Submitted 1 June 2006

Received 2 February 2022

The development of quantum walks in the context of quantum computation, as generalisations of random walk techniques, led rapidly to several new quantum algorithms. These all follow unitary quantum evolution, apart from the final measurement. Since logical qubits in a quantum computer must be protected from decoherence by error correction, there is no need to consider decoherence at the level of algorithms. Nonetheless, enlarging the range of quantum dynamics to include non-unitary evolution provides a wider range of possibilities for tuning the properties of quantum walks. For example, small amounts of decoherence in a quantum walk on the line can produce more uniform spreading (a top-hat distribution), without losing the quantum speed up. This paper reviews the work on decoherence, and more generally on non-unitary evolution, in quantum walks and suggests what future questions might prove interesting to pursue in this area.

1. Introduction

The study of quantum versions of random walks is easily motivated. They have provided the engine for several new quantum algorithms, they are of mathematical interest in their own right, and in physical systems they form a simple example of coherent quantum control over single atoms or photons. They have also found applications from the early days of quantum computation as the clock mechanism in a Feynman computer (Feynman, 1986). The role of decoherence requires more explanation. In physical systems we must of course consider the effects of decoherence when designing our experiments, but this alone does not qualify it as a subject for more general study. Decoherence plays a fundamental role in transforming from the quantum to the classical regime. Quantum walks are simple systems in which the intricacies of decoherence can be studied both analytically and numerically, making connections with fields such as quantum chaos. Taking a broad view of decoherence as any process that tends to reduce quantum coherence, we find that it provides a method for tuning quantum random walks to improve their algorithmic properties. Instead of considering only pure quantum dynamics, we can include non-unitary operations in our quantum random walk algorithms, thereby enlarging the toolbox for controlling their behaviour.

The origins of quantum walks can be traced back to the dynamics of quantum diffusion, well-studied in the physics literature, see for example, Feynman et al. (1964), mostly as models for physical particles moving on regular lattices. Studies of quantum dynamics using a discrete time step described as "quantum random walks" appeared from the late 1980s from Gudder (1988), Grossing and Zeilinger (1988), and Aharonov, Y et al. (1992), the latter with quantum optical applications in mind. Meyer (1996b) studied similar systems with the aim of defining quantum cellular automata (Meyer, 1996a). The current

surge of interest in the context of quantum information started with Farhi and Gutmann (1998) studying continuous-time quantum walks, and continued with Aharonov, D et al. (2001), Ambainis et al. (2001) and Nayak and Vishwanath (2000) studying discrete-time quantum walks, all with the goal of applying them to quantum algorithms. As with classical random walks, there are a wide range of possible dynamics that fit within the general concept, for example, Gottlieb (2004); Gottlieb et al. (2005) defined a discrete-time walk with a continuous space and a coin with a continuous set of states.

In this review we will start with a short overview of purely quantum versions of random walks as studied by the quantum information community in their quest for new quantum algorithms, then in later sections consider the added effects of decoherence. We will cover first discrete-time, coined quantum walks in §2, then continuous-time quantum walks in §3. We mention algorithmic applications in §4, briefly describing two of the known algorithms using quantum walks. In §5 and §6 we consider the effects of decoherence in quantum walks, focusing mainly on its use as a tool for enhancing computational speed up. There are several proposals for implementing a quantum walk directly in a physical system, and most of these studies also contribute analysis of the decoherence relevant to the physical system in question: we provide a short summary of these studies in §7. In general, we deal only with quantum walks on undirected graphs, with a brief summary of what is known about the largely unexplored realm of directed graphs in §8.

This review will assume a basic familiarity with quantum mechanics and quantum information theory. Those wishing to get up to speed on these areas in the context of quantum walks are referred to the excellent and comprehensive introductory review from Kempe (2003a), which assumes only a basic knowledge of quantum mechanics. Those desiring a gentle overview of quantum walks in the context of quantum computing are referred to Kendon (2006b). A brief but accessible review of quantum walk algorithms from a computer science perspective (no mention of decoherence) may be found in Ambainis (2003).

The mathematical results and proofs for quantum walks without decoherence have been presented in great detail and elegance in the original literature: this review summarises what is known without presenting formal proofs but with ample references for those interested to pursue them further. For decoherence effects fewer analytic results have been derived: those that exist are presented in more detail, along with summaries of many related ideas, highlighting the myriad of open avenues that remain to be explored.

2. Coined (discrete-time) quantum walks

In this section we describe quantum walks taking place in a discrete space of positions, with an evolution using discrete time steps. Just as there are many ways to express the dynamics of classical random walks, and many variations on the basic "drunkard's walk", the plethora of different studies of quantum walks have proliferated an equally varied set of notations. For this review, we have chosen one of the more commonly used approaches and we try to maintain a consistent notation, with mention of alternative methods where appropriate. To keep the notation simple, we have taken the liberty of using the same symbols for common quantities throughout, with the precise definition implied by the

context. For example, $P(x;t)$ is a probability distribution over a set of positions denoted by x at a time t during the evolution. In the section on the quantum walk on the line, $P(x;t)$ is for the walk on the line, in the section for the walk on a cycle $P(x;t)$ is for the walk on a cycle, and so on. Extra dependent variable may appear where needed: $P(x;a;t)$ is a probability distribution with the coin state a also specified.

We begin with a brief description of one of the simplest examples, the quantum walk on the line. This will serve both to set up our notation and to indicate the methods of solution. It will also illustrate the first key difference between quantum and classical random walks, the enhanced rate of spreading. This is followed by a discussion of quantum walks on cycles, illustrating several more key differences between classical and quantum random walks. We will finish this section with a brief review of coined quantum walks in higher dimensions, on general graphs and regular lattices.

2.1. Coined quantum walk on an infinite line

In much the same way as we now know almost everything about the properties and possible states of two qubits { though quantum computers will clearly need far more than two qubits to be useful { the simple quantum walk on a line has now been thoroughly studied (e.g., see Ambainis et al., 2001; Bach et al., 2004; Yamasaki et al., 2002; Kendon and Tregenna, 2003; Brun et al., 2003c,a; Konno et al., 2004; Konno, 2002; Carter et al., 2003), though there is no suggestion that it will lead to useful quantum walk algorithms by itself.

First, recall the classical random walk dynamics we are looking for a quantum counterpart of. The walker starts at the origin of an infinite line of discrete points (labelled $\dots -2; -1; 0; 1; 2 \dots$) and tosses an unbiased, two-sided coin. If the coin lands "heads" the walker makes one step in the positive direction; if it lands "tails" the walker steps in the negative direction. This process is repeated T times, and the position of the walker is noted: X_T . If the random walk is repeated many times, the probability distribution obtained $P(x;T)$ is binomial, as is well known and easily shown. The standard deviation of $P(x;T)$ is \sqrt{T} , i.e., the walker is found on average \sqrt{T} steps from the origin after T steps of the random walk.

One obvious approach to creating a quantum counterpart of a classical random walk is to have the quantum walker follow all possible classical random walks in superposition. This is not feasible in the discrete-time quantum walk, as was shown by Meyer (1996b), because it is not reversible, and therefore not unitary (which all pure quantum dynamics is required to be). We thus make the quantum walk dynamics as similar as possible to the classical random walk in a different way, by using a quantum coin. Historically, the role of the quantum coin has caused much confusion, and an equivalent formulation presented by Watrous (2001) using directed graphs seems to be preferred by some computer scientists. For brevity and clarity, in this review we will stick to the formulation using a quantum coin, with brief mention of the Watrous variant in §8. The quantum walker on the line starts at the origin and tosses a two-state quantum system (a qubit). The qubit coin { also called "chirality" with the two states labelled "left" and "right" in many papers {

can be in a superposition of both states, say

$$|j\rangle(t=0) = |j; -1\rangle + e^{i\phi} |j; +1\rangle \quad (1)$$

where the $|j\rangle$ is a standard quantum notation to indicate the complex vector of a pure quantum state. On the r.h.s. the kets are basis states: the first entry is the position on the line ($x = 0$ in this case), and the second is the state of the quantum coin, where we choose to label the two states $j \pm 1$. There is an arbitrary phase $0 \leq \phi < 2\pi$, while α and β are real numbers, with normalisation $\alpha^2 + \beta^2 = 1$. The quantum walker then steps in both directions according to the state of the quantum coin, giving

$$|j\rangle(t=1) = |j-1; -1\rangle + e^{i\phi} |j+1; +1\rangle \quad (2)$$

Keeping to a pure quantum (i.e., unitary) evolution for the moment, the coin toss and step can be written as unitary operators C and S . A single step of the quantum random walk is thus

$$|j\rangle(t+1) = SC |j\rangle(t) \quad (3)$$

where $|j\rangle(t)$ can be expanded as a superposition of basis states,

$$|j\rangle(t) = \sum_{x;c} a_{x;c}(t) |x;c\rangle \quad (4)$$

with complex coefficients $a_{x;c}(t)$ satisfying $\sum_{x;c} |a_{x;c}(t)|^2 = 1$. After T steps we have

$$|j\rangle(T) = (SC)^T |j\rangle(0) \quad (5)$$

The shift operator S has already been specified implicitly by equations (1) and (2), it can be defined by its operation on a basis state $|x;c\rangle$,

$$S|x;c\rangle = |x+c; c\rangle \quad (6)$$

It remains to specify the coin toss C , which can in principle be any unitary operator on the space of a qubit. The equivalence up to a bias (probability p , $0 \leq p \leq 1$, to move in the positive direction, $(1-p)$ in the negative direction) of all coin operators in the walk on a line has been noted by several authors (Ambainis et al., 2001; Bach et al., 2004; Yamasaki et al., 2002). Expressing the unitary operator as a matrix we have

$$C_2 = \begin{pmatrix} p & \sqrt{1-p^2} \\ \sqrt{1-p^2} & -p \end{pmatrix} \quad (7)$$

is thus the only possible type of coin for the quantum walk on a line. For $p = 1/2$ (unbiased), $C_2^{(H)}$ is commonly known as a Hadamard operator,

$$C_2^{(H)} = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix} \quad (8)$$

thus the simple quantum walk on a line is also known as a Hadamard walk. Trivial cases $p = 0, 1$ give oscillatory motion and uniform motion respectively. The full range of behaviour is obtained by choosing different initial coin states, i.e., varying α, β in equation (1).

Fig. 1. Comparison of a classical (dots) random walk and a quantum (crosses) walk with initial coin state $|j=1\rangle$ and a Hadamard coin operator on a line after 100 steps. Only even points are shown since odd points are unoccupied at even time steps (and vice versa).

The quantum walk on the line can be solved analytically in many ways. Straightforward generalisations of methods that work well for classical random walks, such as path counting, and Fourier transformation were both used by Ambainis et al. (2001). We will give examples using these methods in §5. Path counting (path integrals) was further refined in Carteret et al. (2003), and a third method using the algebra of the matrix operators was presented by Konno (2002, 2005a). Solution using the tools of classical (wave) optics can be found in Knight et al. (2003, 2004). Romaneli et al. (2003) analyse the walk on the line by separating the dynamics into Markovian and interference terms, allowing an alternative method of solution for the long-time limits, which they relate to the dynamics of a kicked rotor. They also show that in the continuum limit one obtains the diffusion equation with added interference terms.

