#### Abstract

T he decay pattem of aftershocks in the so-called 'coherent-noise' m odels $\mathbb{M}$.E.J. N ew m an and K. Sneppen, Phys. Rev.E54, 6226 (1996)] is studied in detail. A nalytical and num erical results show that the probability to nd a large event at tim et after an initialm a jor event decreases ast for $s m$ all $t$, $w$ ith the exponent ranging from 0 to values well above 1. This is in contrast to Sneppen und Newm an, who stated that the exponent is about 1, independent of the $m$ icroscopic details of the sim ulation. N um erical sim ulations of an extended model [C.W ike, T. M artinetz, Phys. Rev.E56, 7128 (1997)] show that the power-law is only a generic feature of the original dynam ics and does not necessarily appear in a m ore general context. $F$ inally, the im plications of the results to the $m$ odeling ofearthquakes are discussed.

## 1 Introduction

D ynam ical system swhich display scale-free behaviour have attracted much interest in recent years. Equilibrium therm odynam ic system s do only exhibit scale-free behaviour for a subset of the param eter space ofm easure zero (the critical values of the param eters). $N$ evertheless, in nature scale-free system s can be found in abundant variety (earthquakes [1], avalanches in rice-piles [2], infected people in epidem ics [3], jam sin Intemet tra c [4], extinction events in $B$ iology [5], life-tim es of species [6] and $m$ any $m$ ore. See also [7] and the references therein). The origin of this abundance lies probably in the broad variety of system s far from equilibrium that can be found in nature. W ith the onset of non-equilibrium dynam ics, new mechanism scom e into play which seem to m ake scale-free behaviour a generic feature ofm any system s . H ow ever, unlike equilibrium therm odynam ics, where scaling is thoroughly understood $[8,9]$, for non-equilibrium dynam icalsystem s there does not yet exist a uni ed theory of scale-fire phenom ena (apart from non-equilibrium phase transitions). There
do, how ever, exist several distinct classes of system s w ith generic scale-free dynam ic.

O ne of the rst ideas to explain scale-free behaviour in a large class of dynam ical system s was the notion of Selfo rganized C riticality (SO C ) proposed by Bak, Tang and $W$ iesenfeld in 1987 [10,11]. They proposed that œertain system s w ith local interactions can, under the in uence of a sm all, localdriving force, self-organize into a state $w$ ith diverging correlation length and therefore scalefree behaviour. This state is sim ilar to the ordinary critical state that arises at the critical point in phase transitions, although no ne-tuning of param eters is necessary to reach it. Since 1987 literally thousands of research papers have been w ritten conceming SO C (for a review see [12]), and $m$ any di erent dynam ical system s have been called SO C (e.g. [13\{17]), m ostly just because they showed som e power-law distributed activity pattems. R ecently [18] it has becom e clear that several SO C m odels (sandpile models, forest- re m odels) can be understood in term s of ordinary nonequilibrium critical phenom ena (like e.g. [19]). D riving rate and dissipation act as critical param eters. The critical value, how ever, is 0 . Therefore, it su ces to choose a sm all driving rate and dissipation to ne-tune the system to the critical point, and this choice is usually im plicit in the de nition of the m odel.

Scale-free behaviour does not, how ever, depend crucially on som e sort of criticalphenom enon. A sim plem ultiplicative stochastic process (M SP ) of the form

$$
\begin{equation*}
x(t+1)=a(t) x(t)+b(t) ; \tag{1}
\end{equation*}
$$

where $\mathrm{a}(\mathrm{t})$ and $\mathrm{b}(\mathrm{t})$ are random variables, can produce a random variable $x(t)$ w th a probability-density function (pdf) w th power-law tail [21\{25]. In processes of this type, the power-law appears under relatively weak conditions on the pdf's of a ( $t$ ) and b( $(\mathrm{t}$, thus m aking the interm ittend behaviour a generic feature of such m odels. Applications of Eq. (1) can be found in population dynam ics with extemal souroes [25], epidem ics [3], price volatility in econom ics [26], and others.

A nother class of $m$ odels $w$ th a very simple and robust $m$ echanism to produce scale-free behaviour has been introduced recently by New m an and Sneppen [27]. T hese so called 'coherent-noise' m odels consist of a large array of 'agents' which are foroed to reorganize under extemally im posed stress. In their sim plest form, coherent-noise $m$ odels do not have any interactions betw een the agents they consist of, and hence, certainly do not display criticallity. N evertheless, these m odels show a pow er-law distribution of the reorganization events w th a wide range of di erent exponents [28], depending on the specialim plem entation of the basic $m$ echanism .M oreover they display power-law distributions in several other quantities, e.g., the life-tim e distribution of the agents. These $m$ odels have been used to study earthquakes [27], rice piles [27], and biological extinction [29\{32].

C oherent-noise m odels have a feature that usually is not present in SO C m odels and is never present in M SP's, which is the existence of aftershocks. In $m$ ost coherent-noise $m$ odels the probability for a big event to occur is very $m$ uch increased im m ediately after a previous big event and then decays with a power-law. This leads to a fractal pattem of events that are followed by sm aller ones which them selves are follow ed by even sm aller ones and so on. In m ost SOC m odels and all M SP's, on the contrary, the state of the system is statistically identical before and after a big event. T herefore in these m odels no aftershocks are visible.

The existence or non-existence of aftershock events should be easily testable in natural system s . T his could provide a m eans to decide what m echanism is $m$ ost likely to be the cause for scale-free behaviour in di erent situations [28]. But to achieve this it is im portant to have a deep understanding of the decaypattem of the aftershock events.

The goalof the present paper is to investigate in detail the aftershock dynam ics of coherent-noise $m$ odels. $W$ e concentrate $m$ ainly on the original $m$ odel introduced by N ew m an and Sneppen because there can be obtained several analytical results. W e nd a power-law decrease in tim e of the aftershocks' probability to appear, as has been found already in [28]. But unlike stated there, we can show that the exponent does indeed depend on the $m$ icroscopic details of the sim ulation. We nd a w ide range of exponents, from 0 to values well above 1, whereas in [28] the authors report only the value 1.

