue squares) to those of true cancellations (black circles).

m ore m arket orders, which decreases n_{tot}.

D. Combined cancellation model

We assume that the e ects of n_{imb} , y_i , and n_{tot} are independent, i.e. the conditional probability of cancellation per order is of the form

$$P (C \dot{y}_{i}; n_{im b}; n_{tot}) = \frac{P (y_{i} \dot{j} C) P (n_{im b} \dot{j} C) P (n_{tot} \dot{j} C)}{P (y_{i}) P (n_{im b}) P (n_{tot})} P (C) = A (1 \exp^{y_{i}}) (n_{im b} + B) = n_{tot}; (8)$$

where for AZN A 0:45 and B 0:20.

To test this model we simulate cancellations and compare to the real data. Using the real data, after the placement of each new order we measure y_i , n_{imb} , and n_{tot} and simulate cancellation according to the probability given by equation 8. We compare the distribution of lifetimes from the simulation to those of the true distribution in Figure 7. The simulated lifetime distribution is not perfect, but it is much closer to the true distribution than the Poisson model (compare to Figure 3). It reproduces the power law tail, though with 0.9, in comparison to the true distribution, which has 1.1. For small values of the model underestimates the lifetime probability and for large values of it overestimates the probability. A s an additional test of the model we plotted the average number of simulated cancellations against the actual number of cancellation. A swe would hope the result is close to the identity. Since the resulting plot is uninteresting we do not show it here.

The models of order placement and order cancellation that we have developed here can be used to simulate price formation. We make three additional simplifying assumptions.

All lim it orders have constant size. This is justimed by our earlier study of the on-book market of the London Stock Exchange in (Farm er 2004 et al.). There we showed that orders that remove more than the depth at the opposite best quote are rare. Thus from the point of view of price form ation we can neglect large orders that penetrate more than one price level in the lim it order book, and simply assume that a transaction either removes all shares at the best quote or does nothing. We den end the fraction of time a transaction removes the best quote.

Tick size. Tick size can have an important e ect on prices. For the purposes of this study we assume a constant logarithm ic tick size of 3 10^4 .

O rder placement time. The basic unit of time for the simulation and for the corresponding statistical analysis of the real data is an order placement (whether a market order or a limit order). This assumption is justimed by a recent study showing that uctuations in transaction frequency play only a minor role in determining clustered volatility and the distribution of returns (G illemot, Farmer, and Lillo, 2005).

The simulation of the model proceeds as follows. Each time step corresponds to the generation of a trading order. The order sign¹⁰ is generated using a fractional gaussian process¹¹ as described in Section IV with Hurst exponent H_s. We then generate a trading order with that sign by drawing a relative limit price x from a Student distribution with scale and tail exponent (x), based on the model developed in Section III. If x < s we place a lim it order at price x relative to the opposite best, and otherwise we place a market order. If the result is a market order then we remove all the orders at the opposite price with probability; otherwise the order has no e ect. We then determ ine which orders are cancelled by exam ining each order in the limit order book and generating random numbers with probability given by equation 8 (which has parameters A and B. Note that more than one order can be cancelled in a given timestep. The only exception is if this would result in either side of the lim it order book becoming too empty. To prevent this from happening we in pose an additional condition on order cancellation, and require that after cancellation there be at least two orders remaining on the corresponding side of the book. As a sum mary, in Table II we give the measured values of the seven parameters of the model for the three stocks in our data set.

¹⁰ N ote that we are generating order signs exogenously. This is justimed, for example, under the assumption made in the model of Lillo, Mike, and Farmer (2005) that hidden order arrival is exogenous to price formation.

¹¹ In contrast to the more realistic model of order ow described in Section IV, the fractional gaussian processes does not allow us to control the prefactor of the correlation function, but rather generates a constant prefactor C 0:15. We not that this is close enough to the true values in TableII that this does not make a di erence.

stock ticker	Н	С	(x)	10 ³		А	В
AZN	0.77	0.15	1.31	2:4	0.45	0.45	0.20
BLT	0.80	0.18	1.55	2:0	0.40	0.51	0.21
LLO Y	0.81	0.13	1,25	2 : 6	0.43	0.47	0.22

TABLE II: The measured parameters of our model for the three stocks in our data set. H is the Hurst exponent of the order sign series, C is the prefactor of the sign autocorrelation function, (x) and are the tail exponent and the scale parameter of the order placement distribution,

and is the market order penetration rate. The probability of cancellation for a given order is $P(C_{j_{i}};n_{im}b;n_{tot}) = A(1 e^{y_i})(n_{im}b+B)=n_{tot}$.

The param eters of the simulation for a given stock are based on the param eters in Table II. The simulation generates a series of events that we compare to the real data in the same period where the param eters are measured. The particular sequence of events generated in this manner depends on the random number seed used in the simulation, and will obviously not match the actual data in detail. We instead test the model by comparing its statistical properties to those of the real data.

