The paper by Lyanda-Geller (henceforth LG) [1] predicts a variation from  $\pi$  to zero of Berry's phase, which may manifest itself in a step-like current-magnetic field and current-gate voltage characteristics predicted for in-plane magnetoresistance of rings in noncentrosymmetric materials.

As a demonstrating example LG considers a spin 1/2 evolving according to the following Schrödinger equation

$$\frac{d}{dt} |\psi\rangle = i\mathbf{\Omega} \cdot \boldsymbol{\sigma} |\psi\rangle, \quad (1)$$

where  $\boldsymbol{\sigma}$  is Pauli matrix vector, and the vector  $\mathbf{\Omega}$ , which lies in the  $xy$  plane, is given by

$$\mathbf{\Omega} = (\omega_1 - \omega_0 \cos(\omega t), \omega_0 \sin(\omega t), 0), \quad (2)$$

where  $\omega, \omega_0, \omega_1$  are constants.

The state at the initial time  $t_0 = -\pi/\omega$  is assumed to be an eigenstate of the instantaneous Hamiltonian  $\mathcal{H}(t_0)$ . In general, if  $\omega_1 \neq \omega_0$  and  $\omega$  is sufficiently small the system is expected to evolve adiabatically, namely, at any later time  $t > t_0$  the state  $|\psi(t)\rangle$  will remain approximately an eigenvector of the instantaneous Hamiltonian  $\mathcal{H}(t)$ . However, LG further claims that adiabatic evolution is possible also for the case  $\omega_1 = \omega_0$  provided that  $\omega$  is sufficiently small. Consequently, LG concludes that the conductance may exhibit an abrupt jump as the parameter  $\omega_1$  is varied across the point  $\omega_1 = \omega_0$ .

In this comment we claim that, contrary to Ref. [1], the conductance steps predicted by LG are not abrupt but rather they occur along a finite range. In general,

such abrupt jumps are ruled out since the system under consideration has a linear response [2]. For a finite time interval, the change in the final state of the system cannot remain finite in the limit where the perturbation causing the change (modifying  $\omega_1$ ) approaches zero. This implies that the change in conductance occurs along a finite range.

To probability  $P_{+-}^{(t_1)}$  in Eq. (8) of Ref. [1] is calculated correctly. Indeed, for the case  $\omega_1 = \omega_0$ , the state of the system will remain nearly unchanged as the curve  $\mathbf{\Omega}(t)$  crosses the degeneracy point at the origin provided that  $\omega$  is sufficiently small. However, across this point the local eigenvectors  $|n_{\pm}\rangle$  change abruptly, namely,  $|n_{+}\rangle$  becomes  $|n_{-}\rangle$  and vice versa. Therefore,  $P_{+-}^{(t_1)}$  in Ref. [1] is not the probability to have a state mixing (Zener transition), but rather the probability *not* to have one.

To further support this conclusion we integrate Eq. 1 numerically from  $t_0 = -\pi/\omega$  to  $t_1 = \pi/\omega$  [3]. For the example depicted in Fig. 1 below we chose  $\omega_0/\omega = 1000$ . In Fig. 1 (a) the vector  $\mathbf{\Omega}(t)$  is depicted for the case  $\Delta \equiv (\omega_1 - \omega_0)/\omega_0 = 0.0015$ , and in Fig. 1 (b) the polarization vector  $\langle\psi|\boldsymbol{\sigma}|\psi\rangle$  is seen for the same value of  $\Delta$ . For this example the state at the final time  $t_1$  is nearly orthogonal to the initial state at time  $t_0$ , indicating that a state mixing (Zener transition) occurs. However for larger values of  $|\Delta|$ , adiabaticity is restored, as can be seen in Fig. 1 (c), where the numerically calculated probability of Zener transition is plotted as a function of  $\Delta$ . The same plot also shows the Berry's phase  $\gamma_B$  plotted vs.  $\Delta$ . Near  $\Delta = 0$  indeed  $\gamma_B$  changes by  $\pi$  as predicted by LG, however, this occurs along a finite range of  $\Delta$  rather than abruptly.