## 2 The m odel

W e will now describe the m odel introduced by Newm an and Sneppen [27]. The system consists of $N$ units or 'agents'. Every agent i has a threshold $x_{i}$ again extemal stress. T he thresholds are initially chosen at random from some probability distribution $p_{\text {thresh }}(x)$. The dynam ics of the system is as follow $s$ :
(1) A stress is drawn from some distribution $p_{\text {stress }}()$. All agents $w$ th $\mathrm{x}_{\mathrm{i}}$ are given new random thresholds, again from the distribution $\mathrm{p}_{\text {thresh }}(\mathrm{x})$.
(2) A sm all fraction $f$ of the agents is selected at random and also given new thresholds.
(3) The next tim e-step begins w ith (i).

Step (ii) is necessary to prevent the $m$ odel from grinding to a halt. W ithout this random reorganization the thresholds of the agents w ould after som e tim e be well above the $m$ ean of the stress distribution and average stress could not hit any agents anym ore.

The $m$ ost com $m$ on choices for the threshold and stress distributions are a uniform threshold distribution and som e stress distribution that is falling 0 quickly, like the exponential or the gaussian distribution. U nder these conditions (w ith reasonably small f) it is guaranteed that the distribution of reorganization events that arises through the dynam ics of the system will be a power-law.

There are several possibilities to extend the $m$ odel to $m$ ake it $m$ ore general, w ithout loss of the basic features. T wo extensions that have been studied by Sneppen and Newm an [28] are
a lattioe version where the agents are put on a lattioe and with every agent hit by stress its nearest neighbours undergo reorganization, even if their threshold is above the current stress level.
a 'm ulti-trait' version where, instead of a single stress, there are $M$ di erent types of stress, i.e. the stress becom es a M -dim ensional vector. A ccordingly, every agent has a vector of thresholds $x_{i}$. An agent has to $m$ ove in this $m$ odel whenever at least one of the com ponents of the threshold vector is exceeded by the corresponding com ponent of the stress vector.

A n extension that is especially im portant for the application of coherent noise $m$ odels to biologicalevolution and the dynam ics ofm ass extinctions has been studied recently by $W$ ilke and $M$ artinetz [32]. In biology it is not a good assum ption to keep the num ber of agents (in this case species) constant in tim e. Rather, species which go extinct should be rem oved, and there should be a steady regrow th of new species. In a generalized $m$ odel, the system size is allowed to vary. A gents that are hit by stress are rem oved from the system com pletely, but at the end of every tim e-step a number N of new agents is introduced into the system. H ere N is a function of the actualsystem size N , the $m$ axim al system size $N_{m a x}$ and som e grow th rate $g$. $W$ ilke and $M$ artinetz have studied in detail the function

$$
\begin{equation*}
\left.N=\frac{N_{\max } e^{g}}{N_{\max }+N\left(e^{g}\right.} 1\right) \quad N ; \tag{2}
\end{equation*}
$$

which resembles logistic grow th. In the lim it $g$ ! 1 their $m$ odel reduces to the original one by N ew m an and Sneppen. In the follow ing we will refer to the originalm odel as the 'in nite-grow th version' and to the m odel introduced by W ilke and M artinetz as the ' nite-grow th version'.

3 A nalysis of the aftershock structure

W ebase our analysis of the aftershock structure on them eassurem ent-procedure proposed by Sneppen and $N$ ewm an [28]. They drew a histogram ofall the tim es
whenever an event of size som e constant s happened after an initial event of size som e constant s, for allevents s.C onsequently, we m easure the frequency of events larger than $s_{1}$ occuring exactly $t$ tim e-steps after an initial event larger than $s_{0}$, for all tim es $t$. This $m$ eans that we consider sequences of events in the afterm ath of initial large events. N orm alized appropriately, our $m$ easurem ent gives just the probability to nd an event $s$ at timetafter som e arbitrarily chosen event $s$. For this to $m$ ake sense in the context of aftershocks we usually have $s_{0}>s_{1}$. Throughout the rest of this paper we use $s_{0}$ and $s_{1}$ as peroentage of the $m$ axim al system size. $T$ herefore a value $s_{0}=1$ for exam ple $m$ eans that we are looking for intialevents whid span the whole system.

W e will denote the probability to nd an event of size $s$ s at timetafter a previous large event by $\mathrm{P}_{\mathrm{t}}(\mathrm{s} \quad \mathrm{s})$. In order to keep the notation sim ple we om it the constant $s_{0}$. It will be clear from the context what $s_{0}$ we use in di erent situations. $N$ ote that $P_{t}(s)$ is not a probability distribution, but a function of time $t$. Therefore, every increase or decrease of $\left.P_{t}(s) s\right)$ in time will indicate correlations betw een the initial event and the subsequent aftershocks. Fort! 1 we expect all correlations to disappear, and hence $\left.P_{t}(s) s\right)$ to tend tow ards a constant.

It is possible to obtain som e analytical results about the probability $P_{t}(s \quad s)$ if we restrict ourself to the $m$ odelw ith in nite grow th and a special choice for the threshold and stress distributions. If not indicated otherw ise, throughout the rest of this section we assum e $p_{\text {thresh }}(x)$ to be uniform between 0 and 1 , and the stress distribution to be exponential: $p_{\text {stress }}()=\exp (\quad=)=$.

Furtherm ore, we focus on the case $s_{0}=1$. That $m$ eans that we are looking at the events in the afterm ath of an initial event of 'in nite' size, an event that spans the whole system. This is a reasonable situation because we use a uniform threshold distribution. In this case there is a nite probability to generate a stress which exceedes the largest threshold, thus causing the w hole system to reorganize. For som e of the exam ples presented in Section 4 the probability to nd an in nite event is even higher than $10{ }^{5}$. This probability can be considered relatively large in a system where one has to do about $10^{6} \quad 18^{9}$ tim e-steps to get a good statistics.

