#### Abstract

The continuous variable quantum key distribution has been considered to have the potential to provide high secret key rate. However, in present experimental demonstrations, the secret key can be distilled only under very small loss rates. Here, by calculating explicitly the computational complexity with the channel transmission, we show that under high loss rate it is hard to distill the secret key in present reverse reconciliation continuous variable scheme and one of its advantages, the potential of providing high secret key rate, may therefore be limited. To overcome this problem, new protocols need to be explored.

## I. INTRODUCTION

Due to its potential for providing high key rates, continuous variable (CV) quantum key distribution (QKD) has recently attracted more and more attention. Compared to single photon counting schemes, CVQKD does not require single photon sources and detectors which are technically challenging now. The CVQKD schemes typically use the quadrature amplitude of light beams as information carrier, and homodyne detection rather than photon counting. Some of these schemes use non-classical states, such as squeezed states [1, 2] or entangled states [3, 4], while others use coherent states [5, 6, 7, 8, 19, 10]. Because the squeezed states and entangled states are sensitive to losses in the quantum channel, coherent states are much more attractive for long distance transmission. Among the coherent state schemes, only the reverse reconciliation scheme (RRCVQKD) 10, 11] has the potential to provide high secret key rate over 3dB transmission losses. In addition, a table-top experimental setup at 780 nm that encodes information in the phase and amplitude of coherent states has been demonstrated 11], and recent experiments have shown the feasibility of CVQKD in optical fibers up to a distance of 55 km [12, 13], but without obtaining the final secret keys.

Unlike the single photon QKD schemes, RRCVQKD only provides the continuously distributed key elements 11] that should be converted into common binary bits. It has been proposed that this conversion can be achieved by reconciliation. Nevertheless, how to realize proper reconciliation is still an open problem. The unique existing reconciliation protocol was suggested by G. V. Assche et al [15], in which they subtly combined the sliced error correction with the quantization and optimized each step of the reconciliation. However, using this protocol, the authors of Ref. 11] were able to distill the secret key only with a small loss rate of 3.1 dB , in spite of the

[^0]very sophisticated error correction scheme they have employed. In this work, we will show that the computational complexity is one of the key hurdles for the practical implementation of RRCVQKD to provide a secret key for long distance transmission.

It has been shown that in the RRCVQKD, under the condition without excess noise [11], the signal to noise ratio (SNR) and the mutual information between Alice and Bob is certainly higher than that between Eve and Bob. Therefore through the ideal reconciliation and privacy amplification 17], Alice and Bob can share common secret keys without any information leakage. In principle, if we employ ideal reconciliation, namely, ideal quantization to convert the continuous-element into binary digits without any information loss and ideal error correction [16] to correct errors without too much information leaked to Eve, then after the reconciliation, the mutual information between Alice and Bob can be still larger than that between Eve and Bob, and consequently the secret key can be distilled through privacy amplification. However, quantitative analysis below will show that such reconciliation may be too difficult to implement.

## II. DIFFICULTY WITH RRCVQKD: AN EXAMPLE

Here, we consider a specific example of RRCVQKD. Different from single photon schemes, in RRCVQKD ones, most of the transmitted information can be known by Eve and only a very small portion of information can be kept in secret between Alice and Bob. The SNR between Alice and Bob is only slightly higher than that between Eve and Bob, and the difference of the two may be overwhelmed by the fluctuation of noise. Then, the distilling the secret key will amount to looking for a needle in a haystack. For example, let us take the line loss to be 20 dB ( 100 km fiber with an attenuation coefficient of $0.2 \mathrm{~dB} / \mathrm{km}$ ), under which the maximum secret information per key element carries is about 0.007-bit 11] (i.e., on average, 1 -bit secret key requires $1 / 0.007=143$ key el-
ements). Suppose the variance of Bob's measurement is $2 N_{0}$, where $N_{0}$ denotes the variance of the vacuum noise. Then the mutual information between Alice and Bob is 0.5 -bit and that between Eve and Bob is 0.493bit. On estimating Bob's results, the difference between Alice's and Eve's noise is about $0.01 N_{0}$, which can be calculated from Ref. 11]. To distill the secret key, at first those associated key elements should be converted into binary keys. The quantization will certainly induce information loss, although the loss can be exponentially reduced. To ensure the lost information to be less than 0.007 -bit per key element, the reconciliation should be precise enough to distinguish the slight noise change of $0.01 N_{0}$, so each key element should be converted into at least $0.5 \log _{2}\left(2 N_{0} / 0.01 N_{0}\right) \approx 4$ independent binary digits. After the conversion, Alice and Bob get 4 binary digits from one key element and the secret information contained by them will be certainly less than 0.007 -bit. Since the information per element carry is 0.5 -bit, to correct bit-errors, at least 3.5 -bit additional information should be exchanged for one key element. Then, on average, $143 \times 4=572$ binary digits contribute to less than one secret key and at the same time $143 \times 3.5 \approx 500$-bit additional information should be exchanged. Therefore, the distillation is equivalent to extracting a secret bit at least in 1072 binary digits, which is quite impractical as the error fluctuations in 572 digits may easily overwhelm the 1-bit secret key information to be distilled.

