#### Abstract

W hen an asym m etric bubble collapses it generally produces a wellde ned high velocity jet. This is rem arkable because one $m$ ight expect such a collapse to produce a com plex or chaotic ow rather than an ordered one. I present a dim ensional argum ent for the ubiquity of jets from collapsing bubbles, and model the aspherical collapse of a bubble $w$ ith pieces of $R$ ayleigh's solution for spherical collapse and its cylindrical analogue. $T$ his $m$ odelexplains the ubiquity of jet form ation in aspherical collapse, and predicts the shape and velocity pro le of the resulting jet. These predictions $m$ ay be tested in the laboratory or by num erical calculation. A n application to solid spall is suggested.

## I. Introduction

The aspherical collapse of a bubble or void in a liquid produces a fast liquid jet ${ }^{1}{ }^{3}$. This phenom enon is rem arkably robust. It occurs for axially sym $m$ etric collapse of a single bubble near a solid w all or free surface. It occurs in at least som e of the bubbles produced in turbulent cavitating ow, but it is apparently unknown whether it occurs in all such bubbles, or what initial conditions are required.

Jet production is of great technological im portance. Jets are the $m$ eans by which cavitation dam ages nearby solid surfaces ${ }^{2 ; 4}$. Fast jets are deliberately produced by shaped charges ${ }^{5}$, and are rem arkably insensitive to their geom etry. Jets launch droplets from the sea surface ${ }^{6}$, producing $m$ arine salt aerosols. Jets are also responsible for the sensitization of explosives by microscopic bubbles ${ }^{7}{ }^{8}$.

There are a num ber of elegant analytic theories of jet production ${ }^{9}{ }^{11}$. N um erical calculations of axisym $m$ etric aspherical collapse ${ }^{12} \quad 15$ readily show jet form ation. H ow ever successfil these theories and calculations, they do not explain the robustness of the phenom enon and the applicability of these som ew hat idealized results to the bubbles encountered in practice: jets form from the collapse of bubbles which cannot be expected to be sym $m$ etric, and despite the best $e$ orts of engineers to prevent them. A qualitative $m$ odel of jet form ation $m$ ight help understand why it is so ubiquitous.

A sim ple analytic solution is possible for the collapse of a spheroidalbubble. Laplace's equation for the velocity potential separates in spheroidal coordinates ${ }^{16}$ (either prolate or oblate) (u;v; ). A spheroidalbubble is characterized by $=(u)$. It is readily seen by explicit di erentiation that its aspect ratio does not change during its collapse, so that if it rem ains spheroidal it will not produce a jet. M ore generally, no bubble which possesses inversion sym m etry will produce a jet, because any jet would stagnate against its mirror im age jet upon convergence. In fact, inversion sym $m$ etry $m$ ay be broken by the presence of a nearby wall or free surface, or by the grow th of sm all perturbations, and initially spherical or ellipsoidal bubbles do produce jets, as is seen in the num erical calculations.

## II. W hy Jets

A dim ensional argum ent can be $m$ ade for the ubiquity of jet form ation. Suppose the collapsing bubble is initially approxim ately spherical, so that at each point on its surface the tw o radii of curvature are com parable to each other and have roughly the sam em agnitude everyw here on the surface. Then only one quantity with the dim ensions of length (the approxim ate initial radius) is de ned. The only other independent dim ensional quantity is a velocity $c \quad(P=)^{1=2}$, where is the liquid density and $P$ the pressure at in nity. If viscosity and surface tension are neglected and the bubble contains no uncondensable gas there are also no characteristic dim ensionless num bers. For som e geom etries (spheres and spheroids, for exam ple) void collapse willbe self-sim ilar, $m$ aintaining the shape of the bubble.