The best way to appreciate the most interesting properties of the solution is in a graph, shown in figure 1, of the probability distribution of the position of the walker,

$$P(x; T) = \sum_{c=-1}^{x+1} |\langle c | \psi(T) \rangle|^2; \quad (9)$$

obtained in the standard way by tracing out the coin and taking the square modulus of the wavefunction. The quantum walk looks nothing like the classical random walk, it spreads out much faster in a spiky distribution that is a discrete form of an Airy function (Carteret et al., 2003). It is also asymmetric, with the asymmetry determined by the initial coin state. A symmetric distribution can be obtained by choosing the initial coin state as either $(|j=1\rangle + |j=1\rangle)/\sqrt{2}$, or $\cos(\pi/8)|j=1\rangle - \sin(\pi/8)|j=1\rangle$, see Konno et al. (2004); Tregenna et al. (2003). The moments have been calculated by Ambainis et al. (2001), for asymptotically large times T for a walk starting at the origin,

$$\langle x^2 \rangle(T) = \langle x^2 \rangle_0 + (1 - 1/\sqrt{2})T^2; \quad (10)$$

independent of initial coin state, and

$$\langle x \rangle(T) = \langle x \rangle_0 + (1 - 1/\sqrt{2})T; \quad (11)$$

where σ_1, σ_2 is the initial coin state. The standard deviation (from the origin) $\sigma(T)$ is thus linear in T , in contrast to \sqrt{T} for the classical walk. Moreover, unlike the classical random walk, the quantum walk evolution depends on the initial state at all subsequent times.

2.2. Coined quantum walk on a N -cycle: mixing times

The N -cycle is the Cayley graph of the cyclic group of size N . It is also a line segment with periodic boundary conditions applied, so there is little extra work to do to apply the solution of the quantum walk on the line to the quantum walk on the cycle. In general, when a quantum walk occurs on the Cayley graph of some group, it simplifies greatly on consideration of the Fourier space of the particle (Aharonov, D et al., 2001). On cycles we are interested not in how far the walker strays from its starting point, but in the mixing properties of the distribution on the cycle. Classical random walks on a cycle mix to a uniform distribution in a time $O(N^2)$. That is, after $O(N^2)$ time steps, the walk has all but forgotten its starting state and is equally likely to be found on any site around the cycle. More formally, we can choose any small ϵ and find the mixing time $M(\epsilon)$ such that

$$M(\epsilon) = \min \{ T : \forall x \in \mathbb{Z}_N, \forall y \in \mathbb{Z}_N, \sum_{i=1}^N |P(x; T) - P(y; T)| < \epsilon \} \quad (12)$$

where P_u is the limiting distribution over the cycle, and the total variational distance is defined as

$$\sum_{i=1}^N |P(x; T) - P(y; T)| = \sum_{i=1}^N |P(x; T) - P_u| + \sum_{i=1}^N |P(y; T) - P_u| \quad (13)$$

In general, any reasonable distance function will do the job here, but we will stick with one commonly used in the literature so we can make quantitative comparisons. For a classical random walk on a cycle, $M(\epsilon) = O(N^2 \log(1/\epsilon))$.

In the quantum walk on the cycle, the first observation is discouraging: quantum random walks are deterministic, they oscillate forever and in general do not mix even instantaneously. But by defining a time-averaged distribution,

$$\overline{P}(x; T) = \frac{1}{T} \sum_{t=1}^T P(x; t); \quad (14)$$

quantum walks on cycles do mix. Operationally, this just means choosing randomly a value of t between 1 and T , then measuring the position of the quantum walker after t steps. However, unlike the classical random walk, the limiting distribution $\lim_{T \rightarrow \infty} \overline{P}(x; T)$ for a quantum walk is not, in general, the uniform distribution. This is in stark contrast with a classical random walk, which always mixes to the uniform distribution (on a regular undirected graph).

Exactly as for $M(\epsilon)$ above we can then define the mixing time for $\overline{P}(x; T)$, which we will denote $\overline{M}(\epsilon)$,

$$\overline{M}(\epsilon) = \min \{ T : \forall x \in \mathbb{Z}_N, \forall y \in \mathbb{Z}_N, \sum_{i=1}^N |\overline{P}(x; T) - \overline{P}(y; T)| < \epsilon \} \quad (15)$$

Aharonov, D et al. (2001) proved that the coined quantum walk on a cycle with an odd

number of nodes does mix to the uniform distribution, and has $\overline{M}(t)$ bounded above by $O(\sqrt{N \log N})$, almost quadratically faster (in N) than a classical random walk. They also proved a lower bound on the time-averaged mixing times for quantum walks on general graphs of bounded degree, suggesting a quadratic improvement over classical random walks is the best that can be achieved.

Notice that there is a price to be paid for the time-averaging: the scaling of the mixing time $\overline{M}(t)$ depends on $l=$, compared to $\log(l=)$ for a classical random walk (where no time-averaging of $P(x;T)$ is needed). Aharonov, D et al. (2001) show that this can be avoided by including an amplification step. The quantum walk is run several times, each time starting from the final state of the previous walk. Applied in the optimal way, their bound on the quantum mixing time reduces to $O(N \log N \log(l=))$. Recent work by Richter (2006a,b) improves this result to $O(N \log(l=))$. Since the intermediate measurements render the overall quantum walk dynamics non-unitary, we will postpone more detailed discussion to §5.5.

This speed up in the rate of mixing of quantum walks is a second key difference between quantum and classical random walks. We can also say a little more about their non-classical limiting distributions. For example, Hadamard walks on cycles with an odd number of nodes converge to the uniform distribution (as was proved by Aharonov, D et al., 2001), but those with an even number converge to a non-uniform distribution unless an extra phase is added to the Hadamard coin operator

$$C_2 = \frac{p-1}{e^{i\pi/p}-1} + \frac{e^{i\pi/p}-1}{p-1}; \quad (16)$$

as Tregenna et al. (2003) and Bednarska et al. (2003) show. By appropriate choice of coin operator, a walk on any size cycle can be made to converge either to a uniform or to a non-uniform probability distribution. In classical random walks, the properties of the limiting distribution depend solely on the form of the graph.

2.3. Periodicity in coined quantum walks on cycles

A further curious property of quantum walks on cycles is that for a few special choices of cycle size N , a perfectly periodic walk arises where the quantum walk returns exactly to its starting state after a fixed number of steps, and then repeats the sequence over again, returning at 2 , etc.. The classical random walk has no such behaviour, and returns to its initial state only after irregular numbers of steps. This periodicity is not connected with whether the limiting distribution is uniform or not, since here we are concerned with exact return to the initial state, rather than the time-averaged quantity in equation (14). Some of these periodic walks also mix instantaneously, if we allow a walk on an even cycle to be considered mixed on just the odd or just the even-numbered sites (the same issue arises when considering classical random walks on even-sized cycles).

Using a Hadamard coin, the "cycle" of size $N = 2$ is trivially periodic, returning to its original state after two steps. A cycle of size $N = 4$ has a period of eight steps. This was first noted by Travaglione and Milburn (2002). Tregenna et al. (2003) continued this investigation, and found the cycle with $N = 8$ has a period of 24 steps, but $N = 16$ is

chaotic and does not return to its initial state exactly even after many thousands of steps. These periodic cycles also exhibit instantaneous mixing half way through on their way to returning to the initial state, but instantaneous mixing has not been systematically studied in discrete walks on the cycle. If the coin is allowed to be biased, a few more periodic examples can be found, $N = 6$ with period 12, and $N = 10$ with period 60. With judicious choice of phases in the coin operator, $N = 3$ has a period of 12, and $N = 5$ has a period of 60, clearly related to $N = 6$ and $N = 10$ respectively, but these were the only periodic odd- N cycles found. It is not known whether all periodic quantum walks on a cycle have been identified, but Tregenna et al. (2003) conjecture that there are only a finite number of such solutions and that this is nearly all if not all of them. Neither periodicity nor instantaneous mixing has been explored on more general graphs beyond the trivial extensions of the above to the torus and twisted torus in Tregenna et al. (2003).

2.4. Coined quantum walks on higher dimensional graphs

Classical random walks are not limited to one-dimensional structures, and neither are quantum walks. All that is required for the discrete-time quantum walk is a coin that is large enough to handle the number of choices at each vertex the quantum walker might land on.

Consider a general graph G , with N vertices in a set V , connected by edges from the set E . How one proceeds depends on what prior knowledge one has about V and E . Since we are discussing only undirected graphs, if vertices $x, y \in V$ are connected by an edge $e_{xy} \in E$, then also $e_{yx} \in E$ and one is allowed to travel both from x to y and from y to x . The usual way to represent the structure of the graph is in an adjacency matrix A , which has unit entries for each A_{xy} for which $e_{xy} \in E$, and zeros everywhere else. Since $A_{xy} = A_{yx}$ for an undirected graph, A is symmetric. This representation of the graph assumes that e_{xy} is unique, i.e., there is at most one edge between any two vertices in G . Classically, one can subsume multiple edges between the same vertices into a set of "edge weights". However, a quantum walker might traverse both edges at once but with different phases, which would in general have a different outcome to one weighted edge.

Given no further information about G , there could be as many as $N(N-1)/2$ edges, corresponding to the complete graph, for which every vertex has $N-1$ edges leading from it. In this case the coined quantum walk needs to use a coin of at least this size $(N-1)$, the details of how to implement this quantum walk may be found in Kendon (2006a). If one knows the maximum degree of the graph, d , then one only needs a coin of size d . The details of how to implement this quantum walk, originally from Watrous (2001), are more accessibly described in Ambainis (2004) and Kendon and Sanders (2004). A different approach, using self-loops to make the degree of the graph constant, is mentioned in Kempe (2003a).

Here we summarise the approach given in Kendon and Sanders (2004). First we define our Hilbert space for the quantum walk, H_{vc} which contains the N -dimensional Hilbert space

$$H_v = \text{span}\{ |x\rangle_{i_v} : x \in \mathbb{Z}_N \} \otimes \mathbb{C}^d \quad H_{vc} \quad (17)$$

of vertex states, and for the coin a d -dimensional Hilbert space

$$H_c = \text{span}\{ |i_c\rangle : i_c \in \mathbb{Z}_d \} \text{ and } {}_c\langle i_c | j_c \rangle = \delta_{i_c j_c} \quad (18)$$

where d is the degree of the graph. The basis states of H_{vc} are given by

$$|x; i_c\rangle = |i_c\rangle \otimes |x\rangle, \quad x \in \mathbb{Z}_N, \quad i_c \in \mathbb{Z}_d \quad (19)$$

with cardinality Nd . For a basis state $|x; i_c\rangle$, the index x identifies the vertex number and i_c the i_c^{th} state of the coin. For an edge e_{xx^0} we associate the coin state i_c with the edge at v_x , and the coin state i_c^0 with the other end of the edge at v_{x^0} . The values of i_c and i_c^0 are arbitrary but fixed throughout the quantum walk, to ensure the quantum walker traverses the graph in a consistent manner. We define the mapping

$$: \mathbb{Z}_N \times \mathbb{Z}_d \rightarrow \mathbb{Z}_N \times \mathbb{Z}_d : (x; i_c) \mapsto (x^0; i_c^0); \quad (20)$$

where $(x; i_c)$ and $(x^0; i_c^0)$ label each end of e_{xx^0} .