In Figure 8 we compare the predictions of the model to the empirical distribution of returns and spreads for the stock AZN. The returns are logarithm icm idprice changes between transactions, i.e. $r(t_i) = \log p(t_i) p(t_i t_{i-1})$, where t_i is the time when a transaction occurs and $p(t_i)$ is the midprice $p(t_i) = 1=2(a(t_i) + b(t_i))$ immediately after the transaction. The distribution for the spread is built by recording the best bid and ask prices immediately before transactions¹². The agreement is extremely good, both in terms of magnitude and functional form.

W e want to stress that these predictions are m ade without any adjustment of parameters based on prices. All the parameters of the model are based on the order ow process alone { there are no adjustable parameters to m atch the scale of the returns or the spreads. In Table III we compare summary statistics for the real data to those of the simulation for the three stocks in our sample. We do this for the mean, the standard deviation, and the tail exponent of the spread and the transaction to transaction returns for each stock. The

stock ticker	E (jr	j 10 ⁴	E (s)	10 4	(jrj	10 4	(S)	10 4	(jrj		(s)	
AZN	5.4	12	13.9	0.6	72	2.1	12.1	0.7	2.4	0.2	3.3	0.3
AZN predicted	5.1	0.1	14.3	0.2	7.2	0.3	132	0.2	2.1	0.4	3.0	0.3
BLT	10	0.9	24.1	0.9	17.7	1.6	27.1	12	1.9	0,2	2.8	0.3
BLT predicted	9.4	0.1	22.7	0.1	16.6	0.4	26.4	0.3	22	0.4	2.7	0.3
LLOY	7.6	13	17.1	0.9	8.9	0.6	13.8	0.5	2.4	0.4	3.5	0.2
LLOY predicted	7.4	0.1	16.8	0.1	92	0.1	12.9	0.3	22	0.3	3.2	0.2

¹² The time when the spread is recorded makes a signi cant di erence in the distribution. The spread tends to narrow after receipt of limit orders and tends to widen after market orders or cancellations.

FIG. 8: A comparison of the distribution of absolute returns jrj (upper) and spreads s (lower) predicted by the model to those of the real data for the stock A strazeneca. The error bars for the model were computed by running the model for 20 times the number of events in the data set and taking the standard deviation over the 20 resulting distributions. The solid curve is based on a single run of the model of length equal to the data set.

TABLE III: C om paring the m odel with real data for three stocks in our sample. E (x) = sample m ean of x, (x) = standard deviation of x, and (x) = tail exponent of x. These statistics are based on the absolute logarithm ic returns jrj between transactions and the spread s sampled as described in the text. Error bars are one standard deviation, computed using the variance plot m ethod.

agreem ent is quite good across the board. Out of 3 = 18 possible cases, in all but two

cases the one standard deviation error of the prediction is within the one standard deviation error of the real value. The error in the prediction is in every case less than 10%, and in most cases less than 5%.

The reason the error bars in Table III seem large is because both the absolute returns and the spreads are long-mem ory processes. Long-mem ory has been reported in volatility by many authors (Breidt, Crato and de Lim a 1993, Harvey 1993, Ding, Granger and Engle 1993, Bollerslev and Mikkelsen, Baillie 1996, 1996, Willinger, Taqqu, and Teverovsky, 1999, Gillem ot, Farm er and Lillo 2005). We con methishere, getting H = 0.78 for AZN, H = 0.74for BLT, and H = 0.78 for LLOY. As far as we know we are the rest to report long-mem ory in spreads; sampling before transactions, we nd H = 0.81 for AZN, H = 0.86 for BLT, and H = 0.79 for LLOY¹³. While we have not perform ed signing cance tests (there is no good test that we know of), given the large size of our data set and the fact that these are so large in every case, we are condent that these numbers are all greater than H = 0.5 by a statistically signing cant amount, and these are long-mem ory processes.

For long-m em ory processes the statistical error scales as N ^(H 1), where N is the num ber of data points and H is the Hurst exponent. Standard m ethods for estimating errors fail when applied to long-m em ory processes, and the only applicable m ethod that we are aware of is the variance plot m ethod (Beran 1994). The data set of length N is divided into m disjoint regions of length L = int(N=m), where int(x) is the integer part of x, and any remaining data are discarded. The statistic of interest (the m ean E, the standard deviation or the tail exponent) is computed for each region based on the L data points in that region. The resulting m values are used to compute the standard deviation (m) of the statistic across the m regions. This is done for a variety of di erent values of m. Then log (m) is regressed against logm assuming the linear relation log (m) = (1 H) logm + b, where b is a free param eter. We use values of H computed using the DFA m ethod based on polynom ials of degree one (D eng et al. 1994). The result is extrapolated to m = 1 to compute the error corresponding to the p value for one standard deviation.