At a speci ed elapsed timeta new length scale ct is de ned which is characteristic of that tim e, but not of the collapse process as a whole. If the bubble shape is to undergo a qualitative change (such as the form ation of a jet) its description would require at least one additional characteristic length $r^{0}(t)$, typically a radius of curvature. If $r^{0}(t)$ is tim $e^{-}$ dependent it m ay be constructed from ct. H ow ever, it is not possible to de ne an additional constant $r_{0}^{0}$ which is characteristic of the process as a whole (rather than a speci ctime), because the initial conditions do not contain enough inform ation; a lim iting, nalor tim eindependent radius of curvature would be an exam ple of such a forbidden param eter.

A spherical vacuum bubble satis es this condition by collapsing to a point, rather than reversing its collapse at a nite radius ff. If a collapsing void has an asym $m$ etry or a dimple or pimple on its wall and does not preserve its proportions, the asym $m$ etry $m$ ust either decay or shanpen until the ow becom es singular and a cusp form s. For this reason a grow ing asym $m$ etry will generally lead to a jet which develops singular conditions at its tip. This argum ent for jet form ation also applies to bubbles near walls or other bubbles (usually the source of asym $m$ etry), if all the initial characteristic lengths are com parable to the collapsing bubble's initial radius.

## III. M odel

I suggest the follow ing m odelof jet production: Ifthe tw o principal radiiofcurvature of a bubble are nearly equal, asphericalcollapse is locally approxim ated by sphericalcollapse, as described by a modi ed version ${ }^{17}$ of R ayleigh's classic theory ${ }^{18}$, while if the principal radii of curvature are very di erent it is locally approxim ated by cylindrical collapse. C ollapse of a nite angular range of a cylinder produces a sheet jet (as in a linear shaped charge ${ }^{5}$ ) rather than the linear jet produced by axially sym $m$ etric collapse of an entire cylinder ${ }^{13}$.

In this elem entary model the di erence between spherical (or cylindrical) collapse and that of an aspherical bubble is that in the aspherical case di erent portions of the surface converge to the center at di erent tim es. Instead ofm eeting an oppositely directed convergent ow from the other side, and stagnating against it in a centralpressure peak (as happens in inversion-sym $m$ etric collapse), in the asym $m$ etric case the uid which converges rst forms a uid jet which then penetrates the unconverged uid approaching from the opposite side. Jets are likely to be produced by the collapse of any bubble w ithout inversion sym $m$ etry.

This model is applicable not only to bubbles and to voids in explosives, but also to hem ispherical shaped charges. It is not applicable to conical shaped charges, which are not locally spherical, and whose convergence is not even locally cylindrical at their apices; a cone de nes no quantities w ith the dim ensions of length, and contains a geom etric singularity in its in itialstate.

In the frequently encountered case of a bubble near a plane solid boundary or free surface the collapse is azim uthally sym $m$ etric about the surface norm al, and the spherical solution is applicable to the fastest-collapsing portion of the bubble. The R ayleigh solution for the velocity eld surrounding a sphericalvoid, which has collapsed from an initialradius
$R_{0}$ to a radius $R$, is

$$
\begin{equation*}
v(r)=\frac{2}{3} \frac{P}{-} R_{0}^{3} \quad R^{3} R^{1=2} r^{2} \quad \frac{C_{3}}{r^{2}} \quad(r R) ; \tag{1}
\end{equation*}
$$

where here $P$ is the di erence betw een the pressure at in nity and the pressure in the void. In the $\lim$ it $R=R_{0}!\quad 0, C_{3}!\quad\left[2 P R{ }_{0}^{3} R=(3)\right]^{1=2}$. The distribution of $m$ ass in a spherical cap of solid angle with respect to speci c kinetic energy E $\quad z=2$ is then

$$
\begin{equation*}
\frac{d M}{d E}=\frac{{ }^{11=4}}{2^{1=4} C_{3}^{3=2}} E^{7=4} \quad E \quad \frac{C_{3}^{2}}{2 R^{4}}: \tag{2}
\end{equation*}
$$

Perform ing the integral ${ }^{R} E(M) d M \quad E^{1=4}$ dem onstrates that the kinetic energy is weakly concentrated in the uid with the greatest speci ckinetic energy; that is, at the tip of the jet.

