Abstract

We review the quantum version of a well known problem of cryptography called coin tossing (“flipping a coin via telephone”). It can be regarded as a game where two remote players (who distrust each other) tries to generate a uniformly distributed random bit which is common to both parties. The only resource they can use to perform this task is a classical or quantum communication channel. In this paper we provide a general overview over such coin tossing protocols, concerning in particular their security.

1 Introduction

Coin flipping was introduced in 1981 by Blum [2] as a solution to the following cryptographic problem (cited from [2]): “Alice and Bob want to flip a coin by telephone. (They have just divorced, live in different cities, want to decide who gets the car.) Bob would not like to tell Alice *heads* and hear Alice (at the other end of the line) say: Here it goes... I’m flipping the coin... You lost!”. Hence the basic difficulties are: both players (Alice and Bob) distrust each other, there is no trustworthy third person available and the only resource they can use is the communication channel. Although this problem sounds somewhat artificial, coin tossing is a relevant building block which appears in many cryptographic protocols.

Within classical cryptography coin tossing protocols are in general based on assumptions about the complexity of certain computational tasks like factoring of large integers, which are unproven and, even worse, break down if quantum computers become available. A subset of classical cryptography which suffer from similar problems are public key cryptosystems. In this case however a solution is available in form of quantum key distribution (cf. [4] for a review) whose security is based only on the laws of quantum mechanics and no other assumptions. Hence the natural question is: Does quantum mechanics provide the same service for coin-tossing, i.e. is there a perfectly secure quantum coin-tossing protocol? Although the answer is, as we will see, “no” [8, 10], quantum coin-tossing provides a reasonable security improvement over classical schemes.

The purpose of this paper is to give an overview over this field, emphasizing in particular the game theoretic aspects, and to review some recent results. Therefore its outline is as follows: In Section 2 we give a short survey on classical and quantum systems and operations on them. This enables us in Section 3 to develop a general scheme which allows the description (and comparison) of quantum as well as classical coin tossing protocols (which are considered in Section 4), and which points out the game theoretic aspects of the subject. In Section 5 we show how many questions, in particular optimality, can be reduced to a simplified scheme where only unitary operators and von Neumann measurements are involved. A recent example is given in Section 6 and some conclusions are drawn in Section 7.

2 Systems, states and operations

In general a quantum protocol requires manipulation and exchange of quantum as well as classical data. It is therefore useful, to have a unified description for all possible types of systems and operations which we will encounter (this is only a brief survey; for a more detailed and complete presentation see [7], Ch. 2 and 3.).

- *Quantum Systems:* According to the rules of quantum mechanics, every kind of quantum systems is associated with a Hilbert space $\mathcal{H}$, which for the purpose of this article we can take as finite dimensional. The simplest quantum system has a two dimensional Hilbert space $\mathcal{H} = \mathbb{C}^2$, and is called a *qubit*, for ‘quantum bit’. The observables of the system are given by (bounded) operators. This space will be denoted by $\mathcal{B}(\mathcal{H})$. The preparations (states) are given by density operators, i.e. positive (trace-class) operators $\rho \in \mathcal{B}(\mathcal{H})$ with trace one.
- *Classical probability:* The classical analog of a state of a (finite dimensional) quantum system is a probability distribution $p_x, x \in X$ on a finite set X of “elementary events”, i.e. X describes the possible outcomes of a (classical) statistical experiment, like tossing a coin ($X = \{\text{head, number}\}$) or throwing a dice ($X = \{1, \dots, 6\}$), and p_x is the probability that the outcome x occurs. Without loss of generality we will assume in the following that $X = \{1, \dots, n\}$, $n \in \mathbb{N}$ holds. The classical information contained in p can be transformed easily into quantum information: We just have to prepare for each elementary event $x \in X$ an n -level quantum system (described by a Hilbert space $\mathcal{K}$) in a pure state $|x\rangle\langle x| \in \mathcal{B}(\mathcal{K})$, where $|x\rangle \in \mathcal{K}$, $x \in X$ denotes a distinguished orthonormal basis and $|x\rangle\langle x|$ is the projector onto $|x\rangle$. If the event $x \in X$ occurs with probability p_x , we get in this way quantum systems in the (mixed) state $\rho_p = \sum_x p_x |x\rangle\langle x|$. Each state ρ which is diagonal in the basis $|x\rangle$, i.e. $\rho = \sum_x \rho_x |x\rangle\langle x|$, can be realized in this way, provided the initial probability distribution is $\rho_x, x \in X$. Now we introduce the space $\mathcal{C}(X) \subset \mathcal{B}(\mathcal{K})$ of *diagonal* (with respect to the basis $|x\rangle$) operators on $\mathcal{K}$. According to our previous discussion we can identify the classical state space with the set of density operators in $\mathcal{C}(X)$.
- *Hybrid systems:* This point of view is very handy, if we want to describe a “hybrid system” which contains a classical part, described by the set