To distill the secret key, errors in quantized bits should be corrected. In theory, the errors in 572 bits require at least 500-bit additional information to correct, but the secret information carried by 572 bits is less than 1-bit and Eve can use less than 501-bit additional information to correct her errors, which means that if 501-bit error correction information is exposed there may be no secret information kept from Eve, so to correct the errors in 572 bits and to ensure corrected bits still carry secret information, the publicly exposed reconciliation information should not exceed 501-bit. Then the practical error correction should use less than $501 / 500=1+0.2 \%$ times the theoretical minimum information to correct the errors at a high bit error rate (BER). While in Ref. 20, 21], even at a BER as small as $3 \%$, this ratio can be enhanced to $120 \%$, much higher than $1+0.2 \%$, but still pose a technical challenge. In fact, to improve the practical channel information capacity is a hot topic in classical communications [18]. One major goal is to correct the errors with as little redundant information as possible. Up to now, even under ideal situations (e.g., in the standard channel, at fixed coding rate, under the optimized SNR and distinguishing the BER of each bit), present state-of-the-art error correction schemes, such as Low-Density Parity-Check (LDPC) 18] and Turbo 19] codes, may in theory only get information with low BER from 1.001 times $(0.0045 \mathrm{~dB})$ of the theoretical minimum resource 18]. While in practice, this theoretical performance is still hard to reach at present. In the above example, Alice should get information from less than $572+501=1073$
binary digits without any error, while in theory this information should be obtained from at least 1072 binary digits. The ratio of them is $1073 / 1072=1.0009$ or 0.0040 dB , smaller than 0.0045 dB , which is a huge challenge to the error correction technique. In practice, the required performance of error correction will be much higher. To our knowledge there is no such error correction that can meet its requirement.

In fact, each of the converted digit may be correlated with each other and the channel may be binary asymmetric, so one continuous-element should be converted into many more digits. Also, the correlation will greatly increase the complexity and reduce the efficiency of the error correction. Therefore, in practice, things will be much more difficult than what we have shown in the above example.

## III. COMPUTATIONAL COMPLEXITY OF RRCVQKD

In the following, we will calculate explicitly the computational complexity including channel loss. Suppose after many communications and processes, Alice, Bob and Eve get binary strings $M_{A}=\left(M_{A 1}, \ldots, M_{A m}\right)^{T}$, $M_{B}=\left(M_{B 1}, \ldots, M_{B m}\right)^{T}$ and $M_{E}=\left(M_{E 1}, \ldots, M_{E m}\right)^{T}$ of length $m$, respectively. For convenience, in the following, it is assumed that the channel is binary symmetric, i.e., the binary strings contain equal probabilities of 0's and 1's, and the bits in the strings are uncorrelated. We define $e_{A B}=\operatorname{Pr}\left(M_{A i} \neq M_{B i}\right)$, $e_{E B}=$ $\operatorname{Pr}\left(M_{E i} \neq M_{B i}\right)$ and $e_{A E}=\operatorname{Pr}\left(M_{A i} \neq M_{E i}\right)$ as the BERs. Then the maximum amount of secret key contributed by this string is $m\left[H\left(e_{E B}\right)-H\left(e_{A B}\right)\right]$-bit, where $H(x)=-x \log _{2} x-(1-x) \log _{2}(1-x)$ is the Shannon entropy. To share the common secret key, Alice and Bob should eliminate the errors in their final binary string. Then, they can use, for example, error correction, to tolerate certain amount of errors. Only when the amount of errors is below a threshold value, can they be properly corrected [16]. Suppose Alice and Bob can correct at most $m e_{r e c}$ errors, where $e_{r e c}$ is an introduced parameter. Then $m H\left(e_{\text {rec }}\right)$-bit additional information is required and after the error correction, the maximum amount of secret key becomes $m\left[H\left(e_{E B}\right)-H\left(e_{\text {rec }}\right)\right]$-bit. While the average amount of errors between Alice and Bob is $m e_{A B}$, the actual amount of errors will fluctuate, and the fluctuation obey the binomial distribution with variance $m e_{A B}\left(1-e_{A B}\right)$ [23]. Here, we introduce parameter $\lambda$ and suppose the number of practical errors is $m \lambda$. Then the binomial distribution of errors between Alice and Bob can be approximated by a Gaussian:

$$
\begin{align*}
P(\lambda) \approx & \frac{m}{\sqrt{2 \pi m e_{A B}\left(1-e_{A B}\right)}} \\
& \times \exp \left[-\frac{\left(m e_{A B}-m \lambda\right)^{2}}{2 m e_{A B}\left(1-e_{A B}\right)}\right] \tag{1}
\end{align*}
$$

Only when $\lambda \leq e_{\text {rec }}$ can the errors be corrected, so the
probability that Alice and Bob correct their errors is

$$
\begin{align*}
\beta= & \int_{0}^{e_{r e c}} P(\lambda) d \lambda \approx \int_{-\infty}^{e_{r e c}} \frac{m}{\sqrt{2 \pi m e_{A B}\left(1-e_{A B}\right)}} \\
& \times \exp \left[-\frac{\left(m e_{A B}-m \lambda\right)^{2}}{2 m e_{A B}\left(1-e_{A B}\right)}\right] d \lambda \tag{2}
\end{align*}
$$

To share common secret key with high probability, Alice and Bob should guarantee that $\beta \rightarrow 1$. To distill the secret key, they should maintain $e_{r e c}<e_{E B}$. Then it requires $m$ to be sufficiently large. For given probability $\beta$, error correction criteria $e_{r e c}$ and BER $e_{A B}$, the length $m$ can be given by:

$$
\begin{equation*}
m=\frac{e_{A B}\left(1-e_{A B}\right)}{\left(e_{r e c}-e_{A B}\right)^{2}} Q^{2}(1-\beta) \tag{3}
\end{equation*}
$$

where $Q(x)$ is defined as the solution of the equation $1 / \sqrt{2 \pi} \int_{Q(x)}^{\infty} \exp \left(-y^{2} / 2\right) d y=x$ and we have supposed $e_{r e c}>e_{A B}$.

On the other hand, although the average amount of Eve's errors relative to Bob's is $m e_{E B}$, her errors also obey the probability distribution similar to Eq. (11). Therefore, even when $e_{r e c}<e_{E B}$, Eve can still correct all of her errors with certain probability, denoted as $\alpha$. To ensure security communication, Alice and Bob should keep $\alpha$ as small as possible. By the same way as getting $\beta, \alpha$ can be given by

$$
\begin{align*}
\alpha \approx & \int_{-\infty}^{e_{r e c}} \frac{m}{\sqrt{2 \pi m e_{E B}\left(1-e_{E B}\right)}} \\
& \times \exp \left[-\frac{\left(m e_{E B}-m \lambda\right)^{2}}{2 m e_{E B}\left(1-e_{E B}\right)}\right] d \lambda \tag{4}
\end{align*}
$$

For given $\alpha, e_{r e c}$ and $e_{E B}, m$ can be given by:

$$
\begin{equation*}
m=\frac{e_{E B}\left(1-e_{E B}\right)}{\left(e_{E B}-e_{r e c}\right)^{2}} Q^{2}(\alpha) \tag{5}
\end{equation*}
$$

In practice, $e_{E B}$ and $e_{A B}$ as well as $e_{A E}$ are determined by the quantum channel, $\alpha$ and $\beta$ are determined by practical requirements, so Alice and Bob need to choose proper $e_{r e c}$ and $m$ to satisfy the Eq. (3) and (5). Consequently, the length $m$ should satisfy:

$$
\begin{equation*}
m>\frac{e_{E B}\left(1-e_{E B}\right)}{\left(e_{E B}-e_{A B}\right)^{2}} \max \left[Q^{2}(\alpha), Q^{2}(1-\beta)\right] \tag{6}
\end{equation*}
$$