### 3.1 M ean- eld solution

The exact way to calculate $P_{t}(s \quad s)$ is the follow ing. O ne has to com pute the distribution $t_{1}^{1 ;}{ }^{2}::: \% t^{1}(x)$ which is the distribution that arises if after the big event at tim et=0asequence of stress values $1 ; 2 ;::: ; t_{1}$ is generated
during the follow ing tim e steps. T hen the equation

$$
\begin{gathered}
x_{t}\left(1 ; 2 \text { 它::; t } 1 ; S_{1}\right) \\
t^{1 ;}{ }_{1}^{2} ;:: ; t^{1}\left(x^{0}\right) d x^{0}=S_{1} .
\end{gathered}
$$

has to be solved. That gives the quantity $x_{t}\left({ }_{1} ; 2 ;::: ;{ }_{\mathrm{t}} 1 ; \mathrm{S}_{1}\right)$, the threshold that has to be exceeded by the stress at tim e to generate an event
s.From the stress distribution one can then calculate the corresponding probability $P_{t}{ }^{1 ;}{ }^{2 ;: \% ; t^{1}}$ (s s).F inally the average over allpossible sequences 1; $2 ;::: ;{ }_{t}$ has to be taken to end up $w$ th the exact solution for $P_{t}(s)$. O bviously there is no hope doing this analytically.

Instead of the exact solution for $P_{t}(s \quad s)$ we can calculate a mean-eld solution ifw e average over allpossible sequences 1 ; $2 ;::: ;{ }_{t} 1$ before we solve Eq. (3). $N$ ote that in this context, the notion $m$ ean- eld does not stand for the average state of the system, which does not tell us anything about aftershocks, but for the average uctuations typically found in a tim e-intervall $t$. These average uctuations are a $m$ easure for the retum to the average state, after a large event has caused a signi cant departure from it. C onsequently, them eaneld solution is tim e-dependent. For $t$ ! 1 , the tim e-dependent $m$ ean- eld threshold distribution converges to the average threshold distribution, denoted by ( $x$ ) in [28]

In A ppendix A, we show that the averaging over all uctuations in a tim e intervall of $t$ tim e-steps equals to $t$ tim es iterating the $m$ aster-equation. Therefore, to calculate the $m$ ean-eld solution for $P_{t}(s \quad s)$ we have to insert $t(x)$, the $t$-th iterate of the $m$ aster-equation, into Eq. (3).T he details of this calculation are given in A ppendix B.

### 3.2 A pproxim ation for

In this paragraph we will calculate the dependency of the exponent on $\mathrm{s}_{1}$ under the assum ption that the probability to nd aftershocks decays indeed as a power-law, i.e. that we can assum $\left.e P_{t}(s) s\right) \quad t$. A fairly simple argum ent show $s$ that for the probability $P_{t}(s \quad s)$ to decrease as a pow er-law the exponent $m$ ust be proportional to $1 \quad s$ for $s_{1}$ not too $s m$ all. A gain we concentrate on exponentially distributed stress only.

W e begin $w$ ith an approxim ation of the quantity $x_{t}\left(s_{1}\right)$, which is the average threshold at tim e tabove which a stress value must lie to trigger an event of
size $S$. In the $m$ ean- eld approxim ation, $x_{t}\left(s_{1}\right)$ is de ned by the equation

$$
\int_{0}^{x_{Q}\left(s_{1}\right)} \quad t(x) d x=s_{1}:
$$

Because $t(x)$ and $s_{1}$ are nom alized, we can rew rite this equation (again we assum e pthresh $(x)$ to be uniform between 0 and 1):

$$
\mathrm{z}_{\mathrm{x}_{\mathrm{t}}\left(\mathrm{~s}_{1}\right)}^{\mathrm{t}} \mathrm{t}(\mathrm{x}) \mathrm{dx}=1 \quad \mathrm{~s}:
$$

For them ost reasonable stress distributions the distribution of the agents $t(x)$ form $s$ a plateau in the region close to $x=1$. Therefore for su cient large $s_{1}$ we can approxim ate the integralin Eq. (5) by substituting $t(x)$ w ith its value at $x=1$, which is $t(1)$.Eq. (5) then becom es

$$
\begin{equation*}
1 \quad x_{\varepsilon}\left(s_{1}\right) \quad t(1)=1 \quad s_{1}: \tag{6}
\end{equation*}
$$

The values $t(1)$ are a function of $t$. W e de ne

$$
\begin{equation*}
R(t): t^{(1)} \tag{7}
\end{equation*}
$$

and $n d$ for $x_{t}\left(s_{1}\right)$ :

$$
\begin{equation*}
x_{t}\left(s_{1}\right)=\frac{s_{1} \quad 1+R(t)}{R(t)}: \tag{8}
\end{equation*}
$$

The probability $\left.P_{t}(s) s\right)$ now becom es

$$
\begin{equation*}
P_{t}(s \quad s)=\exp \quad \frac{x_{t}\left(s_{1}\right)}{}=\exp \quad \frac{s_{1} 1+R(t)}{R(t)}: \tag{9}
\end{equation*}
$$

The principal idea to derive a relation between and $s_{1}$ is as follow $s$. The function $R(t)$ is obviously independent of and $s_{1}$. W em ake the ansatz $P_{t}$ ( $s$ $s_{1}$ ) $\quad t$, rearrange Eq. (9) for $R(t)$ and then get a condition on and $s_{1}$ since they should cancel exactly. H ence we have to solve the equation

$$
\begin{equation*}
\text { at }=\exp \frac{s_{1} 1+R(t)}{R(t)} ; \tag{10}
\end{equation*}
$$

where $a$ is the constant of proportionality. $W$ e take the logarithm on both sides to get

$$
\begin{equation*}
\ln a \quad \ln t=\frac{s_{1} \quad 1+R(t)}{R(t)} \tag{11}
\end{equation*}
$$

and nally

$$
\begin{equation*}
R(t)=\frac{1}{1+\ln a} \ln t: \tag{12}
\end{equation*}
$$

$T$ his is of the form $c_{1}=\left(\begin{array}{ll}c_{2} & \ln t\end{array}\right)$, where

$$
\begin{equation*}
\mathrm{c}_{1}=\underline{1 \quad \mathrm{~s}} \tag{13}
\end{equation*}
$$

and

$$
\begin{equation*}
c_{2}=\underline{1+\ln a}: \tag{14}
\end{equation*}
$$

For every function of the form $c_{1}=\left(\begin{array}{ll}c_{2} & \ln t\end{array}\right)$, the constants $q$ and $c_{2}$ are unique, as can be seen if we write

$$
\begin{equation*}
\frac{C_{1}}{C_{2} \quad \ln t}=\frac{C_{1}}{\ln \frac{\exp C_{2}}{t}}: \tag{15}
\end{equation*}
$$