X and a quantum part, described by the Hilbert space $\mathcal{H}$: A state of a composite *quantum* system, consisting of two subsystems with Hilbert spaces $\mathcal{H}$ and $\mathcal{K}$, is given by a density operator ρ on the tensor product $\mathcal{H} \otimes \mathcal{K}$, i.e. $\rho \in \mathcal{B}(\mathcal{H}) \otimes \mathcal{B}(\mathcal{K})$. If one of the subsystem is classical, we only have to replace $\mathcal{B}(\mathcal{K})$ by $\mathcal{C}(X)$. Hence: states of a hybrid system can be described by density operators $\rho \in \mathcal{B}(\mathcal{H}) \otimes \mathcal{C}(X)$. It is easy to see that the elements of $\mathcal{B}(\mathcal{H}) \otimes \mathcal{C}(X)$ are operators which are block-diagonal of the form $\rho = \text{diag}(\rho_1, \dots, \rho_n)$ with $\rho_x \in \mathcal{B}(\mathcal{H})$.

Summarizing our discussion up to now we can say that all three kinds of systems can be described in terms of a Hilbert space $\mathcal{H}'$ and a linear subspace $\mathcal{A} \subset \mathcal{B}(\mathcal{H}')$ which we will call in the following the *observable algebra*¹ of the system. The simple rule we have to follow is: states are described by density operators in $\mathcal{A}$.

This point of view is very useful if we consider *channels* which transform one kind of information into another, e.g. quantum to classical or hybrid. They are most naturally described in terms of *completely positive, trace preserving* maps $T : \mathcal{A} \rightarrow \mathcal{B}$, where $\mathcal{A}$ and $\mathcal{B}$ denote the observable algebras of the input respectively output systems, and $T(\rho)$ is the state at the output side of the channel if the input system was in the state ρ . Alternatively we can consider the *dual* $T^* : \mathcal{B} \rightarrow \mathcal{A}$ of T , which is characterized by the condition $\text{tr}(T^*(A)\rho) = \text{tr}(AT(\rho))$. It describes the operation in the Heisenberg picture, while T is the Schrödinger picture representation. The following list summarizes some special cases (arising from different choices for $\mathcal{A}$ and $\mathcal{B}$) which will be relevant for the rest of the paper.

- *Quantum operations*: If $\mathcal{A} = \mathcal{B} = \mathcal{B}(\mathcal{H})$ the map T describes a quantum operation. The most simple case is just unitary time-evolution, i.e. $T(\rho) = U\rho U^*$ with unitary operator U . In general however, we have to take interactions with additional, unobservable degrees of freedom into account (“environment”) and T becomes

$$T(\rho) = \text{tr}_{\mathcal{K}}(U(\rho \otimes \rho_0)U^*), \quad (1)$$

where $\mathcal{K}$ and ρ_0 denote Hilbert space and initial state of the environment (which can be chosen to be pure) and U describes now the common evolution of both systems. It is a simple consequence of Stinespring’s theorem [14] that each quantum operation can be written this way.

- *Observables*: If $\mathcal{A}$ is quantum ($\mathcal{A} = \mathcal{B}(\mathcal{H})$) and $\mathcal{B}$ is classical ($\mathcal{B} = \mathcal{C}(X)$) we can define $T^{(x)} = T^*(|x\rangle\langle x|)$. It is easy to see that the family $T^{(x)} \in \mathcal{B}(\mathcal{H})$, $x \in X$ of operators forms a POV measure, hence T describes a (generalized) observable and $\text{tr}(\rho T^{(x)})$ is the probability to measure the value x on systems in the state $\rho \in \mathcal{B}(\mathcal{H})$. We will identify in the following the observable T with the family $T^{(x)}$ and write: “let $T = (T^{(1)}, \dots, T^{(n)})$ be an observable”. Note that this interpretation makes sense as well, if we insert for $\mathcal{A}$ a classical or hybrid algebra. Hence we can look at the corresponding observables as special cases of quantum observables.

¹This name originates from the fact that 1. $\mathcal{A}$ is in all three cases not only a linear space but a **-algebra* (i.e., closed under multiplication and adjoints) and 2. that self-adjoint (i.e. “real valued”) elements of $\mathcal{A}$ represent the (projection valued) observables of the system in question.

- *Instruments*: If we are interested in the state of the quantum system after the measurement (in addition to the measuring result), we have to consider “*Instruments*” i.e. channels with quantum input ($\mathcal{A} = \mathcal{B}(\mathcal{H})$) and hybrid output ($\mathcal{B} = \mathcal{B}(\mathcal{H}) \otimes \mathcal{C}(X)$). To each instrument T and each $x \in X$ we can associate a (non trace preserving!) quantum operation $T_x : \mathcal{B}(\mathcal{H}) \rightarrow \mathcal{B}(\mathcal{H})$ by $T_x^*(A) = T^*(A \otimes |x\rangle\langle x|)$. For each input state ρ the density operator $\text{tr}(T_x \rho)^{-1} T(\rho)$ describes the state of the system after the measurement if the value $x \in X$ was obtained, while the probability to measure $x \in X$ is given by $\text{tr}(T_x \rho)$. Hence the observable (i.e. the POV measure) associated to T is $T^{(x)} = T^*(\mathbb{I} \otimes |x\rangle\langle x|)$, $x \in X$.
- *Parameter dependent instruments*: Finally, let us consider a channel with hybrid input and output, i.e. $\mathcal{A} = \mathcal{B} = \mathcal{B}(\mathcal{H}) \otimes \mathcal{C}(X)$. For each $x \in X$ we get an instrument T_x by $T_x(\rho) = T(\rho \otimes |x\rangle\langle x|)$. Hence T describes an instrument whose behavior depends on the additional classical input data $x \in X$.