We have not yet had the opportunity to fully explore the properties of this model. A fuller investigation would test the model on data from many dimensions stocks and on more properties of the price series. The model has several defects that we know of. In particular, the autocorrelation function of returns drops to zero slower than the real data (it takes on values of the order of 1% for about 50 time steps). Another dimensions clustered volatility. While the model displays some clustered volatility, it is weaker and less persistent than that of the real data. For example, for AZN the Hurst exponent of volatility of the model is H = 0.64, in contrast to H = 0.78 for the real data. Another feature of this model that we do not like is that the ad hoc requirement that we preserve at least two orders in each side of the limit order book makes a noticeable dimension in the statistical properties of the simulation, indicating that our existing cancellation model has not fully captured the order book dynam ics.

D espite these caveats, the model does an extrem ely good job of describing the distribution of both returns and spreads. The prediction of the tail behavior for both returns and spread is accurate to within statistical error. Perhaps even more important, unlike previous models, the prediction is for the entire distribution, and not just for the tail exponent. A lthough we

¹³ N ote that both the tails and the autocorrelations of the spread depend strongly on sampling, due to the interaction between transactions and the spread.

FIG.9: A comparison of the distribution of absolute returns jrj for the model using a long-memory sign generation process (red squares) and an IID sign generation process (green diamonds). All other parameters are held xed.

cannot make a m statement based on only three cases, the predicted tail exponent tracks the variations in the realtail exponents of the three stocks we study here quite well. Though not yet fully convincing, this suggests that the tail exponents are not universal, but rather vary from stock to stock¹⁴. Ourmodelmay thus be useful for understanding the factors that cause variations in the behavior of extremerisk between stocks.

A lthough we have not had a chance to make an exhaustive study of the behavior of the model under variation of its parameters, certain features are clear. For example, the long-memory in the order signs is an important driver of the heavy tails of both the return and the spread distributions. To demonstrate this, in Figure 9 we turn on the long-memory of order signs and replace it with IID process with a 50% chance of generating a buy order and a 50% chance of generating a sell order. A lthough still not normally distributed, the tails of the return distribution are clearly much thinner. The tail exponents of returns (jrj) and spreads (s) also depend on other properties of the model, such as the tail exponent for lim it order placement (x) and parameters of the cancellation process, as well as the Hurst exponent H of the order sign process. The return distribution is not just a simple reference of the order placement process, but involves an interaction between all the parts of the model that we do not yet fully understand.

¹⁴ Note also that all three values of (jr) are more than two standard deviations below the value of 3 that is predicted by G abaix et al. (2003).

The results that we have presented here are useful for several reasons. On a practical level they give insight into the factors that generate nancial risk. They suggest that market m icrostructure is important. The distribution of returns in the model is determined by the interaction of order placement and cancellation. A coording to our model the heavy tails in price returns are driven by the long-memory of order signs, but they are also in uenced by order placement and cancellation processes that also have heavy tails. This prediction is quite di erent from previous models that say that they are due to large transactions (G abaix et al, 2003), or that they are caused in a more generic way by nonlinearm arket dynamics, as discussed in the introduction. R esolving this question is interesting form arket design because it suggests that by altering properties of the order placement and cancellation process (e.g. by providing incentives to change behavior) it may be possible to alter the properties of nancial risk.

These results are also interesting at the broader level of m ethodology. It has become traditional in econom ics to require that all theories begin by m odeling preferences. A typical example is sel sh utility m axim ization under rational choice. At the other end are econom etric m odels, which t functional forms to data using purely ad hoc assumptions. Our m odel is som ewhere in between. W e m ake an econom etric m odel for order placem ent and use this as the foundation to m ake predictions about price form ation. The m odel of order placem ent gives insight into decision m aking, but does not m ake any fundam ental assumptions about the m otivations that drive it. This can be regarded as a divide and conquer strategy: R ather than trying to start from rst principles and work forward, we search for regularities in the m iddle. From here one can either work forward to prices or work backward to try to discover what preferences and strategic considerations m ight generate these regularities. W e have chosen to take the much easier path of working forward because it leads to accurate quantitative predictions via a tractable research program.

The path backward is also very interesting, but much less straightforward. We cannot claim to understand the behavior we have documented here until we understand its motivation. Nonetheless, by looking at order placement rather than directly at prices we are able to capture intermediate behavioral regularities that provide in portant clues about their origins, providing a useful benchmark for any attempt to make more fundamental models that address preferences and choice. Is it possible to explain these regularities in terms of rational choice? Or do they represent an example of irrational behavior, that can only be explained in terms of hum an psychology?

Finally our results are interesting because of the accuracy of their predictions. Based on properties of order ow, we are able to predict both the magnitude and the functional form of the return distribution to a high degree of accuracy. The predictions of this model have the kind of accuracy that one expects in physics. The research program is in the spirit of typical models in physics, which connect a set of empirical assumptions at one level to empirical phenom ena at another level, but typically do not attempt to derive results from

rst principles.

A cknow ledgm ents