The unitary quantum walk evolves by repetition of two steps: a coin toss and a conditional swap. The coin operator

$$C : H_{vc} \rightarrow H_{vc} : |x; i_c\rangle \mapsto \sum_{e \in \mathbb{Z}_d} C_{ce}^x |x; e\rangle \quad (21)$$

is a block diagonal matrix with each block labelled by x . The x -dependence of the coin matrix allows sufficient freedom in the quantum walk dynamics for the quantum coherence properties of the coin to vary between vertices, for vertices to act as origins and endpoints, and for vertices to have different degrees from each other. If v_x has degree $d_x < d$, we require $C_{ce}^x = 0$ for all e values not used to label an edge at v_x . This restricts the coin operator so it only produces states that have a valid mapping under γ . If

$$C_{ce}^x = C_{ce}^{x^0} \delta_{i_c, i_c^0}; \quad (22)$$

we have the special case of a fixed degree graph where the coin operator is identical for all vertices, as in the walk on a line or cycle described in the previous sections.

The unitary conditional swap operator is given by

$$S : H_{vc} \rightarrow H_{vc} : |x; i_c\rangle \mapsto |x^0; i_c^0\rangle; \quad (23)$$

which updates the position of the walker and the coin state according to the mapping in equation (20), i.e., moves the walker and coin to the vertex v_{x^0} along edge e_{xx^0} . We note that, by our stipulation that i_c and i_c^0 label opposite ends of e_{xx^0} , it follows that $S = S^{-1}$, and is thus unitary as required for quantum evolution. The sequence of a coin flip and a conditional swap is a transition over the unit time step, which we denote by unitary $U = SC$. The quantum walk can then be written

$$|j(t)\rangle = U^t |j(0)\rangle; \quad (24)$$

where $|j(t)\rangle$ and $|j(0)\rangle$ can be expressed in basis states as per equation (4).

2.5. Coined quantum walks on regular lattices

Analytical solutions of equation (24) can generally only be obtained for special graphs of fixed degree and high symmetry (see, for example, Grimmett et al., 2004). The scattering theory methods of Feldman and Hillery (2004) are worth noting as a possible exception, though few applications have been presented. Numerical studies are less constrained, due to the simplicity of the step by step evolution of quantum walks. Examples of quantum walks on various graphs of degree larger than two can be found in Mackay et al. (2002); Tregenna et al. (2003); Cameiro et al. (2005), and in the quantum walk search algorithm of Shenvi et al. (2003), see x4.1. Many of the basic results for quantum walks on the line and cycle, such as faster spreading, carry over to higher dimensional graphs. This was shown numerically for regular lattices of degree three and four by Mackay et al. (2002). However, higher dimensional coins have a much wider set of possible types of coin operators, and further numerical study (Tregenna et al., 2003) shows that the quantum speed up is not automatic for all possible choices.

The role of the lattice symmetry combined with the symmetry in the dynamics of the quantum walk in determining the spreading has been further studied and clarified by Krovvi and Brun (2006a,b). Most of the examples studied to date have a high degree of symmetry, and it makes sense to choose a quantum coin operator that reflects the symmetry in the problem. Two examples are worth noting. First, the DFT (discrete Fourier transform) coin operator is unbiased, but asymmetric in that you cannot interchange the labels on the directions without changing the coin operator. First used by Mackay et al. (2002), for $d = 3$ it looks like

$$C_3^{(D)} = \frac{1}{3} \begin{pmatrix} 0 & 1 & 1 & 1 \\ 1 & e^{i\frac{2\pi}{3}} & e^{i\frac{4\pi}{3}} & e^{i\frac{6\pi}{3}} \\ 1 & e^{i\frac{4\pi}{3}} & e^{i\frac{2\pi}{3}} & e^{i\frac{6\pi}{3}} \\ 1 & e^{i\frac{6\pi}{3}} & e^{i\frac{4\pi}{3}} & e^{i\frac{2\pi}{3}} \end{pmatrix} A; \quad (25)$$

where $e^{i\frac{2\pi}{3}}$ and $e^{i\frac{4\pi}{3}}$ are the complex cube roots of unity. For $d = 2$, the DFT coin reduces to the Hadamard coin, equation (8), though this is not the only way to generalise the Hadamard coin to higher dimensions (see, for example, Tregenna et al., 2003; Tadej and Życzkowski, 2006). Quantum walks using the DFT coin operator have interesting non-classical properties that have been studied by Mackay et al. (2002); Tregenna et al. (2003); Cameiro et al. (2005); Krovvi and Brun (2006a), but none have yet provided any quantum algorithms.

The second commonly used coin operator is a highly symmetric coin based on Grover's diffusion operator (Grover, 1996) with elements $2/d - \delta_{ij}$, shown in matrix form for $d = 3$,

$$C_3^{(G)} = \frac{1}{3} \begin{pmatrix} 0 & 1 & 2 \\ 1 & 2 & 1 \\ 2 & 1 & 0 \end{pmatrix} A; \quad (26)$$

The Grover coin is biased but symmetric, it is the symmetric unitary operator furthest from the identity. It was first used in quantum walks by Watrous (2001), and is the key ingredient in the quantum walk searching algorithm of Shenvi et al. (2003), see x4.1. Inui et al. (2004) studied the localisation properties related to searching on a two di-

m ensional lattice. Szegedy (2004a,b) introduces a generalisation of the Grover coin that quantises an arbitrary Markov chain: essentially this allows for edge weights on the graph, and works for graphs of variable degree as well as regular graphs.

2.6. Coined quantum walk on the hypercube: hitting times

In one of the few analytical studies of coined quantum walks in higher dimensions, Moore and Russell (2002) use a Grover coin for the hypercube, which has 2^n vertices each of dimension $d = n$. The n -dimensional hypercube is the Cayley graph of Z_2^n , so the solution follows the same general method as for the line and the N -cycle, using Fourier transformation of the position space. Moore and Russell (2002) determine from this solution that the discrete-time quantum walk on the hypercube of size n has approximate instantaneous mixing times,

$$M_{\text{inst}}(t) = \text{ft} : \mathbb{P}(x;t) \rightarrow \mathbb{R}_+ \text{ s.t. } \sum_v \mathbb{P}(x;t) < \epsilon \quad (27)$$

for $t = nk = 4$ for all odd $k > 0$ and $\epsilon = O(n^{-7/6})$. This is an improvement over a classical random walk which mixes in time $O(n \log n)$, but requires measurement of the quantum walk at exactly the right time (else the walk "unmixes" again as it proceeds). They also consider $\mathbb{P}(x;t)$, and using the methods of Aharonov, D et al. (2001), that $M(t)$ is exponentially large, $O(2^n)$.

These results for mixing times are discouraging, but there is another useful property one can test on a hypercube: hitting times. Kempe (2003b, 2005) proved that a quantum walk can travel from one corner of a hypercube to the opposite corner exponentially faster than a classical random walk. Kempe defines two different hitting times: instantaneous, where one measures the destination corner at the optimal time, and concurrent, where one checks the destination after each step to see if the walker arrived yet. This gives us our first taste of non-unitary evolution in a quantum walk, since measuring the destination node at each step destroys some of the coherences in the quantum state. Recent work by Krov and Brun (2006a) expands on these ideas, we will describe them in more detail in §5.6. There are other classical algorithms that can cross a hypercube efficiently, so it does not provide a quantum algorithm with a true advantage over classical.

3. Continuous-time quantum walks

Continuous-time quantum walks on a discrete lattice have their origins back as far as Feynman et al. (1964). Their use for quantum algorithms was first suggested by Farhi and Gutmann (1998), who showed numerically they can reach the ends of certain network configurations more efficiently than classical random walks. A proven exponential speed up in a quantum algorithm using a continuous-time quantum walk came a few years later from Childs et al. (2003), which we will briefly describe in §4.2. In this section we will first describe the continuous-time quantum walk dynamics on a general graph, then compare it (numerically) with the discrete-time walk on the line. We then give two further examples, on cycles and hypercubes, that we will need later.

3.1. Continuous-time quantum walks on general graphs

The continuous-time quantum walk naturally works on any undirected graph. Farhi and Gutmann (1998) simply use the adjacency matrix A , which is symmetric for an undirected graph and therefore Hermitian, to form the Hamiltonian for the evolution of the quantum state,

$$i \frac{d}{dt} |x\rangle(t) = \sum_y |x\rangle \langle x| H |y\rangle \langle y| |y\rangle(t) \quad (28)$$

Here $H = A$, where $\langle x|$ is the hopping rate per edge per unit time, and where $|y\rangle(t)$ is now a vector in the Hilbert space of position (vertices in the graph) only (no coin). Continuous-time quantum walks achieve what was not possible without a coin in a discrete-time quantum walk: the traversing of all possible paths in superposition. The formal solution of equation (28) is

$$|y\rangle(t) = e^{-i A t} |y\rangle(0) \quad (29)$$

On the same graph, a continuous-time classical random walk evolves as

$$\frac{d}{dt} P(x;t) = \sum_y [A_{xy} P(y;t) - A_{yx} P(x;t)] \quad (30)$$

Comparing equation (28) with equation (30) shows that in the quantum walk, the second term, necessary for conservation of probability, is missing. We only need a Hermitian operator for quantum evolution, and since $A_{xy} = A_{yx}$ guarantees this, we are free to examine this dynamics as well as that obtained in more direct analogy to equation (30) by using the Laplacian,

$$i \frac{d}{dt} |x\rangle(t) = \sum_y [|x\rangle \langle x| A |y\rangle \langle y| |y\rangle(t) - |y\rangle \langle y| A |x\rangle \langle x| |x\rangle(t)] \quad (31)$$

For graphs where all the vertices are of the same degree d , the Hamiltonian in equation (31) becomes $H = (A - d\mathbb{1})$, and the solution to this can be written

$$|y\rangle(t) = e^{-i (A - d\mathbb{1}) t} |y\rangle(0) \quad (32)$$

Since A commutes with the identity, the two terms in the exponential can be factored, giving

$$|y\rangle(t) = e^{-i A t} e^{i d \mathbb{1} t} |y\rangle(0) \quad (33)$$

The factor $e^{i d \mathbb{1} t}$ is only an irrelevant global phase that makes no difference to observable quantities if omitted (Ahmadi et al., 2003), thus equation (33) is equivalent to equation (29) for graphs of fixed degree. For graphs of general degree, however, the dynamics with the second term included will have a different evolution, as Childs and Goldstone (2004a) point out. So far, only graphs of fixed degree have been studied in any detail in the literature, so the differences between the two versions have not been explored.