3 Coin tossing protocols

Two players (as usual called Alice and Bob) are separated from each other and want to create a random bit, which can take both possible values with equal probability. However they do not trust each other and there is no trustworthy third person who can flip the coin for them. Hence they only can exchange data until they have agreed on a value 0 or 1 or until one player is convinced that the other is cheating; in this case we will write $\emptyset$ for the corresponding outcome.

To describe such a *coin tossing protocol* mathematically, we need three observable algebras $\mathcal{A}$, $\mathcal{B}$ and $\mathcal{M}$, where $\mathcal{A}$ and $\mathcal{B}$ represent *private information*, which is only accessible by Alice and Bob respectively – Alice’s and Bob’s “notepad” – while $\mathcal{M}$ is a *public* area, which is used by both players to exchange data. We will call it in the following the “mailbox”. Each of the three algebras $\mathcal{A}$, $\mathcal{B}$ and $\mathcal{M}$ contain in general a classical and a quantum part, i.e. we have $\mathcal{A} = \mathcal{C}(X_A) \otimes \mathcal{B}(\mathcal{H}_A)$ and similar for $\mathcal{B}$ and $\mathcal{M}$. A typical choice is $\mathcal{H}_A = \mathcal{H}^{\otimes n}$ and $X_A = \mathbb{B}^m$ where $\mathcal{H} = \mathbb{C}^2$ and $\mathbb{B}$ denotes the field with two elements – in other words Alice’s notepad consists in this case of n qubits and m classical bits.

If Alice wants to send data (classical or quantum) to Bob, she has to store them in the mailbox system, where Bob can read them off in the next round. Hence each processing step of the protocol (except the first and the last one) can be described as follows: Alice (or Bob) uses her own private data and the information provided by Bob (via the mailbox) to perform some calculations. Afterwards she writes the results in part to her notepad and in part to the mailbox. An operation of this kind can be described by a completely positive map $T_A : \mathcal{A} \otimes \mathcal{M} \rightarrow \mathcal{A} \otimes \mathcal{M}$, or (if executed by Bob) by $T_B : \mathcal{M} \otimes \mathcal{B} \rightarrow \mathcal{M} \otimes \mathcal{B}$.

Based on these structures we can describe a coin tossing protocol as follows: At the beginning Alice and Bob prepare their private systems in some initial state. Alice uses in addition the mailbox system to share some information about her preparation with Bob, i.e. Alice prepares the system $\mathcal{A} \otimes \mathcal{M}$ in a (possibly entangled, or at least correlated) state $\rho_A^{(0)}$, while Bob prepares his notepad in the state $\rho_B^{(0)}$. Hence the state of the composite system becomes $\rho^{(0)} = \rho_A^{(0)} \otimes \rho_B^{(0)}$.

Figure 1: Schematic picture of a quantum coin-tossing protocol. The curly arrows stands for the flow of quantum or classical information or both.

Now Alice and Bob start to operate alternately² on the system, as described in the last paragraph, i.e. Alice in terms of operations $T_A : \mathcal{A} \otimes \mathcal{M} \rightarrow \mathcal{A} \otimes \mathcal{M}$ and Bob with $T_B : \mathcal{M} \otimes \mathcal{B} \rightarrow \mathcal{M} \otimes \mathcal{B}$. After N rounds³ the systems ends therefore in the state (cf. Figure 1)

$$\rho^{(N)} = (T_A^{(N)} \otimes \text{Id}_B)(\text{Id}_A \otimes T_B^{(N-1)}) \cdots (T_A^{(2)} \otimes \text{Id}_B)(\text{Id}_A \otimes T_B^{(1)})\rho^{(0)}, \quad (2)$$

where Id_A, Id_B are the identity maps on $\mathcal{A}$ and $\mathcal{B}$. Note that we have assumed here without loss of generality that Alice performs the first (i.e. providing the initial preparation of the mailbox) and the last step (applying the operation T_A). It is obvious how we have to change the following discussion if Bob starts the game or if N is odd. To determine the result Alice and Bob perform measurements on their notepads. The corresponding observables $E_A = (E_A^{(0)}, E_A^{(1)}, E_A^{(0)})$ and $E_B = (E_B^{(0)}, E_B^{(1)}, E_B^{(0)})$ can have the three possible outcomes $X = \{0, 1, \emptyset\}$, which we have described already above. The tuples

$$\sigma_A = (\rho_A^{(0)}; T_A^{(2)}, \dots, T_A^{(N+2)}; E_A), \quad \sigma_B = (\rho_B^{(0)}; T_B^{(1)}, \dots, T_B^{(N+1)}; E_B) \quad (3)$$