A change in $C_{2}$ results in a rescaling of the variable $t_{1}$ while a change in $c_{1}$ results in a rescaling of the whole function. C onsequently, neither $\mathrm{C}_{1}$ nor $\mathrm{C}_{2}$ can depend on or $s_{1}$. This can be seen as follow s. If, e.g., $\mathrm{c}_{1}$ depended on $\mathrm{s}_{1}$, then a change in $s_{1}$ w ould rescale the fiuction $R(t)$. But this function is independent of $s_{1}$ according to its de nition (Eq. (7)). Hence $c_{1} m$ ust be independent of $s_{1}$ in itself. A sim ilar argum ent holds for the variable $c_{2}$. Therefore, $s_{1}$ and m ust cancel exactly in Eq. (13). This leads to the condition

$$
\begin{equation*}
=\frac{1 \quad \mathrm{~s}}{\mathrm{C}_{1}} \quad(1 \quad \mathrm{~s}): \tag{16}
\end{equation*}
$$

Up to now we have not done any assum ptions about the size of the rst big event after which we are $m$ easuring the subsequent aftershocks. T herefore the proportionality ( 1 s) should hold in general, as long as $s_{1}$ is not too sm all. If we additionally assum e the inital event to have in nite size ( $s_{0}=1$ ) we can easily calculate the constant a in Eq. (10).T hem eaning ofthis constant is the probability to get an event of size s im m ediately after the initialbig event, as can be seen by setting $t=1$ :

$$
\begin{equation*}
P_{1}(s \quad s)=a 1 \quad=a: \tag{17}
\end{equation*}
$$

For the case $s_{0}=1$ the distribution of thresholds $O(x)$ is uniform and thus

$$
\begin{equation*}
a=\exp \left(\underline{x_{1}\left(S_{1}\right)}\right)=\exp \left(\underline{S_{1}}\right): \tag{18}
\end{equation*}
$$

W ith Eqs. (9), (10), (13), and (18) we can write the probability $\mathrm{P}_{\mathrm{t}}(\mathrm{s} \quad \mathrm{s})$ as

$$
\begin{equation*}
P_{t}(s \quad s)=e^{s_{1}=} t^{\left(1 \quad s_{1}\right)=\left(c_{1}\right)}: \tag{19}
\end{equation*}
$$

In Section 4 we will nd num erically that $\mathrm{c}_{1}=1$, and therefore $=1 \mathrm{~s}$.

### 3.3 Lim iting cases

For two lim iting cases we can deduce the behaviour of the exponent regardless of the stress distribution. W e begin $w$ th the case $s_{0}=1, s_{1}!1$. From Eq. (16) we nd that ! $0 \mathrm{as}_{1}$ ! 1 under the assum ption ofan exponential stress distribution. B ut this result is $m$ ore general. For $s_{1}=1$ the probability $P_{t}(\mathrm{~s} \quad \mathrm{~s})$ reads sim ply

$$
\mathrm{P}_{\mathrm{t}}(\mathrm{~s} \quad 1)={ }_{1}^{\mathrm{s}^{1}} \mathrm{dx} \mathrm{p}_{\text {stress }}(\mathrm{x})
$$

and hence is constant in time. C onsequently we have $=0$ for any stress distribution. From continuity we have ! 0 as $s_{1}$ ! 1.

A sim ilar argum ent holds when either $s_{0}$ or $s_{1}$ approaches 0 . For $s_{0}=0$, the probability $P_{t}(s \quad s)$ reduces to the $m$ ean probability to nd an event of size $s \quad s$. Hence $=0$. For $s_{1}=0$, the probability $P_{t}(s \quad s)$ becom es 1, because an event of size at least zero can be found in every tim e step. H ence also in this case $=0$. From continuity we have again ! 0 as either $s_{0}!0$ or $s_{1}$ ! 0 .

4 N um erical results

In the previous section we have focused on the behaviour of the system in the afterm ath of an in nite event. This situation is not only analytically tractable, but it also m akes it sim pler to obtain good num erical results. If we want to $m$ easure the probability to nd aftershocks follow ing events exceeding som e nite but large $s_{0}$, we have to wait a long tim e for every single $m$ easurem ent since the num ber of those large events vanishesw ith a pow er-law .T hism akes it hard to get a good statistics within a reasonable am ount of com puting tim e. If, on the other hand, we focus on the situation of an in nite intial event, we can sim ply initialize the agents $w$ ith the uniform threshold distribution, take the $m$ easurem ent up to the tim e $t$ we are interested in and repeat this procedure until the desired accuracy is reached. U nless stated otherw ise, the results reported below have been obtained in this way, and w ith exponentially distributed stress.
$T$ he $t-$ th iteration of the $m$ aster-equation should give exactly the average distribution of the agent's thresholds at tim e t. In Fig. 1 it can be seen that this
is indeed the case. The points, which represent sim ulation results, lie exactly on the solid lines, which stem from the exact analytical calculation.

Them ean- eld approxim ation for $P_{t}(S \quad s)$ should be valid if the agent's distribution at tim et does not uctuate too much about the average distribution $t(x)$. Since there are $m$ any $m$ ore $s m$ all events than big ones the uctuations should occur prim arily in the region of sm all $x$. C onsequently we expect the $m$ ean-eld approxim ation to be valid for large $s_{1}$, and to break down for sm all $s_{1}$. Fig. 2 show $s$ that already for $m$ oderately large $s_{1}$ the $m$ ean-eld approxim ation captures the behaviour of $\left.P_{t}(s) s\right)$, w ith a slight tendency to underestim ate the results of the $m$ easurem ent. $N$ ote that the statistics is becom ing worse with increasing $s_{1}$ due to the rapidly decreasing probability to nd any events of size $s$ for large $s_{1}$.