Equation (29) looks remarkably similar to the discrete case, equation (24): both can be written in the form

$$|y\rangle(t) = U^t |y\rangle(0) \quad (34)$$

with unitary operator $U = SC$ for the discrete-time walk and $U = e^{-i A}$ for the

continuous-time walk. But, unlike the classical case, where the limit of the discrete-time walk as the time step goes to zero can be taken in a way that gives the continuous-time walk, in the quantum case the similarity is deceptive. The discrete and continuous walks have Hilbert spaces of different sizes, since the continuous-time quantum walk has no coin: the continuous-time walk therefore cannot be the limit of the discrete-time walk unless it can be restricted to a subspace that excludes the coin. Strauch (2006b,a) shows how to do this for the walk on the line: it turns out the appropriate limit of the discrete-time quantum walk produces two copies of the continuous-time quantum walk, one for each of the two coin degrees of freedom. Alternatively, if one adds a coin space to the continuous-time quantum walk, a quantum dynamics is obtained that is more obviously the continuum limit of the discrete-time coined quantum walk, see Szegedy (2004b); Childs and Goldstone (2004b). The quantised Markov chain formalism introduced by Szegedy (2004a) is yet another convenient way of constructing quantum walks in a parallel manner to classical random walks (e.g., see Weiss, 1994). The stochastic matrix governing the Markov chain corresponds to the adjacency matrix in the graph-based description above.

3.2. Continuous-time quantum walk on the line

A comparison of the simple case of the walk on the line will show us the main similarities and differences between discrete-time and continuous-time quantum walks. Equation (28) has a straightforward solution in terms of Bessel functions,

$$j_x(t) = \sum_{x=-\infty}^{\infty} (-i)^x J_x(t) j_{x-i}; \quad (35)$$

where $J_x(t)$ is the Bessel function of order x . Using a hopping rate of $\gamma = 0.5$ so the total hopping probability per unit time is one, after 40 units of time we obtain the probability distribution shown in figure 2. The discrete-time quantum walk evolved for 55 time steps is also shown for comparison. We can see that the shapes of the distribution are comparable, the difference in the height of the peaks is due largely to the continuous-time walk having support on both odd and even sites, while the discrete-time walk is restricted to sites with the same parity as the time step. Nonetheless, the continuous-time walk has a very oscillatory nature about it, especially in the central region. The two types of walks propagate at somewhat different speeds, as evidenced by the different time instants at which they have the same width. Both spread linearly, just with different constant prefactors, so both show a quadratic speed up in their spreading compared to classical random walks. For the continuous-time quantum walk starting at the origin, for asymptotically large times T ,

$$\langle x^2 \rangle(T) = \langle x^2 \rangle_i = T^2 =: \quad (36)$$

The continuous-time quantum walk on the line is always symmetric, if the hopping rate is the same for both directions, this is the main difference with the discrete-time walk, where the coin generally skews the walk unless special choices are made for the initial state.

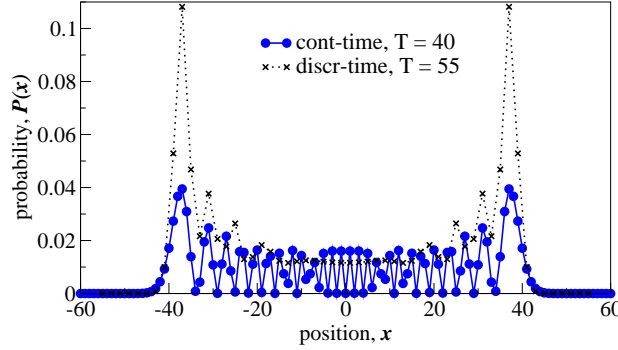

Fig. 2. Comparison of continuous-time (dots) and discrete-time (crosses) quantum walks on a line starting at the origin after 40 and 55 steps respectively. The discrete-time walk has initial coin state $(|j-1\rangle + |j+1\rangle)/\sqrt{2}$, and only even points are shown since odd points are unoccupied at even time steps (and vice versa). All points are shown for the continuous-time walk, which has hopping rate $\gamma = 0.5$.

3.3. Continuous-time quantum walk on a N -cycle and other circulant graphs

The continuous-time quantum walk on a N -cycle is straightforward to analyse. The adjacency matrix A of the N -vertex cycle graph is a circulant matrix, it has eigenvalues $\lambda_x = 2 \cos(2\pi x/N)$ with corresponding eigenvectors \mathbf{p}_x , where $p_x(i) = \frac{1}{\sqrt{N}} \exp(i 2\pi x i/N)$, for $x = 0, 1, \dots, N-1$. Taking the initial state of the quantum walk to be $|j\rangle$, then $|j(t)\rangle = e^{-iHt} |j\rangle$ can be solved by decomposing $|j\rangle$ in terms of the eigenvectors \mathbf{p}_x , giving

$$|j(t)\rangle = \frac{1}{N} \sum_{x=0}^{N-1} e^{-i\lambda_x t} \mathbf{p}_x \cdot \mathbf{j} \quad (37)$$

One can apply the same notions of mixing times for a continuous-time quantum walk as for the discrete-time walk. Like the discrete-time quantum walk on a cycle, the probability distribution $P(x;t)$ of the continuous-time walk does not mix asymptotically, and is known to have exact instantaneous mixing only for a few special cases, $N = 3$ and $N = 4$ (Ahmadi et al., 2003), i.e. even less cases than are known for the discrete-time walk on the cycle as mentioned in 2.3. We can define the continuous-time version of equation (14), the average probability

$$\overline{P(x;T)} = \frac{1}{T} \int_0^T dt P(x;t) \quad (38)$$

where $P(x;t) = \mathbf{j}^\dagger \mathbf{p}_x \mathbf{p}_x^\dagger \mathbf{j}$. While this does mix asymptotically, like the discrete-time walk, in general the limiting distribution is not uniform: it retains one or more peaks reflecting the initial state. Notice that the properties of continuous-time walks on cycles are not dependent on whether the cycle has an odd or even number of nodes, unlike the discrete-time quantum walk.

Adamczak et al. (2003) show that continuous-time walks on cycles are nearly uniform mixing, i.e., if one relaxes the condition on how well they approach the uniform

distribution from an arbitrarily small ϵ , they satisfy

$$\overline{M}(1/4N) = \min_{T \leq t \leq T+1/N} \mathbb{P}(\mathbf{x}; t) - \frac{1}{4N} = O(N^{-1/2}) \quad (39)$$

Adamczak et al. (2003) extend their analysis of mixing in continuous-time quantum walks to a wider variety of circulant graphs, this is continued in Lo et al. (2006): mixing to non-uniform distributions turns out to be the norm for these types of graphs. Carlson et al. (2006) identify graphs where, with the use of edge weights, any distribution on the graph can be obtained (universal mixing). They also identify another class of graphs that are instantaneous uniform mixing, the claw or star graphs.

3.4. Continuous-time quantum walk on the hypercube

Our next example of a continuous-time quantum walk is on a n -dimensional hypercube. Moore and Russell (2002) analytically solved the continuous-time quantum walks on the hypercube as well as the discrete-time walk (see §2.4). The analysis for the continuous-time walk makes use of the hypercube's product graph structure. We label the vertices with n -bit strings, with edges connecting those pairs of vertices that differ in exactly one bit. Then, using the Pauli matrix, X , which is the bit flip operator,

$$X = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}; \quad (40)$$

the adjacency matrix can be decomposed into the sum

$$A = \sum_{j=1}^n X_j \quad (41)$$

where the j th term in the sum has X_j as the j th factor in the tensor product. Each term thus flips the bit in the vertex label corresponding to traversing the edge to the appropriately labelled neighbouring vertex. Using $H = A$ for the quantum walk, we have^y

$$\begin{aligned} U^t &= e^{-iHt} = \sum_{j=1}^n \mathbb{1} \otimes \dots \otimes X_j \otimes \dots \otimes \mathbb{1} e^{-it} \\ &= \begin{pmatrix} \cos(t) & i \sin(t) \\ i \sin(t) & \cos(t) \end{pmatrix}^n; \end{aligned} \quad (42)$$

Applying U^t to the initial state $|j(0)\rangle = |j\rangle^{\otimes n}$, we have

$$U^t |j(0)\rangle = [\cos(t)|j\rangle - i \sin(t)|\bar{j}\rangle]^{\otimes n} \quad (43)$$

which corresponds to a uniform state exactly when t is an odd multiple of $\frac{\pi}{4}$. The choice of $\frac{\pi}{4}$ is thus pivotal for making a fair comparison of the instantaneous mixing time.

^y Moore and Russell (2002) use $U = e^{iH}$, this is just the complex conjugate and makes no difference to observable quantities.

Moore and Russell (2002) choose $\epsilon = 1/n$, so that the total probability of making a hop to any neighbouring site per unit time is unity. With this choice, the continuous-time quantum walk mixes exactly instantaneously in time $O(n)$, a logarithmic improvement over $O(n \log n)$ for the mixing time of a classical random walk. They also showed that for the time-averaged mixing time given by equation (15), the continuous-time walk never mixes. These results can be compared with the discrete-time walk on the hypercube, which has approximate instantaneous mixing (instead of exact), and $\overline{M}(\epsilon)$ mixing in exponential time.

The continuous-time quantum walk on the hypercube also hits the opposite corner in linear time, exponentially faster than a classical random walk: we will obtain this result in §6.3 as a special case of the calculation of the effects of decoherence. As with the coined quantum walk, this exponentially fast hitting time is highly dependent on the symmetry. Keating et al. (2006) apply results from localisation theory (Anderson, 1958) to argue that this behaviour is exceptional, and the norm on less regular graphs is a quantum walk that tends to stay near its starting state.

4. Algorithms using quantum walks

Starting with Shor's algorithm for factoring large numbers (Shor, 1997), many of the quantum algorithms found so far belong to the same family, based on the use of Fourier transforms to identify a hidden subgroup (Lomont, 2004, provides a recent review). This works well (can be exponentially better than known classical methods) for Abelian groups, but extending the method to non-Abelian groups, where some of the notorious hard problems, such as graph isomorphism, lie, is proving tricky. An obvious place to look for new ideas is where classical algorithms are having the most success, to see if a quantum version could be even faster. Randomised algorithms are one such arena, providing the best known algorithms for approximating the permanent of a matrix (Jerrum et al., 2001), finding satisfying assignments to Boolean expressions (kSAT with $k > 2$) (Schoning, 1999), estimating the volume of a convex body (Dyer et al., 1991), and graph connectivity (Motwani and Raghavan, 1995). Classical random walks also underpin many standard methods in computational physics, such as Monte Carlo simulations. Expanding the repertoire of methods for quantum algorithms was the motivation behind the recent upsurge of interest in quantum walks. The first proper algorithms using quantum walks appeared from Childs et al. (2003) and Shenviet al. (2003), and more have since followed: for a short survey, see Ambainis (2003). We will briefly describe the first two quantum walk algorithms, since they are of two distinct generic types, and later algorithms are mostly variants of the quantum walk search outlined in the next section.

4.1. Quantum walk searching

Quadratically faster spreading, as described in §2.1, isn't a quantum algorithm, but quantum searching of an unsorted database (e.g., finding the name corresponding to a given number by searching a telephone directory) is the reverse process: start in a uniform superposition over the whole database and home in on the marked item. The

First quantum algorithm for this problem is due to Grover (1996), using a method of amplitude amplification, from which a quadratic speed up over classical searching is obtained. It can be shown that a quadratic speed up is the best possible improvement for this problem (Bennett et al., 1997). A classical search of an unsorted database potentially has to check all N entries in the database, and on average has to check at least half. A quantum search only needs to make $O(\sqrt{N})$ queries, though the queries ask for many answers in superposition. Shenviet al. (2003) showed that a quantum walk can also search an unsorted database with a quadratic speed up. They represent the database by the vertices of a graph with a regular structure (lattice, hypercube...) and start with the quantum walker in a superposition of all positions on the vertices. The quantum walk proceeds using a Grover coin operator of appropriate dimension at every vertex except the marked item. For the marked item, almost any other coin operator can be used, this is enough to break the symmetry of the quantum walk and cause the walker to converge on the marked vertex in $\approx \sqrt{N}$ steps.