consists of all parts of the protocol Alice respectively Bob can influence. Hence we will call σ_A Alice's and σ_B Bob's strategy. The sets of all strategies of Alice respectively Bob are denoted by Σ_A and Σ_B . Note that Σ_A depends only on the algebras $\mathcal{A}$ and $\mathcal{M}$ while Σ_B depends on $\mathcal{B}$ and $\mathcal{M}$. Occasionally it is useful to emphasize this dependency (the number of rounds is kept fixed in this paper). In this case we write $\Sigma_A(\mathcal{A}, \mathcal{M})$ and $\Sigma_B(\mathcal{B}, \mathcal{M})$ instead of Σ_A and Σ_B . The probability that Alice gets the result $a \in X$ if she applies the strategy $\sigma_A \in \Sigma_A$ and Bob gets $b \in X$ with strategy $\sigma_B \in \Sigma_B$ is

$$\mathbb{P}(\sigma_A, \sigma_B; a, b) = \text{tr}[(E_A^{(a)} \otimes \mathbb{I} \otimes E_B^{(b)})\rho^{(N)}]. \quad (4)$$

²This means we are considering only turn based protocols. If special relativity, and therefore finite propagation speed for information, is taken into account it can be reasonable to consider simultaneous exchange of information; cf. e.g. [6] for details.

³Basically N is the maximal number of rounds: After $K < N$ steps Alice (Bob) can apply identity maps, i.e. $T_A^{(j)} = \text{Id}$ for $j > K$.

If both measurements in the last step yield the same result $a = b = 0$ or 1 the procedure is successful (and the outcome is a). If the results differ or if one player signals $\emptyset$ the protocol fails. As stated above we are interested in protocols which do not fail and which produce 0 and 1 with equal probability. Another crucial requirement concerns *security*: Neither Alice nor Bob should be able to improve the probabilities of the outcomes 0 or 1 by “cheating”, i.e. selecting strategies which deviate from the predefined protocol. At this point it is crucial to emphasize that we do not make any restricting assumptions about the resources Alice and Bob can use to cheat – they are potentially unlimited. This includes in particular the possibility of arbitrarily large notepads. In the next definition this is expressed by the (arbitrary) algebra $\mathcal{R}$.

Definition 3.1 *A pair of strategies $(\sigma_A, \sigma_B) \in \Sigma_A(\mathcal{A}, \mathcal{M}) \times \Sigma_B(\mathcal{B}, \mathcal{M})$ is called a (strong) coin tossing protocol with bias $\epsilon \in [0, 1/2]$ if the following conditions holds for any (finite dimensional) observable algebra $\mathcal{R}$*

1. Correctness: $\mathbb{P}(\sigma_A, \sigma_B; 0, 0) = \mathbb{P}(\sigma_A, \sigma_B; 1, 1) = \frac{1}{2}$,
2. Security against Alice: $\forall \sigma'_A \in \Sigma_A(\mathcal{R}, \mathcal{M})$ and $\forall x \in \{0, 1\}$ we have

$$\mathbb{P}(\sigma'_A, \sigma_B; x, x) \leq \frac{1}{2} + \epsilon \quad (5)$$

3. Security against Bob: $\forall \sigma'_B \in \Sigma_B(\mathcal{R}, \mathcal{M})$ and $\forall x \in \{0, 1\}$ we have

$$\mathbb{P}(\sigma_A, \sigma'_B; x, x) \leq \frac{1}{2} + \epsilon \quad (6)$$

The two security conditions in this definition imply that neither Alice nor Bob can increase the probability of the outcome 0 or 1 beyond the bound $1/2 + \epsilon$. However it is more natural to think of coin tossing as a game with payoff defined according to the following table

	Alice	Bob
a=b=0	1	0
a=b=1	0	1
other	0	0

(7)

This implies that Alice tries to increase only the probability for the outcome 0 and not for 1 while Bob tries to do the contrary, i.e. increase the probability for 1 . This motivates the following definition.

Definition 3.2 *A pair of strategies $(\sigma_A, \sigma_B) \in \Sigma_A(\mathcal{A}, \mathcal{M}) \times \Sigma_B(\mathcal{B}, \mathcal{M})$ is called a weak coin tossing protocol, if item 1 of Definition 3.1 holds, and if items 2 and 3 are replaced by*

- 2' Weak security against Alice: $\forall \sigma'_A \in \Sigma_A(\mathcal{R}, \mathcal{M})$ we have

$$\mathbb{P}(\sigma'_A, \sigma_B; 0, 0) \leq \frac{1}{2} + \epsilon, \quad (8)$$

- 3' Weak security against Bob: $\forall \sigma'_B \in \Sigma_B(\mathcal{R}, \mathcal{M})$ we have

$$\mathbb{P}(\sigma_A, \sigma'_B; 1, 1) \leq \frac{1}{2} + \epsilon. \quad (9)$$

Here $\mathcal{R}$ stands again for any finite dimensional (but arbitrarily large) observable algebra.