D uring collapse of cap sphericalconvergence is assum ed (otherw ise (1) and (2) would not be applicable), but after convergence this can no longer be the case. I assum e that the uid then form s a parallel jet, w th the distribution of speed and kinetic energy given by (1) and (2). This is not required by any conservation law, even for a perfect uid, but is the sim plest possible assum ption. It is plausible for a cap of sm all because the convergent velocities are nearly parallel and are readily collim ated, and because in a narrow jet the zero pressure boundary condition along its sides ensures that any longitudinal pressure gradient and acceleration are sm all.

It is necessary to introduce an upper cuto $\mathrm{F}_{\mathrm{f}}$ ax on E (or, equivalently, a lower cuto $R_{m}$ in $=\left(P=3 E_{m} a x\right)^{1=3} R_{0}$ on $\left.R\right)$, because otherw ise all the kinetic energy would appear in an in nitesim alm ass of uid. This cuto $m$ ay be the consequence of the onset of com pressibility (surface tension and viscosity are readily veri ed to be negligible in the converged ow if they were negligible in the original bubble) or a breakdow $n$ in the geom etric assum ptions. The resulting value

$$
\begin{equation*}
\mathrm{C}_{3}=\underline{2}^{1=2}{\frac{\mathrm{PR}}{0}{ }_{0}^{3}}^{2=3} \mathrm{E}_{\mathrm{m}}^{1=6} \tag{3}
\end{equation*}
$$

is fortunately only weakly dependent on $\mathrm{E}_{\mathrm{m}}$ ax ; the lim iting speed $\mathrm{V}_{\mathrm{m}}$ ax $\quad\left(2 \mathrm{E}_{\mathrm{m}} \text { ax }=\right)^{1=2}$. For water, plausible values (assum ing com pressibility is the lim iting mechanism) are $E_{m a x} 210^{10} \mathrm{erg} / \mathrm{cm}^{3}$ and $\mathrm{V}_{\mathrm{m}}$ ax $210^{5} \mathrm{am} / \mathrm{sec} ; \mathrm{R}_{\mathrm{m}}$ in $0: 026 \mathrm{R}_{0}$ if $\mathrm{P}=1 \mathrm{bar}$. The high velocity tip of the jet $m$ ay be di cult to observe, because it is eroded by residual gas in the bubble and by m ore slow ly converging uid on the opposite side of the bubble.

A s the jet propagates it stretches. If its convergence occurs instantaneously and at one point then its radius $s$ at a distance ' from that point at a tim e tafter convergence is

$$
\begin{equation*}
\mathrm{s}=\overline{2}_{2}^{1=2} \frac{\mathrm{C}_{3}^{3=4} \mathrm{t}^{3=4}}{\sqrt{5=4}} \quad\left(\curlyvee<\mathrm{v}_{\mathrm{m} \text { ax }} \mathrm{t}\right) ; \tag{4}
\end{equation*}
$$

which is obtained by changing variables in (2) from $E$ to $v$ and using ' $=v t$; the jet term inates at $\quad \mathrm{V}_{\mathrm{m}}$ ax t . This form is easier to test against laboratory data than (2) because it is easier to $m$ easure the shape of a bounding surface than a uid velocity.

In the case of cylindrical sym $m$ etry the solution analogous to (1) for the velocity eld is

$$
\begin{equation*}
v(r)=\frac{P}{-\left(_{0}^{2} \quad R^{2}\right)} \ln \left(R_{1}=R\right) \quad r^{1} \quad \frac{C_{2}}{r} \quad(r \quad R) ; \tag{5}
\end{equation*}
$$

where $R_{1}$ is an upper cuto (set by the system size) on the range of the velocity eld. In the $\lim$ 辻 $R=R_{0}!0, C_{2}!\operatorname{fP} R_{0}^{2}=\left[\ln \left(R_{1}=R\right)\right] g^{1=2}$. The distribution ofm ass $w$ ith respect to $E$ is