Since then, several variations on quantum searching for a single item have been analysed, all essentially searching for a set of marked items of some sort (Magniez et al., 2005; Childs and Eisenberg, 2005; Ambainis, 2004). Spatial searching, where it is also counted as a cost to move from one item in the database to the next, is also faster with a quantum algorithm, and curiously, the continuous-time walk finds this a little harder than the discrete-time walk: in low dimensions it needs a coin too (Childs and Goldstone, 2004a,b).

4.2. "Grover trees" algorithm

Childs et al. (2003) proved that a continuous-time quantum walk could perform exponentially faster than any classical algorithm when finding a route across a particular sort of network, shown in figure 3. This is a rather artificial problem, but proves in principle that quantum walks are a powerful tool. The task is to find your way from the entrance node to the exit node, treating the rest of the network like a maze where you cannot see the other nodes from where you stand, only the choice of paths. It is easy to tell which way is forward until you reach the random joins in the centre. After this, any classical attempt to pick out the correct path to the exit get lost in the central region and takes exponentially long, on average, to find the way out. A quantum walk, on the other hand, travels through all the paths in superposition, and the quantum interference between different paths allows the quantum walker to figure out which way is forward right up to the exit, which it finds in time proportional to the width of the network. The proof is quite technical, involving oracles and consistent colourings of the network, and the ability to simulate a continuous-time quantum walk on a discrete quantum computer. We refer the reader to the original paper for the details (Childs et al., 2003), since we do not need them here for our discussions of decoherence.

Discrete and continuous-time quantum walks are generally expected to have the same computational power. They give broadly similar results for algorithmic properties such as mixing times and hitting times in those cases where both forms have been applied to the same problem, with the possible exception of spatial search (Childs and Goldstone,

Fig. 3. "Glued trees" graph used in the algorithm of Childs et al. (2003). Example shown is for $N = 4$, with $2N + 2 = 10$ columns labelled at the bottom of the figure, and $2(2^{N+1} - 1) = 62$ nodes. The task is to travel from entrance to exit without getting lost in the randomly joined middle section of the graph. The gap between columns 4 and 5 is for clarity in the figure and is not significant in the algorithm.

2004a), which, as noted above, requires a coin for maximum efficiency even in the continuous-time walk in low dimensions (Childs and Goldstone, 2004b). For a discussion of how both discrete and continuous-time quantum walk implementations would use roughly the same computational resources for the "glued trees" problem, see Kendon (2006a).

5. Decoherence in coined quantum walks

As we have seen, while there are many similarities between discrete and continuous-time quantum walks, there are also some distinctly different behaviours, and this turns out to be true also under the influence of decoherence. We will thus devote a separate section to each type, starting here with coined quantum walks and following in §6 with continuous-time quantum walks. We are going to take a very broad view of decoherence in this review as any dynamics that tends to remove the quantum coherences in some way, be it unwanted (as in environmental decoherence in an experimental system), intentional (to tune the properties of the quantum walk), or a byproduct of some other operation, such as measurement. One of the earliest uses of non-unitary quantum walks is measurement-based, by Aharonov, Y et al. (1992).

Quantum walks are a very broad class of quantum dynamics, with overlap into related areas such as quantum graphs (Kottos and Smilansky, 1997). One way to justify a particular quantum dynamics as being a "quantum walk" is to see if it turns into a classical random walk when decohered. Since classical random walks are also a very broad class of dynamics, this gets reasonably close to a workable definition of a quantum walk, at least for the discrete-time case. Many early studies of quantum walks took the trouble to show numerically that, for specific cases, their quantum walks decohered into classical random

walks, (e.g., see Mackay et al., 2002) who dephase the coin in their study of a quantum walk on the line. A more systematic treatment of the quantum to classical transition in a general quantum walk appears in Kendon and Sanders (2004), emphasising the importance of demonstrating that quantum walks exhibit both wave (pure quantum) and particle (decohered) dynamics and, for a non-unitary quantum walk, being able to interpolate between these two modes of behaviour by tuning the decoherence up or down. Koskiet al. (2006) explicitly calculate the cases of Grover and DFT coins on a Cartesian lattice (\mathbb{Z}^d), with random phase shifts applied to the coin to induce decoherence, rather than measurements. They show that the resulting distributions match the expected classical random walks (which may be biased if the initial state or coin operator is biased, compare 2.1).

Decoherence is usually modelled as a non-unitary evolution of the quantum walk, so we will need some extra formalism for fixed states using density matrix operators. Following the notation in 2.4, the (time-dependent) density operator

$$\rho = \sum_{x,c} \sum_{x',c'} \rho_{xx';cc'} |x;cx^0\rangle \langle x';c'x'^0| \quad (44)$$

is a positive ($\rho = \rho^\dagger$ with positive real spectrum), unit-trace, bounded linear operator on H_{vc} , in the basis B_{vc} , equation (19). In the decomposition of ρ into the computational basis, the rows and columns of ρ are indexed by xc and x'^0c' , which run over the position states and coin states of the Hilbert space. The state is pure if $\rho^2 = \rho$. A typical initial condition is $\rho(t=0) = |j;0;0\rangle \langle j;0;0|$ corresponding to the walker starting at vertex v_0 carrying a coin in the state labelled zero. In general the density operator is mapped to a new density operator via a completely positive (CP) map

$$U : \rho \mapsto \rho' \quad (45)$$

The CP map U performs both the coin flip and the conditional swap over one time step. More explicitly, we can write

$$U = \sum_{j \in \mathcal{I}} U_j^y U_j; \quad \sum_{j \in \mathcal{I}} U_j^y U_j = \mathbb{1}; \quad (46)$$

with j an index of non-unitary evolutionary ‘instances’ and U_j the corresponding Kraus operator. These instances may be discerned by a measurement record, with j the record index. The cardinality of \mathcal{I} can be finite, countably infinite, or even uncountable. In the case of unitary evolution, \mathcal{I} has a cardinality of one, so there is a single, unitary U for which $\rho' = U \rho U^\dagger$. Unitary quantum walk evolution can be expressed as

$$\rho(t) = U^t \rho(0); \quad U = SC; SC \quad SC \quad C^y S^y; \quad (47)$$

where, for the discrete-time walk, we assume $t \in \mathbb{Z}$. Thus, for the unitary walk, a single step is given by $U = SC$, while for the non-unitary walk we can either add an extra non-unitary operation (measurement) FP_j ,

$$U : \rho \mapsto \sum_{j \in \mathcal{I}} P_j SC \quad C^y S^y P_j^y; \quad (48)$$

or, replace the coin and/or the shift operators by non-unitary operators, depending on what sort of decoherence or measurements we are considering.

Most of this section consists of unpacking equation (48) into specific cases, and analysing the effects. One may ask, for example, how quickly the quantum walk becomes classical as the decoherence is increased. Are quantum walks sensitive to small amounts of decoherence, or are the quantum effects robust under environmental disturbance? The first studies of decoherence, beyond merely verifying the classical limit is a classical random walk, were analysis of the likely errors in proposed experimental implementations in Travaglione and Milburn (2002); Sanders et al. (2003); Dur et al. (2002). These, too, are focused on the properties of the pure quantum walk, we provide a short summary in x7. The first consideration of the algorithmic properties of partly decohered quantum walks were by Kendon and Tregenna (2003), who used numerical simulation on a variety of discrete coined quantum walks. We will briefly review their results for the walk on the line, to provide an overview of the typical effects of decoherence, then examine some of the analytical calculations that confirm and expand these initial observations. An alternative approach is to model the entire system of quantum walker plus environment, we include examples of this in x5.4, where the different methods of decohering the coin are compared.

5.1. Effects in the walk on the line

First we unpack the superoperator notation of equation (48) into the specific case of decoherence events or measurements occurring independently at each time step,

$$\rho(t+1) = (1-p)SC \rho(t)C^\dagger S^\dagger + p \sum_j P_j SC \rho(t)C^\dagger S^\dagger P_j^\dagger: \quad (49)$$

Here P_j is a projection that represents the action of the decoherence and p is the probability of a decoherence event happening per time step, or, completely equivalent mathematically, to a weak coupling between the quantum walk system and some Markovian environment with coupling strength p . Equation (49) lends itself readily to numerical simulation since ρ , S and C can be manipulated as complex matrices, while the P_j generally remove some or all of the off-diagonal entries in ρ . Kendon and Tregenna (2003) took equation (49) and evolved it numerically for various choices of P_j , projection onto the position space, projection into the coin space in the preferred basis $j = 1$, and projection of both coin and position. Motivated by the likely form of experimental errors, they also modelled an imperfect Hadamard by applying a Gaussian spread of standard deviation $\sqrt{p} \bar{p} = 4$ about the perfect value of $\bar{p} = 2$ in implicit equation (8), compare Mackay et al. (2002). Shapira et al. (2003) later modelled imperfect quantum walk operations such as this in more detail, still numerically, and drew the same conclusions, while Konno (2005b) treated the general case of a randomised coin, showing analytically that the classical random walk is obtained. An imperfect shift by the walker has been studied in Dur et al. (2002), see x7, and also (in the form of broken links) by Ronanelli et al. (2004), see x5.3.

To quantify the change in behaviour in the walk on the line, we can calculate the standard deviation, equation (10), which is now also a function of the decoherence rate.

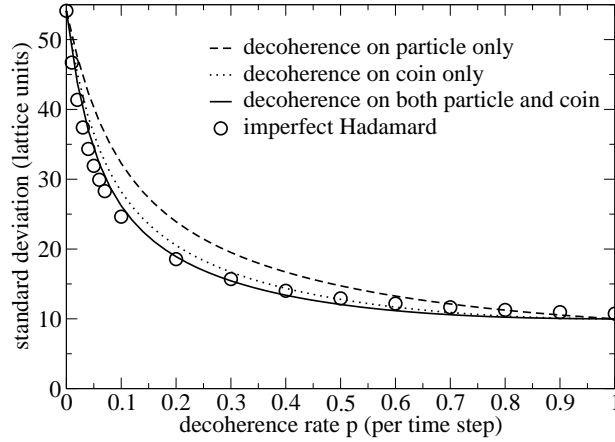

Fig. 4. Standard deviation $\sigma(T;p)$ of the position on a line for different models of decoherence, for $T = 100$ time steps, (from Kendon and Tregenna, 2003).

Fig. 5. A quantum walk on a line of 100 steps is progressively decohered by random measurements with probability p per time step as given in the key. for $p = 0.03$, an approximately 'top hat' distribution is obtained.