Good coin tossing protocols are of course those with a small bias. Hence the central question is: What is the smallest bias which we have to take into account, and how do the corresponding optimal strategies look like? To get an answer, however, is quite difficult. Up to now there are only partial results available (cf. Section 7 for a summary).

Other but related questions arises if we exploit the game theoretic nature of the problem. In this context it is reasonable to look at a whole class of quantum games, which arises from the scheme developed up to now. We only have to fix the algebras⁴ $\mathcal{A}$, $\mathcal{B}$ and $\mathcal{M}$ and to specify a payoff matrix as in Equation (7). The latter, however, has to be done carefully. If we consider instead of (7) the payoff

	Alice	Bob
a=b=0	1	-1
a=b=1	-1	1
other	0	0

(10)

we get a zero sum game, which seems at a first look very reasonable. Unfortunately it admits a very simple (and boring) optimal strategy: Bob produces always the outcome 1 on his side while Alice claims always that she has measured 0. Hence they never agree and nobody has to pay. The game from Equation (7) does not suffer from this problem, because a draw is for Alice as bad as the case $a = b = 1$ where Bob wins.

4 Classical coin tossing

Let us now add some short remarks on classical coin tossing, which is included in the general scheme just developed as a special case: We only have to choose classical algebras for $\mathcal{A}$, $\mathcal{B}$ and $\mathcal{M}$, i.e. $\mathcal{A} = \mathcal{C}(X_A)$, $\mathcal{B} = \mathcal{C}(X_B)$ and $\mathcal{M} = \mathcal{C}(X_M)$. The completely positive maps T_A and T_B describing the operations performed by Alice and Bob are in this case given by matrices of *transition probabilities* (see Sect. 3.2.3 of [7] to see how to relate these matrices to the operations T). This implies in particular that the strategies in Σ_A , Σ_B are in general *mixed strategies*. This is natural – there is of course no classical coin tossing protocol consisting of pure strategies, because it would lead always to the same result (either always 0 or always 1). However, we can decompose each mixed strategy in a unique way into a convex linear combination of pure strategies, and this can be used to show that there is no classical coin tossing protocol, which admits the kind of security contained in Definition 3.1 and 3.2.

Proposition 4.1 *There is no (weak) classical coin tossing protocol with bias $\epsilon < \frac{1}{2}$.*

⁴In contrast to the security definitions given above this means that we assume limited recourses (notepads) of Alice and Bob. This simplifies the analysis of the problem and should not be a big restriction (from the practical point of view) if the notepads are fixed but very large.

Proof. Assume a classical coin tossing protocol (σ_A, σ_B) is given. Since its outcome is by definition probabilistic, σ_A or σ_B (or both) are mixed strategies which can be decomposed (in a unique way) into pure strategies. Let us denote the sets of pure strategies appearing in this decomposition by Σ'_A, Σ'_B . Since the protocol (σ_A, σ_B) is correct, each pair $(s_A, s_B) \in \Sigma'_A \times \Sigma'_B$ leads to a valid outcome, i.e. either 0 or 1 on both sides. Hence there are two possibilities to construct a zero-sum game, either Alice wins if the outcome is 0 and Bob if it is 1 or the other way round. In both cases we get a zero-sum two-person game with perfect information, no chance moves⁵ and only two outcomes. In those games one player has a *winning strategy* (cf. Sect. 15.6, 15.7 of [15]), i.e. if she (or he) follows that strategy she wins with certainty, no matter which strategy the opponent uses. This includes in particular the case where the other player is honest and follows the protocol. If we apply this arguments to both variants of the game, we see that either one player could force both possible outcomes or one bit could be forced by both players. Both cases only fit into the definition of (weak) coin tossing if the bias is $1/2$. This proves the proposition. $\square$

Note that the proof is not applicable in the quantum case (in fact there are coin tossing protocols with bias less than $1/2$ as we will see in Section 6). One reason is that in the quantum case one does not have perfect information. E.g. if Alice sends a qubit to Bob, he does not know what qubit he got. He could perform a measurement, but if he measures in a wrong basis, he will inevitably change the qubit.

Another way to circumvent the negative result of the previous proposition is to weaken the assumption that both players can perform *any* operation on their data. A possible practical restriction which come into mind immediately is limited computational power, i.e. we can assume that no player is able to solve intractable problems like factorization of large integers in an acceptable time. Within the definition given above this means that Alice and Bob do not have access to all strategies in Σ_A and Σ_B but only to certain subsets. Of course, such additional restrictions can be imposed as well in the quantum case. To distinguish the much stronger security requirements in Definition 3.1 and 3.2 a protocol is sometimes called *unconditionally secure*, if no additional assumptions about the accessible cheating strategies are necessary (loosely speaking: the “laws of quantum mechanics” are the only restriction).

