## Delta Hedged Option Valuation with Underlying Non-Gaussian Returns

L. Moriconi

Instituto de F sica, Universidade Federal do Rio de Janeiro, C.P. 68528, 21945-970, Rio de Janeiro, RJ, Brazil

The standard B lack-Scholes theory of option pricing is extended to cope with underlying return uctuations described by general probability distributions. A Langevin process and its related Fokker-P lanck equation are devised to model the market stochastic dynamics, allowing us to write and form ally solve the generalized B lack-Scholes equation in plied by dynamical hedging. A system atic expansion around a non-perturbative starting point is then in plemented, recovering the M atacz's conjectured option pricing expression. W e perform an application of our form alism to the real stock market and nd clear evidence that while past nancial time series can be used to evaluate option prices before the expiry date with reasonable accuracy, the stochastic character of volatility is an essential ingredient that should necessarily be taken into account in analytical option price m odeling.

PACS num bers: 89.65 G h, 05.10 G g

There has been a great interest in the study of the stochastic dynamics of nancial markets through ideas and techniques borrow ed from the statistical physics context. A set of well-established phenom enological results, universally valid across global markets, yields the motivating ground for the search of relevant models [1, 2, 3].

A unry of activity, in particular, has been related to the problem of option price valuation. Options are contracts which assure to its owner the right to negotiate (i.e., to sell or to buy) for an agreed value, an arbitrary

nancial asset (stocks of som e com pany, for instance) at a future date. The writer of the option contract, on the other hand, is assumed to com ply with the option ow ner's decision on the expiry date. Options are a crucial element in the modern markets, since they can be used, as convincingly shown by Black and Scholes [4], to reduce portfolio risk.

The Black-Scholes theory of option pricing is a closed analytical form ulation where risk vanishes via the procedure of dynam ical (also called \delta") hedging, applied to what one might call \log-norm all cient markets". Realmarkets, however, exhibit strong deviations of lognorm ality in the statistical uctuations of stock index returns, and are only approximately e cient.

O ur aim in this letter is to introduce a theoretical framework for option pricing which is general enough to account for important features of real markets. We also perform empirical tests, taking the London market as the arena where theory and facts can be compared. M ore concretely, we report in this work observational results concerning options of european style, based on the FT SE 100 index, denoted from now on as  $S_t$  [5].

To start with, we note, in fact, that the returns of the FTSE 100 index do not follow log-norm al statistics for sm all time horizons. We have considered a nancial time series of 242993 m inutes (roughly, two years) ending on 17th november, 2005. The probability distribution function (pdf) (!) of the returns given by !  $\ln (S_t=S_{t-1})$ ,

taken at one m inute intervals is shown in F ig 1. We verify that the Student t-distribution with three degrees of freedom conjectured by Borland [6] provides a good t to the data. A slightly better thing is produced if a sm ooth gaussian envelope is introduced to truncate the distribution at the far tails, viz:

$$(!) / \frac{1}{(a^2 + !^2)^2} \exp(\frac{!^2}{2b^2}) : \qquad (1)$$

FIG. 1: The pdf of returns evaluated for one m inute time horizons for the FTSE 100 index, along a period of about two years, ending on 11/17/2005. The solid line is the truncated Student t-distribution given by Eq. (1), with a = 2.3  $10^{-4}$  and b=a = 5.

A time-dependent family of self-similar T sallis distributions [7],  $(!;t) / (a^2(t) + !^2)^{1=(1-q)}$ , with variance

 $a^2$  (t) /  $t^{2=(3 q)}$ , was previously considered in option price modeling [6]. The time parameter t refers here to the time horizon of return uctuations, while q ' 1:5 is indicated from empirical pdfs. Even though suggestive results were found by Borland for a set of option prices taken from the realm arket, the time dependence of the variance  $a^2$  (t) disagrees with observations. It is wellestablished that the variance of return uctuations grows linearly with the time horizon within a certain range of days, and that the return pdfs are not self-sim ilar (there is a crossover to the log-norm alpro le). A further di culty has to do with the matching between the theoretical and observed volatilities. As reported in Ref. [6], for instance, the model volatility needed to reproduce the volatility sm iles of options based on the S& P 500 futures in june 2001 is set to 32:95% . However, as the analysis of the S& P 500 futures tim e series reveals, the actual volatility for that period was considerably smaller, close to 14:5% [8].

The essential reason for the speci c choice of a(t) in the above pdf is that it is related to a form erly known Langevin equation, which leads, on its turn, to a partial di erential equation for option prices. An alternative and m ore general point of view { to be pursued here { is not to advance, a priori, any hypothesis on the form of the return pdfs, while still dealing with a Langevin description of return uctuations.