In each of these cases Kendon and Tregenna (2003) found the same general form for the decay of $\sigma(T;p)$ from the quantum to the classical value, with small differences in the rates, as shown in figure 4. The slope of $\sigma(T;p)$ is finite as $p \rightarrow 0$ and zero at $p = 1$. The decay of the spreading rate (as quantified by $\sigma(T;p)$), is much as one might have expected given quantum states are generally fragile in the face of environmental disturbance. The interesting feature is seen in the shape of the distribution of the position as decoherence begins to take effect. The changing shape as decoherence is increased is shown in figure 5. Notice the good approximation to a top-hat distribution between $T = \bar{T}$ that appears for $p = 0.03$. For computational physicists who use random walks to sample distributions, this is a very desirable feature, since it provides uniform sampling over a specific range. Moreover, this result is only obtained when decohering the position, compare the three examples in figure 6. The optimal decoherence rate p_u can be obtained by calculating the

Fig. 6. Distribution of the position for a quantum walk on a line after $T = 200$ time steps. Pure quantum (dotted), fully classical (dashed), and decoherence at rate shown on part of system indicated by key (solid). Uniform distribution between $T = -200$ to $T = 200$ (crosses) also shown, (from Kendon and Tregenna, 2003).

total variational distance, equation (13), between the actual distribution and an ideal top hat distribution. The optimum decoherence rate depends on the number of steps in the walk, $p_d T \approx 2.6$ for decoherence on both coin and position and $p_d T \approx 5$ for decoherence on the position only (obtained numerically in Kendon and Tregenna (2003)). Intriguingly, recent work by Malyer and Kendon (2006) shows that the optimal top-hat occurs for the decoherence rate that just removes all the quantum correlations by the end of the quantum walk.

Decoherence on the coin only does not produce a top hat distribution, instead the distribution develops a cusp as it passes from quantum to classical. The work of Lopez and Paz (2003) provides some insight into why decoherence on the coin and on the position produce qualitatively different results. Lopez and Paz present an elegant analysis of decoherence in the quantum walk using a discrete Wigner function to bring out the pattern of correlations and their decay when the coin is subject to decoherence. Their decoherence model follows much the same approach as Brun et al. (2003a), which will be described in §5.2. In their study, Lopez and Paz (2003) restrict the dynamics to cycles. However, most of their results are for a short number of time steps such that the walk has not joined up round the cycle, and the results are identical to the walk on the line. Wigner functions represent quantum dynamics in a quantum phase space, thus showing the behaviour of both position and momentum degrees of freedom in the same picture. This brings out beautifully that while decohering the coin state is sufficient to reduce a quantum walk on a cycle to a classical walk, if the walker started in a superposition of two position states, this remains untouched by the decoherence. Such a walker with a decohered coin performs a superposition of two classical random walks, each starting at a different po-

sition. The converse does not apply, because the position is conditioned on the state of the coin, equation (2), thus decohering the position decoheres the coin with it.

Our first example of decoherence has given us a good guide for what to expect in general: besides the rapid degradation of quantum behaviour, there are interesting effects in particular ranges of low decoherence. These effects are not algorithmically significant, that is, they don't alter the scaling of quantum processing, but nevertheless may be useful in practice, and represent intriguing and complex behaviour worthy of study in their own right. For practical purposes (assuming that one day we have a quantum computer available), the improved top hat problem might still be a useful optimisation to get the most out of the computational resources.

5.2. Dephasing the coin in the walk on the line

In the next two sections we will consider the analytical treatment of decoherence in the walk on the line in some detail. First we consider decoherence only on the coin. This will also provide an example of how to use Fourier transforms to simplify the dynamics and obtain the solution. We follow the method of Brun et al. (2003a,b) to solve equation (48) for the coined quantum walk on a line with dephasing applied to the coin. We thus have S given by equation (6),

$$S|j;ci = |j + c;ci$$

where $|j;i\rangle$ and $|j;i\rangle$ are basis states, and C by equation (8)

$$C_2^{(H)} = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix} :$$

Transforming from the position basis $|j;i\rangle$ to the Fourier basis $|k;i\rangle$ such that,

$$|j;ci = \sum_x e^{ikx} |k;ci \quad (50)$$

we find that

$$U_k |j;ci = C_k |j;ci \quad (51)$$

where C_k acts only on the coin degrees of freedom,

$$C_k = \frac{1}{\sqrt{2}} \begin{pmatrix} e^{ik} & e^{ik} \\ e^{-ik} & e^{-ik} \end{pmatrix} : \quad (52)$$

We now move to density matrix formulation, for a walk starting at the origin in coin state $|j_0;i\rangle$ (not necessarily a basis state),

$$\rho_0 = |j_0;i\rangle\langle j_0;i| = \int \frac{dk}{2} \int \frac{dk^0}{2} |k;i\rangle\langle k^0;i| \rho_{kk^0}^0 |j_0;i\rangle\langle j_0;i| \quad (53)$$

where $|k;i\rangle$ is the tensor product $|k;i\rangle = |j_0;i\rangle$. Using equation (48) to introduce a decoherence operator, we can thus write

$$\rho(t) = \int \frac{dk}{2} \int \frac{dk^0}{2} |k;i\rangle\langle k^0;i| P_{kk^0}^t |j_0;i\rangle\langle j_0;i| \quad (54)$$

where

$$P_{kk^0j_0ih_0j} = \sum_j P_j C_{kj_0ih_0} P_{k^0j}^y P_j^y; \quad (55)$$

and the set of projectors $\{P_j\}$ is the decoherence acting on the coin that we will need to specify in order to carry out explicit evaluation of equation (54).

While it will in general be difficult to evaluate $\langle x^m(t) \rangle$ explicitly, the second moment will give us the main information we need to determine how fast the walk spreads. Calculating the moments allows considerable simplification even before specifying the form of decoherence,

$$\langle x^m \rangle = \sum_x x^m P(x;t) = \sum_x x^m \int \frac{dk}{2} \int \frac{dk^0}{2} \langle x|k\rangle \langle k^0|x\rangle T_{rc} P_{kk^0j_0ih_0j}^t; \quad (56)$$

where $T_{rc}[\cdot]$ traces over the coin degrees of freedom to aggregate the probability over the different coin states. From equation (50), $\langle x|k\rangle = e^{ikx}$, and we may carry out the sum over x , giving

$$\langle x^m \rangle = \frac{(1)^m}{2} \int dk \int dk^0 \delta^{(m)}(k - k^0) T_{rc} P_{kk^0j_0ih_0j}^t; \quad (57)$$

where $\delta^{(m)}(k - k^0)$ is the m th derivative of the delta function. This can then be integrated by parts.

Brun et al. (2003b) chose pure dephasing for the form of the decoherence on the coin, the coin projectors in equation (55) are thus

$$P_j = \frac{1}{2} \begin{pmatrix} e^{-i} & 0 \\ 0 & e^i \end{pmatrix}; \quad (58)$$

This can be solved explicitly, giving in the large t limit,

$$\langle x^2 \rangle = \langle x^2 \rangle' t (\cot^2 2 + \csc^2 2) + O(1); \quad (59)$$

where m measures the strength of the dephasing, $m = 4$ being complete dephasing (classical walk) and $m = 0$ is a pure quantum walk (the approximation above is not valid for exactly $m = 0$). This shows that even a small amount of decoherence renders the quantum walk classical in the sense that the standard deviation of the position scales as \sqrt{t} , but with a larger prefactor the smaller the dephasing, $\cot^2 2 \rightarrow 1 = 2^2$ for small m .

We will return to decohering the coin in §5.4 where a variety of other ways to decohere the coin will be considered and compared. Next, we will complete the picture for decohering a walk on the line with a calculation of the effects of decoherence in the position.

5.3. Decohering the position in the walk on the line

When decoherence acts on the position degrees of freedom, the simplification offered by the factorisation of the dynamics in Fourier space no longer helps: we would have to apply the Fourier transform to the decoherence superoperator too. The following calculations of the asymptotic behaviour for small $p \ll 1$ illustrate how real space (path

counting) methods may be used instead. Following Kendon and Tregenna (2002), we calculate $\langle T; p \rangle$ analytically for $pT \ll 1$ and $T \ll 1$ for the case where the $f_{\mathbf{p};\mathbf{g}}$ are the projectors onto the preferred basis $f_{\mathbf{p};\mathbf{x}i\mathbf{g}}$, i.e., decoherence affecting both walker and coin simultaneously. Since, as already explained, decohering the position also decoheres the coin, it makes only a small difference whether or not we also decohere the coin explicitly.

The probability distribution for finding the walker in the state $\mathbf{p};\mathbf{x}i$ in the presence of decoherence can be written,

$$P(\mathbf{x};\mathbf{a};T;p) = (1-p)^T P(\mathbf{x};\mathbf{a};T) + p(1-p)^{T-1} P^{(1)}(\mathbf{x};\mathbf{a};T) + \dots; \quad (60)$$

where $P(\mathbf{x};\mathbf{a};T)$ is the distribution obtained for a perfect walk and $P^{(i)}(\mathbf{x};\mathbf{a};T)$ is the sum of all the ways to have exactly i noise events. For example, we can write

$$P^{(1)}(\mathbf{x};\mathbf{a};T) = \sum_{t=1}^T \sum_{\mathbf{y}} \sum_{\mathbf{b}} \mathbf{X}^T \mathbf{X} \mathbf{X} P(\mathbf{y};\mathbf{b};t) P_{\mathbf{y}\mathbf{b}}(\mathbf{x};\mathbf{a};T-t); \quad (61)$$

where $P_{\mathbf{y}\mathbf{b}}(\mathbf{x};\mathbf{a};T-t)$ is the distribution obtained from a perfect walk starting in state $\mathbf{y};\mathbf{b}i$ for $T-t$ steps. For the ideal walk, $\langle T \rangle = \sum_{\mathbf{x}} \sum_{\mathbf{a}} \mathbf{x}^2 P(\mathbf{x};\mathbf{a};T)$, and for the walk with decoherence,

$$\langle T; p \rangle = \sum_{\mathbf{x}} \sum_{\mathbf{a}} \mathbf{x}^2 P(\mathbf{x};\mathbf{a};T;p); \quad (62)$$

Taking equation (60) to first order in p , and substituting along with equation (61) into equation (62) gives to first order in p

$$\langle T; p \rangle = \sum_{\mathbf{x};\mathbf{a}} \mathbf{x}^2 \left[(1-p)^T P(\mathbf{x};\mathbf{a};T) + p \sum_{t=1}^T \sum_{\mathbf{y};\mathbf{b}} \mathbf{X}^T \mathbf{X} P(\mathbf{y};\mathbf{b};t) P_{\mathbf{y}\mathbf{b}}(\mathbf{x};\mathbf{a};T-t) \right]; \quad (63)$$

The first term on the r.h.s. is (by definition) $(1-p)^T \langle T \rangle$. Noting that $P_{\mathbf{y}\mathbf{b}}(\mathbf{x};\mathbf{a};T-t)$ is a translation of a walk starting at the origin, $P_{\mathbf{y}\mathbf{b}}(\mathbf{x};\mathbf{a};T-t) = P_{0\mathbf{b}}(\mathbf{x}-\mathbf{y};\mathbf{a};T-t)$, and relabelling the summed variable \mathbf{x} to $(\mathbf{x}+\mathbf{y})$ then enables the sums over \mathbf{x} and \mathbf{a} to be performed in the second term,

$$\begin{aligned} & p \sum_{t=1}^T \sum_{\mathbf{y}} \sum_{\mathbf{b}} \mathbf{X}^T \mathbf{X} \mathbf{X} P(\mathbf{y};\mathbf{b};t) \sum_{\mathbf{x}} \sum_{\mathbf{a}} (\mathbf{x}+\mathbf{y})^2 P_{0\mathbf{b}}(\mathbf{x};\mathbf{a};T-t) \\ &= p \sum_{t=1}^T \sum_{\mathbf{y}} \sum_{\mathbf{b}} \mathbf{X}^T \mathbf{X} \mathbf{X} P(\mathbf{y};\mathbf{b};t) \sum_{\mathbf{a}} \langle T-t \rangle_{0\mathbf{b}}^2 + 2\mathbf{y} \mathbf{h}\mathbf{x}i_{0\mathbf{b}}^{(T-t)} + \mathbf{y}^2 \sum_{\mathbf{a}} 1; \end{aligned} \quad (64)$$