5 The unitary normal form

A special class of quantum coin tossing arises if: 1. all algebras are quantum, i.e. $\mathcal{A} = \mathcal{B}(\mathcal{H}_A)$, $\mathcal{B} = \mathcal{B}(\mathcal{H}_B)$ and $\mathcal{M} = \mathcal{B}(\mathcal{H}_M)$ with Hilbert spaces $\mathcal{H}_A$, $\mathcal{H}_B$ and $\mathcal{H}_M$; 2. the initial preparation is pure: $\rho_a = |\psi_A\rangle\langle\psi_A|$ and $|\psi_B\rangle\langle\psi_B|$ with $\psi_A \in \mathcal{H}_A \otimes \mathcal{H}_M$ and $\psi_B \in \mathcal{H}_B$; 3. the operations $T_A^{(j)}, T_B^{(k)}$ are unitarily implemented: $T_A^{(j)}(\rho) = U_A^{(j)} \rho U_A^{(j)*}$ with a unitary operator $U_A^{(j)}$ on $\mathcal{H}_A \otimes \mathcal{H}_M$ and something similar holds for Bob and 4. the observables E_A, E_B are projection valued. It is easy to see that the corresponding strategies $(\sigma_A, \sigma_B) \in \Sigma_A \times \Sigma_B$ do not admit a proper convex decomposition into other strategies. Hence we will call them in the following *pure strategies*. In contrast to the classical case it is possible

⁵That means there are no *outside* probability experiments like dice throws.

to construct correct coin tossing protocols with pure strategies. The following proposition was stated for the first time (in a less explicit way) in [9] and shows that we can replace a mixed strategy always by a pure one without losing security.

Proposition 5.1 *For each strategy $\sigma_A \in \Sigma_A(\mathcal{A}, \mathcal{M})$ with $\mathcal{A} \subset \mathcal{B}(\mathcal{H}_A)$ there is a Hilbert space $\mathcal{K}_A$ and a unitary strategy $\tilde{\sigma}_A \in \Sigma_A(\tilde{\mathcal{A}}, \mathcal{M})$ with $\mathcal{A} = \mathcal{B}(\mathcal{H}_A \otimes \mathcal{K}_A)$ such that*

$$\mathbb{P}(\sigma_A, \sigma_B; x, y) = \mathbb{P}(\sigma'_A, \sigma_B; x, y) \quad (11)$$

holds for all $\sigma_B \in \Sigma_B(\mathcal{B}, \mathcal{M})$ (with arbitrary Bob algebra $\mathcal{B}$) and all $x, y \in \{0, 1, \emptyset\}$. A similar statement holds for Bob's strategies.

Proof. We will only give a sketch of the proof here; the details are given in [3]. Note first that all observable algebras $\mathcal{A}$, $\mathcal{B}$ and $\mathcal{M}$ are linear subspaces of pure quantum algebras, i.e. $\mathcal{A} \subset \mathcal{B}(\mathcal{H}_A)$, $\mathcal{B} \subset \mathcal{B}(\mathcal{H}_B)$ and $\mathcal{M} \subset \mathcal{B}(\mathcal{H}_M)$. In addition it can be shown that Alice's operations $T_A : \mathcal{A} \otimes \mathcal{M} \rightarrow \mathcal{B}(\mathcal{H}_A) \otimes \mathcal{B}(\mathcal{H}_M)$ can be extended to a channel $\tilde{T}_A : \mathcal{B}(\mathcal{H}_A) \otimes \mathcal{B}(\mathcal{H}_M) \rightarrow \mathcal{B}(\mathcal{H}_A) \otimes \mathcal{B}(\mathcal{H}_M)$, i.e. a quantum operation [11]; something similar holds for Bob's operations. Hence we can restrict the proof to the case where all three observable algebras are quantum. Now the statement basically follows from the fact that we can find for each item in the sequence $T_A = (\rho_A; T_A^{(2)}, \dots, T_A^{(N)}; E_A)$ a “dilation”. For the operations $T_A^{(j)}$ this is just the ancilla representation given in Equation (1), i.e.

$$T_A^{(j)}(\rho) = \text{tr}_2(V^{(j)}(\rho \otimes |\phi^{(j)}\rangle\langle\phi^{(j)}|)V^{(j)*}) \quad (12)$$

with a Hilbert space $\mathcal{L}^{(j)}$, a unitary $V^{(j)}$ on $\mathcal{H}_A \otimes \mathcal{L}^{(j)}$ and a pure state $\phi^{(j)} \in \mathcal{L}^{(j)}$ (and tr_2 denotes the partial trace over $\mathcal{L}^{(j)}$). Similarly, there is a Hilbert space $\mathcal{L}^{(0)}$ and a pure state $\phi^{(0)} \in \mathcal{H}_A \otimes \mathcal{L}^{(0)}$ such that

$$\rho_A = \text{tr}_2(|\phi^{(0)}\rangle\langle\phi^{(0)}|) \quad (13)$$

holds (i.e. $\phi^{(0)}$ is the purification of ρ_A ; cf. [7] Sect. 2.2), and finally we have a Hilbert space $\mathcal{L}^{(N+2)}$, a pure state $\phi^{(N+2)}$ and a projection valued measure $F^{(0)}, F^{(1)}, F^{(\emptyset)} \in \mathcal{B}(\mathcal{H}_A \otimes \mathcal{L}^{(N+2)})$ with