Le us assume, therefore, that at time t=0 the underlying index is  $S_0$  and that its subsequent values are given by

$$S_t = S_0 \exp[t + x(t)];$$
 (2)

where x(t) is a dynamic random variable described, at time t, by an arbitrary pdf (x;t). We take x = 0 at t = 0.0 bserve that it is a simple exercise to write, from Eq. (2), the form alexpression for the pdf of returns with time horizon t, in a statistically stationary regime.

As an inverse problem, we are now interested to da = f(x;t), so that (x;t) be derived from the Langevin equation

$$\frac{dx}{dt} = f(x;t) \quad (t); \qquad (3)$$

where (t) is a random gaussian eld, de ned by h (t) i = 0 and h (t) ( $\ell$ )  $i = (t \ \ell$ ). A ctually, it is not di cult to compute f (x;t) as a functional of (x;t). We just write down the Fokker-Planck equation that is satis ed by (x;t)  $\beta$ ],

$$\frac{\theta}{\theta t} = \frac{1}{2} \frac{\theta^2}{\theta x^2} (f^2); \qquad (4)$$

to obtain, from the direct integration of (4),

$$[f(\mathbf{x};t)]^{2} = \frac{2}{(\mathbf{x};t)} \int_{1}^{Z} d\mathbf{x}^{0} d\mathbf{x}^{0} d\mathbf{x}^{0} \frac{\theta}{\theta t} (\mathbf{x}^{0};t) : (5)$$

The function f(x;t) is an important element in the option pricing problem, within the dynamical hedging strategy of investment. Considering the writer of an option contract who owns a number of the underlying asset, dynamical hedging, a concept rstly introduced by Black and Scholes, consists of de ning option prices V = V(S;t) as a function of the asset's value S and time t, so that = @V=@S, and the \minimal" portfolio

(S;t) S (S;t) V (S;t) is in posed to evolve according to the market risk-free interest rate r, as if (S;t) were converted to cash and safely deposited into an interest earning bank account. Under these conditions, a straightfow and application of Ito's lemma leads to the generalized B lack-Scholes equation,

$$\frac{\theta}{\theta t} V = rV + rS \frac{\theta}{\theta S} V + \frac{1}{2} f^2 S^2 \frac{\theta^2}{\theta S^2} V = 0 : \quad (6)$$

E xact solutions of this equation m ay be given in terms of statistical averages. For the case of call options which expire at time t , we get

$$V = \exp[r(t + t)]h (S \exp(t) = E)(S \exp(t) = E)i;$$
(7)

where  $= \frac{K_t}{t} dt(\underline{x} + r - \frac{1}{2}f^2)$  is a random variable described by some pdf = (;T), with T = t the being the option's time to expire. One may check, by direct substitution, that (7) solves, in fact, Eq. (6). The putcall parity relation is also satisfied by our solution, as any bona de option pricing form ula should do. It is worth noting that the case where f(x;t) is constant corresponds to the standard B lack-Scholes problem.

In order to develop analytical expressions for V (S;t), let Z () = hexp (i) i be the characteristic function associated to the distribution (;T). We may write, without bss of generality, Z () =  $Z_a$  (; 0) $Z_a$  (0; ) $Z_b$  (), where  $Z_a$  (<sub>1</sub>; <sub>2</sub>) = hexp [i <sub>1</sub> ( $_t$  dt(<u>x</u> + r)  $_2\frac{1}{2}$   $_t$  dtf<sup>2</sup>)]i. It is clear that Z<sub>a</sub> and Z<sub>b</sub> can be computed, in principle, with the help of the cumulant expansion. However, a non-perturbative analysism ay be readily addressed when one realizes that  $Z_a$  (;0) is nothing but the characteristic funtion of (x;T). The remaining problem, then, is to evaluate the corrections due to  $Z_a(0; )$  and  $Z_b()$  (they are in fact small in realistic cases). Up to  $\underset{R_t}{\text{rst order in}}$ , we have  $Z_b() = 1$  and  $Z_a(0;) = 1$   $i\frac{R_t}{2} t dthf^2 i$ . Using (5), we get  $Z_a(0; ) = 1$   $i_{-2}h[x^2(t) x^2(t)]i'$ expf  $i_{-2}h[x^2(t) x^2(t)]$ ig. Taking now, as a phenom enological input, that the volatility depends linearly on the time horizon T, we write  $Z_a(0; )' \exp[i_2 \frac{2}{0}T]$ , which in plies that

$$(;T) = (rT + {}_{0}^{2}T = 2;T):$$
 (8)

It is not di cult to verify that the above expression is exact when f(x;t) = 0, and leads to an option pricing form ula previously proposed by M atacz [10], which was based on heuristic arguments. However, the usefulness

of the approximation given by Eq. (8) is restricted to the cases where the far tails of (x;t) decay faster than  $jxj^1 \exp(jx)$ , because of the exponential factor in Eq. (7).