$$
\begin{equation*}
\frac{d M}{d E}=-\frac{{ }^{2} C_{2}^{2}}{4} \quad E \quad \frac{C_{2}^{2}}{2 R^{2}} \quad ; \tag{6}
\end{equation*}
$$

where is the arc of the collapsing portion of a cylinder. The integral ${ }^{R} E(M) d M \ln E$, so that kinetic energy is evenly distributed per decade across the speci cenergy spectrum . A $n$ upper cuto $\mathrm{F}_{\mathrm{n}}$ ax and a low er cuto $\mathrm{R}_{\mathrm{m}}$ in are again required as $\mathrm{R}!0$. The thickness h of a collapsed sheet is found, in analogy to (4),

$$
\begin{equation*}
h=\frac{C_{2}^{2} t^{2}}{B} \quad\left(r<v_{m a x} t\right): \tag{7}
\end{equation*}
$$

C ollapsing bubbles whose rate of convergence is interm ediate betw een cylindrical and spherical in their region of fastest collapse $m$ ay perhaps be param etrized by solutions of
non-integer dim ension $n$. T he velocity eld is

$$
\begin{equation*}
v(r)=\frac{2(n \quad 2)}{n} \frac{P}{\left(R_{0}^{n} \quad R^{n}\right) R^{n} 2^{1=2} r^{1} n \quad \frac{C_{n}}{r^{n} 1} \quad(r \quad R): ~: ~} \tag{8}
\end{equation*}
$$

The resulting $m$ ass distribution in the $\lim$ it $R=R_{0}!0$ is

$$
\left.\frac{d M}{d E} / \bar{E}^{(3 n \quad 2)=\left(2 n^{2}\right.}\right) C_{n}^{n=\left(\begin{array}{ll}
n & 1 \tag{9}
\end{array}\right) \quad E \quad \frac{C_{n}^{2}}{\left.2 R^{2(n} 1\right)} ; ~}
$$

where the constant of proportionality includes the contributing fraction of the $n$-sphere. The shape of the jet's cross-section depends on the details of convergence, but with the previous assum ptions its cross-sectional area A is

$$
\begin{equation*}
A / \frac{\left.t^{n=(n ~} 1\right)}{(2 n \quad 1)=\left(n^{n} 1\right)} \quad\left(r<V_{m} \text { axt }\right): \tag{10}
\end{equation*}
$$

This $m$ ay be tted to em pirical data or to num erical calculation to determ ine an ective dim ension n of the convergent ow .

## IV . D iscussion

T he m odels of jets discussed in this paper can be tested by com parison to com puted jets and to experim ent. The $m$ ost general form is (10), which introduces the non-integer dim ensionality param eter $n$, but which reduces to the spherical results (1) \{ (4) for $n=3$ and to the cylindrical results (5) $\{$ (7) for $n=2$.

A related problem is the production of $m$ icroscopic particulate spall upon shock reection from a solid surface, at tensile loads insu cient to dismupt the bulk. This is related to uid jet form ation, because both processes involve concentration of energy. Solid spall is a $m$ ore com plicated phenom enon because it involves $m$ aterials $w$ ith nite strength, $a$ variety of heterogeneities in the bulk and at the surface, and (usually) anisotropy. It is unclear w hether spall is produced by elastic stress concentration at comers (surface scratches, cracks, grain boundaries, etc.), follow ed by brittle fracture, or by plastic ow convergence and jetting at surface scratches and cracks. The latter process would resemble jet form ation upon the collapse of a bubble, w the curved solid surface taking the place of the
bubble surface. The plastic ow and brittle fracture hypotheses $m$ ay be distinguished by $m$ icroscopic exam ination of the surfaces of spall fragm ents. It $m$ ight also be inform ative to do experim ents on spall from shocked liquid surfaces and am onphous substances, which $m$ ay be prepared w ithout surface im perfections or heterogeneities in the bulk.

I thank K. C ase and F.J.D yson for discussions and the $O$ of $N$ aval Research, DARPA and NSF AST 94-16904 for support.