From equation (10), $\langle T \rangle_{0\mathbf{b}}^2$ does not depend on \mathbf{b} , so the summation over \mathbf{y} and \mathbf{b} may be performed trivially. The remaining summation over \mathbf{y} and \mathbf{b} applied to \mathbf{y}^2 gives $\langle T \rangle$ by definition. This leaves only the evaluation of

$$\sum_{t=1}^T \sum_{\mathbf{y};\mathbf{b}} \mathbf{X}^T \mathbf{X} P(\mathbf{y};\mathbf{b};t) \mathbf{y} \mathbf{h}\mathbf{x}i_{0\mathbf{b}}^{(T-t)} = 2p \left(1 - \frac{p}{2} \right) \sum_{t=1}^T \sum_{\mathbf{y};\mathbf{b}} \mathbf{X}^T \mathbf{X} P(\mathbf{y};\mathbf{b};t); \quad (65)$$

where we have used equation (11) for $\mathbf{h}\mathbf{x}i$. We note that this term does not depend on whether the initial coin state is plus or minus one and so we may include both

these possibilities equally. Also, by the symmetry of the walk, it is possible to rewrite a probability function for travelling from state $|j; c\rangle$ to $|i; b\rangle$ in the reverse order, i.e. as a probability for moving from $|i; b\rangle$ to $|j; c\rangle$. Care must be taken to ensure that the signs of each term due to the coefficient y_b in the summation are maintained. We obtain

$$\begin{aligned} \sum_{t,y,b}^X P(y;b;t) y_b x_{0b}^{(T-t)} &= p \left(1 - \frac{p}{2} \right)^{X^T} \sum_{t=1}^T \sum_{y;b;c}^X (1 - \frac{p}{2}) y_b P_{yb}(0;c;t) \\ &= p \left(1 - \frac{p}{2} \right)^{X^T} \sum_{t=1}^T \sum_{y;b;c}^X y_b P_{yb}(0;c;t) \sum_{y;b}^X y_b P_{yb}(0;b;t); \end{aligned} \quad (66)$$

treating the two parts with and without a delta function independently. Expanding the summations over b and translating the position basis by $-y$ gives

$$\begin{aligned} \sum_{t=1}^T \sum_{y;b}^X P(y;b;t) y_b x_{0b}^{(T-t)} &= p \left(1 - \frac{p}{2} \right)^{X^T} \sum_{t=1}^T \sum_{y;c}^X y P_{0,-1}(y;c;t) \sum_y^X y P_{y,+1}(y;+1;t); \end{aligned} \quad (67)$$

The final summation over y may be bounded above by noting that

$$\begin{aligned} P_{0,-1}(y;-1;t) &= \frac{1}{2} y; -1 j^T j; -1 i^2 \\ &= \frac{1}{2} y+1; 1 j^{t-1} j; -1 i - \frac{1}{2} y+1; -1 j^{t-1} j; -1 i^2 \\ &= \frac{1}{2} \sum_c^X P_{0,-1}(y+1;c;t-1); \end{aligned} \quad (68)$$

Using this in equation (67) gives,

$$\begin{aligned} \sum_{t,y,b}^X P(y;b;t) y_b x_{0b}^{(T-t)} &= p \left(1 - \frac{p}{2} \right)^{X^T} \sum_{t=1}^T \sum_{y;b}^h y y_{0,-1}^{(t-1)} - 2 y y_{0,-1}^{(t-1)} + 2 y_{0,-1}^{(t-1)} \\ &= p \left(1 - \frac{p}{2} \right)^{X^T} \sum_{t=1}^T \left(1 - \frac{p}{2} \right)^{t-1} \sum_y^h y y_{0,-1}^{(t-1)}; \end{aligned} \quad (69)$$

where equation (11) has been used for the average values. Note that equation (11) is exact only for asymptotically large times, so the second step in equation (69) introduces further approximations from the contributions to the sum at small times t . Combining these results in the full expression for $\sigma^2(T;p)$, equations (63, 64), and performing the summations over t using $\sum_{t=1}^T t = T(T+1)/2$ and $\sum_{t=1}^T t^2 = T^3/3 + T^2/2 + T/6$, gives

$$\sigma^2(T;p) = \frac{p}{6} T(T+1) - \frac{p^2}{6} T + p \left(\frac{p}{2} - 1 \right) + \dots; \quad (70)$$

Taking the square root gives as an upper bound on the standard deviation,

$$\sigma(T;p) = (T+1) \sqrt{\frac{p}{6}} + \sqrt{\frac{p}{2}} \left(1 - \frac{p}{2} \right) + O(p^2; 1=T); \quad (71)$$

Equation (71) compares well with simulation data in Kendon and Tregenna (2003), once a second order correction for $\langle T \rangle = (1 - \frac{p}{2})^{1=2} \langle T - 1 = T \rangle$ is taken into account. The bounding procedure applied here is reasonably accurate, numerical studies give the coefficient of p in the above expansion as 0.09566, compared with the bound of 0.20711. The first order dependence is thus proportional to pT , the number of decoherence events during the whole quantum walk. For a given decoherence rate p , the standard deviation initially decreases linearly in T . This calculation first appeared in Kendon and Tregenna (2002).

A similar expansion at the classical end of the full sum in equation (60) gives

$$P(x; a; T; q) = (1 - q)^T P^{(T)}(x; a; T) + q(1 - q)^{T-1} P^{(T-1)}(x; a; T) + \dots; \quad (72)$$

where we have defined $q = (1 - p)$ as the small parameter. We know that $P^{(T)}(x; a; T)$ is the classical walk, so

$$\sigma_c^2(T) = T = \sum_x \sum_a x^2 P^{(T)}(x; a; T); \quad (73)$$

and we can write

$$\begin{aligned} \sigma^2(T; q) &= \sum_x \sum_a x^2 P(x; a; T; q) \\ &= (1 - q)^T \sigma_c^2(T) + q(1 - q)^{T-1} \sum_x \sum_a x^2 P^{(T-1)}(x; a; T) + \dots; \end{aligned} \quad (74)$$

However, to see a difference between the classical and quantum walks, we need to have four consecutive steps of the quantum walk, since the position distributions are identical for the first three steps. The first term that differs from classical is thus derived from part of $P^{(T-4)}(x; a; T)$ given by

$$P^{(4cq)}(x; a; T) = \sum_{t=1}^{T-4} \sum_{y; z; b; c} P^{(T)}(y; b; t) P_{(y;b)}^{(0)}(z; c; 4) P_{y+z;c}^{(T)}(x; a; T-4-t); \quad (75)$$

i.e., t classical steps, 4 quantum steps, $T-4-t$ classical steps. (Also included in $P^{(T-4)}(x; a; T)$ are combinations with the 4 quantum steps not adjacent to each other.) Since classical segments of the walk are not influenced by the initial state, we may estimate the variance of the total contribution of $P^{(4cq)}(x; a; T)$ by summing the variances of the segments:

$$\sigma_{(4cq)}^2(T) = \sum_{t=1}^{T-4} \sigma_c^2(t) + \sigma^2(4) + \sum_{t=1}^{T-4} \sigma_c^2(T-t-4) = (T-4)[T-4 + \sigma^2(4)]; \quad (76)$$

Explicit calculation ($P(x; a; 4)$ has sixteen terms) gives $\sigma^2(4) = 5$. From the continued expansion of equation (72) the prefactor is $q^4(1 - q)^{T-4}$, so for small q and large T , we have $\sigma^2(T; q) \sim T(1 + q^4)$ and for the standard deviation

$$\sigma(T; q) \sim \sqrt{T} \left(1 + \frac{q^4}{2} \right); \quad (77)$$

to lowest order in $q = 1 - p$.

A simple model of decoherence in both position and coin space is solved by Romaneli et al. (2004). They apply measurements at regular intervals and project the coin into the $|y\rangle$ basis, to preserve the symmetry of the walk. They obtain a spreading rate that is basically classical, with a prefactor controlled by the rate of the measurements. The average squared distance from the start, measured by the variance, grows as a series of arcs at the quantum rate (quadratic), with regular resetting due to the measurements, pulling the overall rate back to linear (classical). They also generalise to random intervals between measurements, drawing analogy with Brownian motion.

A unitary decoherence model affecting the position also appears in the same paper Romaneli et al. (2004) where they analyse a quantum walk in which links between the positions on the line are broken with probability p . The transition that should have taken place is turned into a self loop for that step of the walk. The unitary operator for each step is modified to take account of the links that happen to be broken at that time step. For low rates of link-breaking, the quantum behaviour persists, while for high rates the walk makes less progress than even an unimpeded classical random walk.

5.4. Multiple coins in the walk on the line

Another analytically tractable approach to reducing coherences in the walk on a line is to enlarge the size of the coin state space, and use parts of it in turn as the walk progresses. This has the advantage of the dynamics remaining purely unitary, rendering the calculations simpler. The first such study, by Brun et al. (2003c), considered multiple coins used in sequence, with the sequence repeating after all the coins had been used once. This produces a quantum walk that still spreads linearly with the number of steps, but with the rate of spreading reduced inversely by the number of coins. Only if a new coin is used for every step of the walk does it become equivalent to the classical random walk. This is in contrast with the behaviour obtained by decohering the coin, (Brun et al., 2003a), which always results in classical limiting behaviour, as pointed out in Brun et al. (2003b). Classical behaviour is thus associated with an environment so large that one never comes close to the Poincaré recurrence time over the timescales considered.

Related studies that observe or exploit the behaviour when the coin space is limited include Flitney et al. (2004) who use multiple coins to create a Parrondo game, by having the amplitude of the coin flip depend on several previous coins rather than just one. Ermann et al. (2006) use an enlarged coin space to show explicitly that the behaviour changes from classical back to quantum once the size of the environment space is used up. They use the coins in a random order rather than sequentially as Brun et al. (2003a) do. Ribeiro et al. (2004) study quasi-periodic sequences of coin operators using numerical simulation, and again find different spreading rates, but still an overall linear dependence on the number of steps. More realistic models of a finite-sized environment would have the environment degrees of freedom interacting with each other, but this has not yet been studied in the context of quantum walks.

Fig. 7. Numerical data for $\overline{M}(p)$ on cycles of size $N = 48, N = 49, N = 50$ and $N = 51$, for coin (dotted), position (dashed) and both (solid) subject to decoherence, using $\gamma = 0.002$. Both axes logarithmic.