The value of $m$ will determine the computational complexity of the error correction. Generally, the computational complexity is of order $O\left(m^{2}\right)$ 18]. In single photon schemes, after the quantum communication, almost all the information of the distributed binary string is kept in secret from Eve, i.e., $e_{E B}$ or $e_{A E}$ are much larger than $e_{A B}$, so the required $m$ can be very small. However, in RRCVQKD, most of the information may be tapped by Eve, and consequently, the minimum $e_{E B}$ is only slightly larger than $e_{A B}$, so that the required $m$ will be very large. In the example considered in Sec.II, the average BER $\bar{e}_{A B}$
of the converted binary string is given by $4 H\left(\bar{e}_{A B}\right)=3.5$ and the average secret information each digit carries is less than $0.007 / 4=0.00175$-bit. Thus $\bar{e}_{A B} \approx 0.29$ and $\bar{e}_{E B}-\bar{e}_{A B}<1.4^{\wedge} 10^{-3}$. If we set $1-\beta=10^{-7}$ and $\alpha=10^{-7}$, then $Q^{2}(\alpha)=Q^{2}(1-\beta) \approx 27$. Using Eqs. (3) and (5), we obtain $m>10^{7}$. That means, to share common secret key with high probability and to restrain the probability that Eve gets their key, Alice and Bob should set the criteria of the error correction at least to $10^{7}$ digits. Then, even with ideal error correction technique, the required block size should be larger than $10^{7}$. For present LDPC coding, only under the simulation condition and with a very simple code, can this block size be realized 18].

For the general case, suppose the secret information carried by an element is $\triangle I$. Then the conversion should guarantee the lost information to be less than $\triangle I$. Hence the quantization should be precise enough to distinguish the noise variance change of about $\gamma \triangle I N_{0}$, where $\gamma=2 \ln 2$. Consequently, one key element should be quantized into at least $I-0.5 \log _{2} \gamma \triangle I$ binary digits, where $I$ denotes the mutual information between Alice and Bob. Then, on average, the secret information carried by single digit is less than $\triangle I /(I-$ $\left.0.5 \log _{2} \gamma \triangle I\right)$-bit, and the required additional information for error correction is $-0.5 \log _{2} \gamma \triangle I$-bit. We thus obtain $e_{E B}-e_{A B}<\triangle I /\left\{\left(I-0.5 \log _{2} \gamma \triangle I\right) \log _{2}[(1-\right.$ $\left.\left.\left.e_{A B}\right) / e_{A B}\right]\right\}$, where $e_{A B}$ can be approximately given by $\left(I-0.5 \log _{2} \gamma \triangle I\right) H\left(e_{A B}\right)=-0.5 \log _{2} \gamma \triangle I$. Then we have

$$
\begin{align*}
m> & e_{A B}\left(1-e_{A B}\right)\left(\log _{2} \frac{1-e_{A B}}{e_{A B}}\right)^{2}\left(\frac{I-0.5 \log _{2} \gamma \triangle I}{\triangle I}\right)^{2} \\
& \max \left[Q^{2}(\alpha), Q^{2}(1-\beta)\right] \tag{7}
\end{align*}
$$

From Eq. (7), we conclude that the computational complexity of the error correction is at least of order $O\left(1 / \triangle I^{4}\right) \geq O\left(1 / G^{4}\right) \approx O[\exp (0.18 L)]$, where $G$ denotes the channel transmission, $L$ denotes the transmission distance in units of km , and the fiber attenuation efficiency has been chosen to be $0.2 \mathrm{~dB} / \mathrm{km}$. In the above discussion, we have not considered the difference of each digit's BER, the correlation between them and the asymmetry of 0 and 1 . If those factors are taken into account, $m$ will be much larger than that given by Eq. (7). Actually, as the loss increase, the influence of those factors will be more and more severe.

The authors of Ref. 11], can distill the secret key only within 3.1 dB loss $(G \approx 0.5,15 \mathrm{~km}$ fiber $)$, even though high performance error correction was used. While under the condition of $10 \mathrm{~dB} \operatorname{loss}(G=0.1,50 \mathrm{~km}$ fiber), the required error correction will be at least 600 times more complex. Under the 100 km fiber case, it will be at least $6^{\wedge} 10^{6}$ times more complex. Then, whether the secret key can be distilled becomes doubtful. Moreover, as the error correction becomes very complex, the practical computation speed of the algorithm will certainly become very low. Therefore, even though the secret key can be distilled and the physical modulation and detection rate can
be very high, the practical secret key rate, which will be limited by computational complexity, cannot be actually improved.

## IV. CONCLUSION AND OUTLOOK

In conclusion, we have discussed in detail the computational complexity of RRCVQKD. For single photon schemes, the single photon source and detector are the main limitations to the transmission distance and the secret key rate [22], while for present RRCVQKD we have shown that the computational complexity may be the key hurdle. Although the RRCVQKD solve the problem of the light source and detection, it brings a new problem, computational complexity.

With the progress of the computer and new error correction technique, the computational complexity of the RRCVQKD may no longer be a problem, but under existing techniques, its strict requirements are difficult to satisfy. To overcome this difficulty, new protocols need to be developed to reduce the computational complexity.