$$\text{tr}(E_A^{(x)}\rho) = \text{tr}(F^{(x)}(\rho \otimes |\phi^{(N+2)}\rangle\langle\phi^{(N+2)}|)), \quad (14)$$

this is another consequence of Stinesprings theorem. Now we can define the unitary strategy $\tilde{\sigma}_A$ as follows:

$$\mathcal{K}_A = \mathcal{L}^{(0)} \otimes \mathcal{L}^{(2)} \otimes \dots \otimes \mathcal{L}^{(N)} \otimes \mathcal{L}^{(N+2)} \quad (15)$$

$$\psi_A = \phi^{(0)} \otimes \phi^{(2)} \otimes \dots \otimes \phi^{(N)} \otimes \phi^{(N+2)} \quad (16)$$

$$U_A^{(j)} = \mathbb{I}_0 \otimes \mathbb{I}_2 \otimes \dots \otimes V^{(j)} \otimes \dots \otimes \mathbb{I}_N \otimes \mathbb{I}_{N+2} \quad (17)$$

$$\tilde{E}_A^{(x)} = \mathbb{I}_0 \otimes \dots \otimes \mathbb{I}_N \otimes F^{(x)}, \quad (18)$$

where $\mathbb{I}_k$ denotes the unit operator on $\mathcal{L}^{(k)}$ and in Equation (17) we have implicitly used the canonical isomorphism between $\mathcal{H}_A \otimes \mathcal{K}_A$ and $\mathcal{L}^{(0)} \otimes \dots \otimes \mathcal{H}_A \otimes$

$\mathcal{L}^{(j)} \otimes \dots \otimes \mathcal{L}^{(N+2)}$. What remains to show, but is omitted here, is to check that this $\tilde{\sigma}_A$ satisfies Equation (11). $\square$

This result allows us to restrict many discussions to pure strategies. This is very useful for the proof of no-go theorems or for calculations of general bounds on the bias of coin-tossing protocols. This concerns in particular the results in [1] which apply, due to Proposition 5.1 immediately to the general case introduced in Section 3. Many concrete examples (cf. the next section) are however mixed protocols and to rewrite them in a pure form is not necessarily helpful.

6 A particular example

In this section we are giving a concrete example for a strong coin tossing protocol. It has a bias of $\epsilon = 0.25$ and is derived from a quantum bit commitment protocol. (a procedure related to coin tossing) given in [12]. Bit commitment is another two person protocol which is related to coin tossing. It is always possible to construct a coin tossing protocol from a bit commitment protocol but not the other way round (cf. [6]). Hence statements about the security of certain bit commitment protocols can be translated into statements about the bias of the related coin tossing protocols. This shows together with [12] that the given protocol has the claimed bias.

6.1 The protocol

In this protocol we take $\mathcal{H}_A = \mathcal{H}_M = \mathbb{C}^3$, $\mathcal{H}_B = \mathbb{C}^3 \otimes \mathbb{C}^3$ plus classical parts of at most 2 bits for each notepad. The canonical base in the Hilbert space $\mathbb{C}^3$ is denoted by $|i\rangle, i = 0, 1, 2$

1. *preparation step*: Alice throws a coin, the result is $b_A \in \{0, 1\}$, with probability $1/2$ each. She stores the result and prepares the system $\mathcal{B}(\mathcal{H}_A) \otimes \mathcal{B}(\mathcal{H}_M)$ in the state $|\psi_{b_A}\rangle\langle\psi_{b_A}|$, where $|\psi_0\rangle = \frac{1}{\sqrt{2}}(|0, 0\rangle + |1, 2\rangle)$ and $|\psi_1\rangle = \frac{1}{\sqrt{2}}(|1, 1\rangle + |0, 2\rangle)$ are orthogonal to each other. Bob throws a similar coin, and stores the result b_B . The initial preparation of his quantum part is arbitrary.
2. Bob reads the mailbox (i.e. swaps it with the second part of his Hilbert space) and sends b_B to Alice.
3. Alice receives b_B and puts her remaining quantum system into the mailbox.
4. Bob reads the mailbox and puts the system into the first slot of this quantum register.
5. *results*: The result on Alice's side is $b_A \oplus b_B$, where $\oplus$ is the addition modulo 2. Bob performs a projective measurement on his quantum system with $P^{(0)} = |\psi_0\rangle\langle\psi_0|$, $P^{(1)} = |\psi_1\rangle\langle\psi_1|$ and $P^{(\emptyset)} = \mathbb{I} - P^{(0)} - P^{(1)}$, with result b'_A . If everybody followed the protocol $b'_A = b_A$. So the result on Bob's side is $b'_A \oplus b_B$.