In $F$ ig. 3 a m easurem ent of the probability $P_{t}(s \quad s)$ is presented for a num ber of sim ulations w ith di erent values of the param eter $f$. A $s$ it can be seen, the param eter $f$ does not a ect the exponent of the power-law, but lim its the region where scaling can be observed. N ote the di erence between the e ect seen here and typical cut o e ects in the theory of phase transitions. The quantity $P_{t}(s \quad s)$ is not a probability distribution, but a tim e dependent probability, which tends tow ards a constant fort! 1 . Therefore, we do not se an exponential decrease at the cut o tim escale. Instead, the probability $P_{t}(s \quad s)$ levels out to the tim e-averaged value $P$ ( $\left.s \quad s\right)$, which is the average probability to nd events of size $s \mathrm{~s}$.

In section 32 we showed that 1 s, under the condition of a su ciently large $s_{1}$. Sim ulations indicate that the constant of proportionality is just 1 , which $m$ eans the constant $c_{1}$ in Eq. (13) equals ${ }^{1}$. If this hypothesis is true, Eq. (19) becom es

$$
\begin{equation*}
P_{t}(s \quad s)=e^{s_{1}=} t^{\left(1 s_{1}\right)}: \tag{21}
\end{equation*}
$$

$T$ his $m$ eans, a rescaling of the form

$$
\begin{equation*}
P_{\text {scaled }}={\left.\frac{P_{t}(S \quad S}{}\right)^{e^{s_{1}=}}}^{1=\left(s_{1} 1\right)} \tag{22}
\end{equation*}
$$

should yield a functional dependency $P_{\text {scaled }}(t)=t{ }^{1} . F$ ig. 4 show $s$ the results of such a rescaling for di erent and $s_{1}$. All the data-points lie exactly on top of each other in the region where the statistics is good enough (about $t<100$ ). W e nd that for up to 0.1, Eq. (21) is very accurate for $s_{1}$ between about 0.1 and 1.W th sm aller , Eq. (21) holds even form uch $s m$ aller $s_{1}$.

The situation becom es $m$ ore com plicated if we study the sequence of aftershocks caused by an initial event of nite size. The probability to nd an event of size $s \quad s$ after som $e$ initial event of size $s \quad \$$ decreases with a
power-law, but the exponent is not a sim ple function of $s_{1}$. R ather, it depends on $s_{0}$ as well. In F ig. 6 we have displayed the results of a m easurem ent w ith $s_{1}=3 \quad 10^{4}$ and severaldi erent $s_{0}$, ranging from $5 \quad 10^{4}$ to 1 . The curve for $s_{0}=1$ has been obtained $w$ th the $m$ ethod described at the beginning of this section. We nd that the aftershocks' decay pattem for $s_{0}<1$ continuously approaches the one for $s_{0}=1$ as $s_{0}!1$. This show sthat it is indeed justi ed to study the system in the afterm ath of an in nite initial event and then to extrapolate to nite but large initialevents. $N$ ote that in $F$ ig. $6, s_{1}$ is so sm all that Eq. (21) does not hold anym ore.

Sneppen and N ewm an have argued that the decay pattem of the aftershocks is independent of the respective stress distribution. O ur results do not support that. D espite the fact that the exponent of the power-law seem $s$ to be independent of in the case of exponential stress, as we could show above, the exponent is not independent of the functional dependency of the stress distribution. If we im pose, for exam ple, gaussian stress w ith $m$ ean 0 and variance , we nd ( $F$ ig.5) exponents larger than 1 form oderate $s_{1}$. W e do event nd a qualitatively new behaviour of the system. The exponent is getting larger $w$ th increasing $s_{1}$, as opposed to the exponent getting sm aller for exponential stress. $O f$ course, this can only be true for interm ediate $s_{1}$. U ltim ately, we must have ! 0 for $s_{1}$ ! 1 .
$F$ inally, we present som e results about system $s w$ ith nite grow th. In these system s , there exists som e com petitive dynam ics betw een the rem oval of agents w ith sm all thresholds through stress and their regrow th. A ftershocks appear in the in nite grow th $m$ odel because the reorganization event leaves a larger proportion of agents in the region ofsm allthresholds, thus increasing the probability for succeding large events. In the nite grow th version, on the contrary, this can happen only if the regrow th is faster than the constant rem oval of agents with sm all thresholds through average stress. If the regrow th is too slow, the probability to nd large events actually is decreased in the after$m$ ath of an initial large event. The intenplay between these two $m$ echanism $s$ is show $n$ in $F$ ig. 7. The regrow th of species is done according to Eq. (2). For a sm allgrow th rate $g$, the probability to nd aftershocks is reduced signi cantly, and it aproaches the equilibrium value after about 100 tim e-steps. $W$ ith larger $g$, the probability $P_{t}(s \quad s)$ increases in tim e untila $m$ axim um wellabove the equilibrium level is reached, and then decreases again. The maxim um $m$ oves to the left to earlier tim es $t w$ ith increasing $g . W$ hen $g$ is so large that the $m$ axim um coincides with the post intial event, the original power-law is restored. $N$ ote that, as in the case of in nite grow th, the $m$ easurem ent depends on the choige of the param eters $s_{0}$ and $s_{1}$. C onsequently, with a di erent set of param eters the curves w ill look di erent, and the m axim um w ill appear at a di erent tim e. $N$ evertheless, we nd that the qualitative behaviour is not altered if we change $s_{0}$ or $s_{1}$.

Instead of logistic grow th, we can also think oflinear grow th, i.e. $\mathrm{N}=\mathrm{gN}$ max, where $g$ is again the grow th rate. In order to keep the system nite, we stop the regrow th whenever the system size N exceedes the m axim al system size $\mathrm{N}_{\mathrm{max}}$. In such a system, aftershodks can be seen for much sm aller grow th rates ( F ig. 8). N ote that apart from the grow th rate, all other settings are identical in $F$ ig. 7 and $F$ ig. 8. Linear grow th re lls the system much quicker than logistic grow th w ith the sam e grow th rate. T herefore the tim e intervall in which aftershocks are suppressed is $m$ uch shorter for linear grow th.