In a more empirically oriented approach, we may attempt to compute V (S;t), as de ned by Eq. (), from realorM onte C arb simulated nancial time series, without having any information on the pdf (x;t). Since we would not be entitled to use Eq. (5) anymore, it is necessary to rewrite the expression  $_{t}^{R_{t}}$  dtf<sup>2</sup> that appears in the de nition of in terms of known quantities. Observing that Ito's lemma yields, from Eq. (3),

$$e^{x} \frac{d}{dt}e^{x} = x + \frac{1}{2}f^{2}$$
; (9)

we write, for a time series of tem poral length T = N ,

$$\frac{1}{2} \int_{t}^{Z_{t}} dt f^{2} (x_{N} x_{0}) N \exp(x_{i+1} x_{i})];$$

$$= 0$$
(10)

where  $x_i = x (i + t)$ . Substituting (10) into (7), we d, then, a pragmatical form ula to work with num erical sam – ples.

FIG. 2: Volatility sm iles related to the option values taken on (a) 02dec05 and (b) 09dec05 (see Table I). The black and white dots refer to EP and MKT premium s, respectively.

A stochastic process  $fx_ig$  was generated from a highfrequency time series of the logarithm s of FTSE 100 index, ln (S<sub>i</sub>), consisting of 242990 m inutes ending on 17th novem ber, 2005 (it is essentially the same data used to establish the histogram depicted in Fig.1). The series was

TABLE III: Comparison between Black-Scholes (BS) and M onte-C arlo simulations based on the Student t-distribution (ST). We use the modeling parameters (S; ;r) reported in Table I. Expiry date is 16dec05 as well.

partitioned into 94 pieces of 2585 m inutes each (roughly one nancial week). In each one of these pieces, the market drift parameter was determined by the least squares method. Then, according to Eq. (2), we de ne  $x_{i+1}$   $x_i = \ln (S_{i+1} = S_i)$ . W e have found that Xi in proved results are obtained if extrem ely intense uctuations are removed from the series, since they are likely to correspond to the market's reaction to unexpected events (we have checked this assumption in a number of cases). Once the standard deviation for the whole series is  $_0 = 2.6$  10  $^4$  , we removed from the series the uctuations given by  $j \times j > 3$  10<sup>3</sup> 10 <sub>0</sub> (only 144 elements were taken out from the  $x_i$  series). A sequence of 3000 sam ples, separated in time by one hour translations, was used in each option price evaluation. It turns out that the sam ples are related to a period of reasonably well-behaved volatility (it uctuates around som e stable value). W e also introduce a phenom enological factor q, so that trials with series of di erent m ean volatilities are obtained in a simple way from the mapping  $x_i \mid q \mid x_i$ .

W e have computed in this way option prem ium s based on the London FTSE 100 index (with = 1 m inute). The results are shown in Tables I and II, where market (MKT) and evaluated prices (EP) are compared. In the tables, NA stands for \not available" data, while X stands for prices we did not evaluate; the values between brackets correspond to instances where the time series extension was not large enough to get accurate predictions. The daily closing values of the FTSE 100 index, S, the gfactors, and the m odel and observed m ean volatilities ( and , respectively) are reported in the table captions. The num erical errors in the EP columns vary typically from 0:5% for the larger prem ium s to 10% for the sm aller ones. When comparing the market and numerical results, one should keep in m ind the existence of the usual bid-ask spread of option prices.

A s clearly shown in Fig. 2, we have been able to m odel

volatility smiles which are in good agreement with the m arket ones. The remarkable feature of these results is that implied volatilities can be obtained from a single model volatility, , which is in fact close to the actual observed market volatility .

W e have, along sim ilar lines, evaluated option prices through M onte C arb sim ulations. The stochastic process f xig is now generated as independent events from the Student t-distribution with three-degrees of freedom . As shown in Table III, the Black-Scholes (BS) and Student tdistribution-based evaluations (ST) yield relatively close (and not good) answers for option prices. It is important to note the num erical results do not di er too m uch if M atacz's analytical option price form ula is used with convolutions of the truncated Student t-distribution, Eq. (1), once the log-norm alretum pdf cores get large enough for time horizons of a few days.

To sum m arize, we have provided strong evidence, from the empirical analysis of non-gaussian market data, that the combination of delta-hedging strategy and suitable Langevin m odeling allow s one to com pute option prem ium s w ith reasonable con dence, from the use of Eqs. (7)and (10). On the other hand, we have found that both the M onte C arlo simulations and the delta-hedging analytical fram ework based on fat-tailed distributions and tim e-independent volatilities which are close to the observed averaged values, fail to predict realm arket option prices. Our results point out that e cient option pricing analytical tools have necessarily to dealw ith the stochastic nature of volatility uctuations, a main distinctive aspect of nancial time series.

The author thanks M arco M oriconi for a critical reading of the manuscript. This work has been partially supported by FAPERJ.