6.2 Possible cheating strategies

Now we will give possible cheating strategies for each party which lead to the maximal probability of achieving the preferred outcome. For simplicity we just look at the case where Alice prefers the outcome to be 0, whereas Bob prefers it to be 1, cheating strategies for the other cases are easily derivable. A cheating strategy for Bob is to try to distinguish in step 2 whether Alice has prepared $|\psi_0\rangle$ or $|\psi_1\rangle$. For this purpose he performs the measurement $(|0\rangle\langle 0|, |1\rangle\langle 1|, |2\rangle\langle 2|)$. If the result $c_B \neq 2$ (the probability for this in either case is $1/2$) he can identify $b_A = c_B$ and set $b_B = c_B \oplus 1$ to achieve the overall result 1. If $c_B = 2$ holds, he has not learned anything about b_A . In that case he just continues with the protocol and hopes for the desired result, which appears with the probability $1/2$.⁶ So the total probability for Bob to achieve the result 0 is $\frac{1}{2} + \frac{1}{2} \cdot \frac{1}{2} = \frac{3}{4}$.

A cheating strategy for Alice is to set in the initial step $b_A = 0$ and to prepare the system $\mathcal{B}(\mathcal{H}_A) \otimes \mathcal{B}(\mathcal{H}_M)$ in the state $|\widetilde{\psi}_0\rangle = \frac{1}{\sqrt{6}}(|0, 0\rangle + |0, 1\rangle + 2 \cdot |1, 2\rangle)$. Then she continues until step 3. If $b_B = 0$ she just continues with the protocol. Then the probability that in the last step Bob measures $b'_B = 0$ equals $\text{tr}(|\widetilde{\psi}_0\rangle\langle\widetilde{\psi}_0| \cdot |\psi_0\rangle\langle\psi_0|) = |\langle\psi_0|\widetilde{\psi}_0\rangle|^2 = \frac{3}{4}$. If $b_B = 1$ she first applies a unitary operator, which swaps $|0\rangle$ and $|1\rangle$, on her system before she sends it to Bob. The state on Bob's side is then $|\widetilde{\psi}_1\rangle\langle\widetilde{\psi}_1|$ with $|\widetilde{\psi}_1\rangle = \frac{1}{\sqrt{6}}(|1, 0\rangle + |1, 1\rangle + 2 \cdot |0, 2\rangle)$. The probability that Bob measures $b'_B = 1$ equals $\text{tr}(|\widetilde{\psi}_1\rangle\langle\widetilde{\psi}_1| \cdot |\psi_1\rangle\langle\psi_1|) = |\langle\psi_1|\widetilde{\psi}_1\rangle|^2 = \frac{3}{4}$. So the total probability for Alice to get the outcome 0 is $\frac{1}{2} \cdot \frac{3}{4} + \frac{1}{2} \cdot \frac{3}{4} = \frac{3}{4}$.

7 Conclusions

The previous example shows that quantum coin tossing admits, in contrast to the classical case, a nontrivial bias. However, how secure quantum coin tossing really is? Can we reach the optimal case ($\epsilon = 0$)? The answer actually is “no”, or to state it more explicitly:

Theorem 7.1 *There is no (strong or weak) coin tossing protocol with bias $\epsilon = 0$.*

This was first proven by Mayers, Salvail and Chiba-Kohno [10]. Later on Ambainis recalls the arguments in a more explicit form [1]⁷. It is still an open question, whether there exists quantum coin tossing protocols with bias arbitrarily near to zero. Ambainis also shows that a coin tossing protocol with a bias of at most ϵ must use at least $\Omega(\log \log \frac{1}{\epsilon})$ rounds of communication. Although in that paper he gives only the proof for strong coin tossing, it holds in the weak

⁶After that measurement he is no longer able to figure out which outcome occurs on Alice's side, so he just sets his outcome to 1. A similar situation occurs in the cheating strategy for Alice, but she is in neither case able to predict the outcome on Bob's side with certainty.

⁷The first attempt for a proof, given by Lo and Chau [8]. However, its validity is restricted to the case where ‘cheating’ always influences the probabilities of *both* valid outcomes. More precisely they demand that the probabilities for the outcomes 0 and 1 are equal, for any cheating strategy. This restriction is too strong, even if Alice and Bob sit together and throw a real coin one of them can always say he (she) does not accept the result (and for example refuses to pay his loss) and so put the probability for one outcome to zero while the probability for the other one and the outcome invalid are $1/2$ each.

case as well. It follows that a protocol cannot be made arbitrarily secure (i.e. have a sequence of protocols with $\epsilon \rightarrow 0$) with just increasing the amount of information exchanged in each step. The number of rounds has to go to infinity (although very slow).

The strong coin tossing protocol given in section 6 has a bias of $\epsilon = 0.25$. Another one with the same bias is given by Ambainis [1]. No strong protocol with provable smaller bias is known yet. The best known weak protocol is given by Spekkens and Rudolph [13] and has a bias of $\epsilon = \frac{1}{\sqrt{2}} - \frac{1}{2} = 0.207\dots$. Although this is still far from arbitrarily secure, it shows another distinction between classical and quantum information, as in a classical world no protocol with bias smaller than 0.5 is possible.

Another interesting topic in quantum coin tossing is the question of cheat-sensitivity, that means how much can each player increase the probability of one outcome without risking being caught cheating. For more about this cf e.g. [13] or [5].