5 C onclusion

W e could show in the present paper that the decay pattem of the aftershock events depends on the details of the $m$ easurem ent. A though the qualitative features rem ain the same for di erent param eters $s_{0}$ and $s_{1}$ (e.g. a powerlaw decrease in the in nite-grow th version), the quantitative features vary to a large extend. The exponent of the power-law is signi cantly a ected by an alteration of $s_{0}$ or $s_{1}$. Therefore the $m$ easurem ent-procedure proposed by Sneppen and Newm an can reveal the com plex structure of aftershock-events only if the change of the $m$ easured decay pattem $w$ th varying $s_{0}$ and $s_{1}$ is recorded over a reasonably large intervall of di erent values. T his should be considered in a possible com parison between the aftershocks' decay pattem from a model and from experim ental data. A $m$ ore in-depth analysis could probably be achieved w ith the form alism ofm ultifractality (see e.g. [33]).

W e found the aftershocks' decay pattem to vary $w$ ith di erent stress distributions. This is in clear contrast to Sneppen and Newm an. They reported a power-law w ith exponent $t 1$ for the in nite grow th version, independent of the respective stress distribution they used. T he question rem ains why Sneppen and Newm an measured such an exponent in all their sim ulations. The answer to this lies in the fact that they did only sim ulations with $\mathrm{s}_{0}<1$. For the reasons explained at the beginning of Section 4, under this condition one has to choose a relatively sm all $\mathrm{s}_{0}$, and accordingly, a very sm all $\mathrm{s}_{1}$. This causes the $m$ easurem ent alm ost inevitably to lie in the interm ediate region between the lim iting cases of Sec. 3.3. In this region, for the $m$ ost reasonable stress distributions and a large array of di erent values for $s_{0}$ and $s_{1}$, we nd indeed exponents around 1.

The application of coherent-noise $m$ odels to earthquakes has been discussed in [27]. T w o very im portant observations regarding earthquakes, the $G$ utenberg$R$ ichter law $[34,35]$ and $O m$ ori's law [36], can be explained easily with a coherent-noise $m$ odel. The $G$ utenberg $R$ idhter law states that earthquake $m$ agnitudes are distributed according to a pow er-law. O m ori's law , which interests us here, is a sim ilar statem ent for the aftershocks' decay pattem of earth-
quakes. In the data from real earthquakes, the num ber of events larger than a certain $m$ agnitude $M_{1}$ decreases ast in the afterm ath ofa large initialearthquake. C onsequently, we can only apply in nite-grow th coherent-noise m odels to earthquakes. B ut this is certainly no draw back, since we expect the thresholds against m ovem ent at various points along a fault (w ith which we identify the agents of the coherent-noise m odel) to reorganize alm ost instantaneously during an earthquake.

The exponent is not universal, but can vary signi cantly, e.g., in [1] from
$=0: 80$ to $=1: 58$. This would cause problem $s$ if the statem ent was true that for coherent-noise models we have 1. But as we could show above, the exponent can assum e values in the observed range, depending on the stress distribution, the size of the initialevent, and the low er cut-o (which we called $M_{1}$ for earthquakes and $S_{1}$ throughout the rest of the paper).

For a further com parison, it should be interesting to study the dependency of the exponent on variation of the cut-o $M_{1}$ in realdata. W e are only aw are of a single work where that has been done [37]. Interestingly, the authors do not nd a clear dependency $\left(M_{1}\right)$.N evertheless, this is not a strong evidence against coherent-noise m odels, since the aftershock series analysed in [37] consists $m$ ainly of very large earthquakes $w$ th $m$ agnitude betw een 6 and about 8 , which does not allow a su cient variation of M ${ }_{1}$. Statistical variations in the exponent are probably larger for this aftershodk series than the possible variations because of an assum ed $\left(M_{1}\right)$ dependency.
$N$ um erical sim ulations of the nite-grow th version have revealed a $m$ uch $m$ ore com plex structure of aftershodk events than present in the in nite-grow th version. T he com petition betw een regrow th of agents and agent rem oval through reorganization events leads to a pattem where the probability to nd events after an initial large event is suppressed for short tim es, enhanced for inter$m$ ediate tim es and then falls o to the badkground level for long tim es. This observation can be im portant for the application of coherent-noise models to biological extinction. It $m$ ight be possible to identify a tim e of reduced and a tim e of enhanced extinction activity in the afterm ath of a m ass extinction event in the fossil record. This would be a good indication for biological extinction to be dom inated by extemal in uences (coherent-noise point of view ) rather than by coevolution (SO C point of view).

A cknow ledgem ents

W e thank Mark N ewm an for interesting conversations about coherent-noise m odels.

In this appendix we are interested in the average state a coherent-noise system willbe found in several tim e-steps after som e initial state w ith threshold distribution $t_{0}(x)$. O ur calculations $w i l l$ lead to a rederivation of the $m$ asterequation for coherent-noise system $s$. A though a m aster-equation has already been given for the in nitegrow th version and has been generalized to the nite-grow th version, these $m$ aster-equations have not been derived in a stringent way, but just have been wrilten down intuitively. O ur calculation will con m the m ain term s of the previously used equations, but we will nd an additional correcting term that becom es im portant for large f.
$C$ onsider the case of in nite grow th. At tim e $t_{0}$ the threshold-distribution $m$ ay be $t_{0}(x)$.W e construct the distribution $t_{0}+1(x)$, whidn is the distribution that arises at time to $+\frac{1}{R}$ if a stress is generated at time to. A stress will cause a proportion $s={ }_{0} d x t_{0}(x)$ of the agents to $m$ ove. $W$ e have to distinguish two regions. For $x<$, all agents are rem oved. T hen they are redistributed according to $s p_{\text {thresh }}(x)$. A $s m$ all fraction $f$ of the agents is then mutated, which results in

$$
t_{0}+1(x)=\left(\begin{array}{ll}
1 & f \tag{A.1}
\end{array}\right) s p_{\text {thresh }}(x)+f_{\text {thresh }}(x) ; x<\quad:
$$

For $x$, the redistribution of the agents gives $t_{0}(x)+s p_{\text {thresh }}(x)$.W ith the subsequent m utation we obtain:

$$
\mathrm{t}_{0}+1(\mathrm{x})=\left(\begin{array}{ll}
1 & \mathrm{f} \tag{A2}
\end{array}\right) \quad \mathrm{t}_{0}(\mathrm{x})+\mathrm{s} \mathrm{p}_{\text {thresh }}(\mathrm{x})+\mathrm{f}_{\text {thresh }}(\mathrm{x}) \quad ; \mathrm{x} \quad:
$$

W e take the average over to get the distribution $t_{0}+1(x)$ that w illon average be found one tim e-step after $t_{0}(x)$ :

$$
\begin{align*}
& 21 \\
& t_{0}+1(x)=d_{0} p_{\text {stress }}()_{t_{0}+1}(x) \\
& \begin{array}{ll}
0 & Z \\
Z^{1}
\end{array} \\
& =\int_{0} d p_{\text {stress }}() p_{\text {thresh }}(x)\left(\begin{array}{ll}
1 & f
\end{array}\right) \quad t_{0}\left(x^{0}\right) d x^{0}+f \\
& \mathrm{Z}^{\mathrm{x}} \\
& +d \mathrm{P}_{\text {stress }}()_{\mathrm{t}_{0}}(\mathrm{X})(1 \quad \mathrm{f}) \\
& 0 \\
& =p_{\text {thresh }}(x) f+(1 \\
& \text { f) } d p_{\text {stress }}()^{Z} t_{0}\left(x^{0}\right) d x^{0} \\
& +\quad t_{0}(x)(1 \quad f)(1 \quad \text { Rove }(x)): \tag{A3}
\end{align*}
$$

$H$ ere, $p_{m}$ ove ( $x$ ) is the probability for an agent $w$ ith threshold $x$ to get hit
by stress, viz. $p_{m}$ ove $(x)=\frac{R_{1}}{x} d x^{0} p_{\text {stress }}\left(x^{0}\right)$. To proceed further we have to interchange $\mathrm{R}_{\mathrm{R}}$ the order of integration in the rem aining double integral. $N$ ote that ${ }_{0}^{R_{1}} d \quad{ }_{0} d x^{0}=R_{0}^{R_{1}} d x^{0}{ }_{x^{0}} d$, and therefore

$$
\begin{align*}
& 27 \\
& t_{0}+1(x)=p_{\text {thresh }}(x) f+\left(\begin{array}{ll}
1 & f
\end{array}\right) d x^{0} d p_{\text {stress }}()_{t_{0}}\left(x^{0}\right) \\
& +t_{0}(x)(1 \quad \text { f) }(1 \quad \text { Pove }(x)) \\
& 2 \\
& =p_{\text {thresh }}(x) f+\left(\begin{array}{ll}
1 & f
\end{array}\right) d x^{0} t_{0}\left(x^{0}\right) p_{m} \text { ove }\left(x^{0}\right) \\
& +t_{0}(x)(1 \quad f)(1 \quad \operatorname{Rove}(x)) \\
& 2 \\
& =p_{\text {thresh }}(x) d x^{0} f+\left(\begin{array}{ll}
1 & f
\end{array}\right) P_{\text {din ove }}\left(x^{0}\right) \quad t_{0}\left(x^{0}\right) \\
& +\quad t_{0}(x)(1 \quad \text { f) (1 Pove }(x)) \tag{A.4}
\end{align*}
$$

W e are thus led to the $m$ aster-equation

$$
\begin{equation*}
\mathrm{t}(\mathrm{x})=\quad \mathrm{f} \quad \mathrm{P}_{\text {ove }}(\mathrm{x})+\mathrm{f} \mathrm{p}_{\mathrm{m} \text { ove }}(\mathrm{x}) \quad \mathrm{t}(\mathrm{x})+\mathrm{A} \mathrm{P}_{\text {thresh }}(\mathrm{x}) ; \tag{A.5}
\end{equation*}
$$

where $A$ is the norm alization constant $\begin{gathered}R_{1} \\ 0\end{gathered} d x^{0}\left(f+\left(\begin{array}{ll}1 & f\end{array}\right)\right.$ pove $\left.\left(x^{0}\right)\right) t\left(x^{0}\right)$.

W e notice the appearance of the term $f_{m}$ ove $(x)$ which was not present in the $m$ aster-equation used by Sneppen and $N$ ew $m$ an. The term arises if one takes into account the fact that the agents which are hit by stress get new thresholds before the $m$ utation takes place. Therefore every agent $w$ th threshold $x$ has the probability $f_{m}$ ove $(x)$ to get tw o new thresholds in one tim e-step. But obviously this is exactly the sam e as geting only one new threshold. C onsequently, the term $\mathrm{fp}_{\mathrm{m}}$ ove $(\mathrm{x})$ has to be present to avoid double-counting of those agents which are hit both by stress and by mutation. Nevertheless, this term does not a ect the scaling behaviour of the system, because the derivation of the event size distribution in [28] has been done under the assum ption $f 1$.

Eq. (A.4) gives the average state of the system one tim e-step after the initial state $t_{0}(x)$. If we are interested in the average state $t$ tim e-steps after the initial state, we have to repeat the calculations in Eqs. (A.1)-(A.4) t tim es. Since all averages in these calculations can be taken independently, this is exactly the sam e as tim es iterating the $m$ aster-equation (A.5).

B C alculation of the $m$ ean- eld solution.

W e assum e that at tim et=0 a big event takes place and produces the distribution $o(x)$. Ifwe apply them aster-equation (A.5) ttim es to this distribution $o(x)$, we will end up with a distribution $t(x)$ that tells us the average state of the system at tim et after the big event.

In the follow ing we will use

$$
T(x):=\left(\begin{array}{lll}
1 & f \tag{B.1}
\end{array}\right)(1 \quad \text { Pove }(x))
$$

and w rite $A_{t}$ for the norm alization constant that appears on the right-hand side of Eq. (A.5) at timet. The average distribution at time then becom es

$$
\begin{align*}
t(x) & =T(x) t 1(x)+A_{t} P_{\text {thresh }}(x) \\
& =T^{t}(x) 0(x)+x_{k=1}^{x^{t}} T^{t}(x) A_{k} P_{\text {thresh }}(x): \tag{B2}
\end{align*}
$$

W e integrate both sides of Eq. (B 2) and nd a recursion relation for the constants $\mathrm{A}_{\mathrm{t}}$ :

$$
\begin{equation*}
A_{t}=1 \quad T^{\mathrm{Z}}(x) 0(x) d x+{ }_{k=1}^{x^{1}} A_{k}^{z} T^{t k}(x) p_{\text {thresh }}(x) d x: \tag{B3}
\end{equation*}
$$

A $1 l$ integrals can be calculated analytically for a special choige of the threshold and stress distributions. A s threshold distribution, we choose the uniform distribution $p_{\text {thresh }}(x)=1 ; 0 \quad x<1$, and as stress distribution we choose the exponential distribution $\mathrm{p}_{\text {stress }}()=\exp (\quad=)=$. Furtherm ore, we as sume that the initial event was so large as to span the whole system, i.e. $o(x)=1 ; 0 \quad x<1$.

U nder the above assum ptions there is basically one integral that appears in Eq. (B 3), which is

and Eq. (B 3) becom es

$$
\begin{equation*}
A_{t}=1 \quad E_{k=1}^{X^{1}} I_{k} A_{k}: \tag{B.5}
\end{equation*}
$$

$W$ th the aid of the binom ial expansion $(1+a)^{n}={ }^{P}{\underset{k}{n}=0}_{n}^{n} a^{k}$ we nd

W e are now in the position to calculate the probability that an event of size $s \quad s$ occurs at tim e $t$ after the initial big event. The $m$ inim al stress value m in that su ces on average to generate such an event is the solution to the equation

$$
\quad \frac{\mathrm{I}_{\mathrm{i}} \text { in }}{\mathrm{dx}} \mathrm{t}(\mathrm{x})=\mathrm{S}_{1} \text { : }
$$

The corresponding probability is $P_{t}(s \quad s)=\exp (\quad m$ in $=) . W e$ invert this expression and insert it into Eq. (B.7).T he resulting equation determ ines the probability $\left.P_{t}(s) s\right)$ :

$$
\int_{0}^{\left.\ln _{Z_{t}(s}^{s} s_{1}\right)} \quad d x_{t}(x)=s_{1}:
$$

The integrals that appear after inserting $t(x)$ into the above equation are very sim ilar to the integral $I_{n}$ de ned in Eq. (B.4). $W$ e de ne

$$
J_{n}(P):=\int_{0}^{\mathrm{Zn}^{\ln P}} \mathrm{~T}^{\mathrm{n}}(\mathrm{x}) \mathrm{dx}:
$$

$T$ his integral can be taken in the same fashion as the calculation of $I_{n}$ in Eq. (B.6).Wend

$$
\left.J_{n}(P)=\begin{array}{lll}
1 & f
\end{array}\right)^{n} \quad \ln P+\underbrace{X^{n}}_{k=1} n_{k}^{!} \frac{\left(1^{k}\right.}{k}\left(\begin{array}{ll}
1 & P \tag{B.10}
\end{array}\right):
$$

Eq. (B.8) now becom es

$$
J_{t} P_{t}\left(\begin{array}{ll}
s & s
\end{array}\right)+X_{k=1}^{t} J_{t k} P_{t}\left(\begin{array}{ll}
s & s \tag{B.11}
\end{array}\right) A_{k}=s_{1}:
$$

A 11 the quantities which appear in this equation are given above in analytic form . Therefore solving Eq. (B .11) is sim ply a problem of root- nding.W ith a
com puter-algebra program such asM athem atica, the recursion relation for the constants $A_{k}$ as well as the sum $s$ that appear in the quantities $I_{n}$ and $J_{n}(P)$ can be evaluated analytically if we restrict ourselves to $m$ oderate $t$. $T$ hen the only num erical calculation involved in the com putation of $\left.P_{t}(s) s\right)$ is the calculation of the root of Eq. (B.11).

Fig. 2. The probability $P_{t}\left(s \quad s_{1}\right)$ for $=0: 1$ and $f=10{ }^{5}$. The solid lines show the $m$ ean- eld approxim ation, the dots show the sim ulation results.

Fig. 3. The probability $P_{t}\left(s \quad s_{1}\right)$ in sim ulations with $=0: 1, s_{1}=0: 06$ and several di erent values for $f$ (from bottom to top: $f=10^{4}, f=10^{3}, f=10^{2}$, $\mathrm{f}=10^{1}$ ) .

Fig. 4. T he rescaled probability $\mathrm{P}_{\mathrm{t}}$ ( s
$\left.s_{1}\right)$. The solid line show s a $t^{1}$ decrease for com parison.

$F$ ig. 5. The probability $P_{t}\left(s \quad S_{1}\right)$ after an initial in nite event in a sim ulation w th gaussian stress. P aram eters are $=0: 1, \mathrm{f}=10^{5}$, and, from bottom to top, $s_{1}=0: 2, s_{1}=0: 1, s_{1}=0: 02$. In a sim ulation $w$ ith gaussian stress the distribution is getting steeper $w$ ith increasing $s_{1}$.

Fig. 6. The probability $P_{t}\left(s \quad s_{1}\right)$ after an initial nite event. Param eters are $=0: 05, \mathrm{f}=10^{5}, \mathrm{~s}_{1}=310^{4}$, and, from bottom to top, $\mathrm{s}_{0}=510^{4}$, $s_{0}=210^{3}, s_{0}=0: 01, s_{0}=0: 1$ and $s_{0}=1$.

Fig. 7. The probability $P_{t}\left(s_{1} \quad 3 \quad 10{ }^{4}\right)$ after an event of size $s_{0} \quad 0: 001$ in a simulation w ith nite logistic grow th. Param eters are $=0: 5, f=10{ }^{5}$, and, from bottom to top, $\mathrm{g}=2 \quad 10^{4}, \mathrm{~g}=2 \quad 10^{3}, \mathrm{~g}=2 \quad 10^{2} \mathrm{~g}=2 \quad 10^{1}, \mathrm{~g}=10$. A pow er-law can only be seen for relatively large grow th rates. For sm all grow th-rates, the probability to nd aftershocks is reduced signi cantly.

Fig. 8. The probability $P_{t}\left(s_{1} \quad 3 \quad 10{ }^{4}\right)$ after an event of size $s_{0} \quad 0: 001$ in a simulation w ith nite linear grow th. Param eters are $=0: 5, f=10{ }^{5}$, and, from bottom to top, $g=10^{5}, g=10^{4}, g=10^{3}, g=10$. A ftershocks are seen for m uch sm aller grow th rates than in the version with logistic grow th.