5.5. Effects in the walk on the N -cycle

Recall from §2.2 that pure discrete-time quantum walks on cycles don't mix (except instantaneously for a few small special cases mentioned in §2.3), unless the time-averaged probability distribution, equation (13) is considered. In that case, mixing to the uniform distribution $\overline{M}(\cdot)$, equation (15), does occur for some choices of coin operator, but this comes at the cost of requiring a number of steps linear in the inverse accuracy $1/\epsilon$ instead of logarithmic, unless a number of repetitions are combined in an amplification procedure. Kendon and Tregenna (2003) carried out numerical studies of decoherence in cycles. They evaluated $\overline{M}(\cdot; p)$, the mixing time for $P(x; T; p)$ c.f. equation (15), for walks on cycles of sizes up to $N \leq 80$, both for pure states, and in the presence of the same types of decoherence as described in §5.2 for the walk on a line. They did not include any amplification procedure. For odd- N cycles with no decoherence, they report that $\overline{M}(\cdot) \approx N$ as compared to the upper bound of $\overline{M}(\cdot) \approx N \log N^{\frac{1}{2}}$ given by Aharonov, D et al. (2001). Richter (2006b) has recently confirmed this analytically.

Under the action of a small amount of decoherence, the mixing time becomes shorter for all cases, typical results are shown in figure 7. If the coin operator is chosen such that the even- N cycles do not mix to the uniform distribution in the pure quantum walk, then the addition of decoherence causes them to mix to the uniform distribution. Although for N divisible by 4, the coin-decohered mixing time shows a minimum below the classical value at $p = 2/N$, this mixing time is $\approx N^2/32$, i.e., still quadratic in N . Thus, although noise on the coin causes the even- N cycle to mix to the uniform distribution, it does not produce a significant speed up over the classical random walk. Decoherence on the position produces a minimum mixing time $\overline{M}_{\min}(\cdot; p) = O(N)$, thus the even- N cycle mixes to uniform in linear time for a suitable choice of decoherence rate $p_{\min} \approx 16/N^2$, independent of N .

Fig. 8. Numerical data for $M(p)$ on cycles of size $N = 48$ to $N = 51$, for decoherence applied to coin only (dotted), position only (dashed) and both (solid), using $\epsilon = 0.002$. Both axes logarithmic.

For all types of decoherence, the odd- N cycle shows a minimum mixing time at a decoherence rate somewhat earlier than the even- N cycle, roughly $p = 2/N^2$, but because of the oscillatory nature of $P(x; T; p)$, the exact behaviour is not a smooth function of p or N . (Kendon and Tregenna (2003) illustrate this in their figure 4, we will show a similar example later.) As decoherence on the position (or both coin and position) increases, the oscillations in $P(x; T; p)$ are damped out. At $p \sim 16/N^2$, the mixing time passes smoothly through an inflexion and from then on behaves in a quantitatively similar manner to the adjacent-sized even- N cycles, including scaling as $M_{\min}(p) = O(N)$ at the inflexion. Thus for $0 < p \leq 16/N^2$ there is a region where the mixing time stays linear in N .

However, one can do better than this: decoherence causes the quantum walk to mix to the uniform distribution without any averaging of $P(x; T; p)$, thus retaining the logarithmic scaling with N for the mixing times. It is obvious that decoherence must do this, since high decoherence rates reproduce the classical random walk, which has this property. The only question is whether it does so effectively enough to be useful, and the answer is that it does, for decoherence on the position (Kendon and Malyer, 2006; Richter, 2006b). Figure 8 shows the mixing time $M(p)$ corresponding to $P(x; T; p)$ as a function of p for cycles of size 48 to 51. Since even-sized cycles only have support on half the positions at any one time, we have defined the uniform distribution only on the sites where it has support (we can easily fix this if necessary by averaging over two consecutive time steps). It thus behaves like an odd-sized cycle of half the size. Other than this technicality, the behaviour is the same, oscillating peaks end abruptly at the minimum mixing time, followed by a smooth rise to the classical value as the decoherence rate is turned up. The decoherence rate at the minimum mixing time is approximately $\sim N$ (odd-sized) or $2 \sim N$ (even-sized), and the mixing time itself scales as $O(N \log(1/\epsilon))$.

Fig. 9. Difference between the probability distribution $P(x;T;p)$ and the uniform distribution expressed as the total variational distance, equation (13), for $N = 49$ for the case with decoherence on both coin and position. Both axes logarithmic. The value of ϵ used in figures 7 and 8 is shown as a horizontal line.

This thus provides a quadratic improvement over the classical mixing time, which scales as $O(N^2 \log(1/\epsilon))$.

If we take a look at the behaviour of $|P(x;T;p) - P_u^iv|$, shown in figure 9 for $N = 49$, we can see this too is fluctuating at the quantum end, with the period of fluctuation lengthening as it reaches the minimum. On the classical side of the minimum it increases smoothly to the classical value. The time at which the curves last cross the horizontal line at $\epsilon = 0.002$ is the mixing time as plotted in figure 8. In the quantum regime, a different choice of p thus causes a jump in the value of $M(\epsilon; p)$ if it happens to touch the next peak in $|P(x;T;p) - P_u^iv|$. This transition from underdamped (oscillating) to overdamped (smooth) has been observed in a number of decoherence studies, such as the hypercube (Kendon and Tregenna, 2003), described in the next section, and the studies of decoherence in continuous-time quantum walks described in x6. The critical damping point also seems to be associated with the point at which all quantum correlations are destroyed by the decoherence (Malyer and Kendon, 2006), just as this marks the optimal top hat distribution in the walk on the line.

Richter (2006b) actually proves not only that the optimal mixing time is $O(N \log(1/\epsilon))$, but also that three different strategies for optimising the mixing time are equally effective. The "warm start" from Aharonov, D et al. (2001) can be viewed as running the quantum walk for several segments of random length separated by measurements. The decoherence applied with probability p is a quantum walk of length T interrupted by pT measurements at random times. Simply running the quantum walk for several segments of equal length with measurements applied at the end of each is also effective: the random outcomes from the measurements are sufficient to optimise the mixing. This shows that the effects of decoherence are quite robust, insensitive to the precise way in which it is applied. The overall conclusion is thus the same as for the walk on a line, there is a useful

window within which decoherence enhances rather than degrades the quantum features of the walk. Moreover, it is actually necessary to ensure the scaling with the precision is efficient. Additionally, decoherence ensures the quantum walk mixes to a uniform distribution, regardless of the initial conditions or choice of coin operator.

5.6. Effects in the walk on the hypercube

Kempe (2003b, 2005) picked up from where Moore and Russell (2002) left off and analysed hitting times in discrete-time quantum walks on the hypercube. By hitting time we mean the time it takes for the quantum walk to reach the opposite corner from where it started from. Kempe considers two types of hitting times, one-shot, where a measurement is made after a predetermined number of steps, and concurrent, where the desired location is monitored continuously to see if the walker has arrived. While the one-shot hitting time is a pure quantum dynamics, the continuous monitoring of the concurrent hitting time measurement removes part of the quantum coherences, thus it constitutes a type of decoherence. More recently, Krovi and Brun (2006a) have defined a hitting time in closer analogy with the usual classical hitting time, the average time of first arrival at the target location.

Following Kempe, the one-shot hitting time $H_{\text{one-shot}}(r_0)$ between $|j_0\rangle$ and $|j_f\rangle$ is

$$H_{\text{one-shot}}(r_0) = \min_{t \geq 0} \langle j_f | U^t | j_0 \rangle^2 \geq r_0; \quad (78)$$

where r_0 is a threshold probability of being at the target state, U is the evolution of one step of the walk, $|j_0\rangle$ is the starting state and $|j_f\rangle$ is the location being hit.

To define the remaining two hitting times, we need to define a measured quantum walk, both Kempe, and Krovi and Brun give essentially equivalent definitions. For hitting a single final location we need a measurement with two outcomes (this is easily generalised), say P_f and $Q_f = \mathbb{1} - P_f$, where $P_f = |j_f\rangle\langle j_f| \otimes \mathbb{1}_c$, i.e., the projector onto the state $|j_f\rangle$ for any coin state. If the walker is found at $|j_f\rangle$, the walk is assumed to end, it acts as an absorbing boundary. If the walk does not reach $|j_f\rangle$ after t steps, the state of the walk can be written

$$|\psi(t)\rangle = \frac{U_Q^t}{\text{Tr}[U_Q^t]} |j_0\rangle \quad (79)$$

where $U_Q = Q_f U + U^\dagger Q_f^\dagger$. This differs from equation (48) in that we keep only one outcome from the measurement and renormalise the density matrix. Since we know the measurement outcome, we know whether the walk has arrived or not, so we only need to keep the part that did not yet arrive at $|j_f\rangle$. The first arrival (also called first crossing) probability after t steps can thus be written

$$r(t) = \text{Tr}[U_P U_Q^{t-1}] \quad (80)$$

Kempe defines the concurrent hitting time as

$$H_{\text{concurrent}}(r_0) = \min_{t \geq 0} \{t : r(t) > r_0\} \quad (81)$$

The hitting time defined by Krovvi and Brun is

$$H_{\text{average}} = \sum_{t=0}^{\infty} \text{tr}(t); \quad (82)$$

the average arrival time. Krovvi and Brun compare the concurrent hitting time with their average hitting time and find they both scale in a similar polynomial manner, compared with the exponentially long hitting time of a classical random walk, provided they use a Grover coin for the quantum walk, and consider $|x_0\rangle = |j_0\rangle$ and $|x_f\rangle = |j_f\rangle$. Their numerical results suggest the bound of $H_{\text{concurrent}}(1) = O(n^2 \log n^2)$ obtained by Kempe (2003b, 2005) is not tight, the actual hitting time looks to be better than this in the large- n limit.

Krovvi and Brun also investigate the effects of breaking the symmetry of the Grover coin, by using a DFT coin, and by distorting the hypercube lattice. The DFT coin has the property that for certain configurations the hitting time becomes infinite, while a Grover coin with a small distortion of the hypercube lattice increases the hitting time somewhat, though it is still less than the classical random walk hitting time. Analogous results for coined quantum walks on the "glued trees" graph were noted by Tregenna et al. (2003). Further work by Krovvi and Brun (2006b) on the question of whether and under what conditions quantum walks show dramatically different properties (speed up or slow down) compared with classical random walks suggests that it is highly dependent on the symmetry of the graph. For the Grover coin, this is exemplified by the quantum walk search algorithm of Shenviet al. (2003) (described in x4.1), where any disturbance of the symmetry causes the walker to converge on the marked state.

Kendon and Tregenna (2003) investigated the effects of adding extra decoherence to the quantum walk on a hypercube over and above that implied by the measurements of the target location. For both one-shot and concurrent hitting times (this work predates Krovvi and Brun (2006a)), the key parameter is the probability $r(t)$ of finding the walker at the chosen location. Their numerical calculations show that all forms of decoherence have a similar effect on $r(t)$, see figure 10, reducing the peaks and smoothing out the troughs. For the one-shot hitting time this is useful, raising $r(t)$ in the trough to well above the classical value, so it is no longer necessary to know exactly when to measure. For $p = 1/n$, the height of the first peak scales as $r_p(t) = r(t)(0) \exp(-(n+1)pt)$, where $0 \leq t \leq 2$ depending on whether coin, position or both are subject to decoherence. An exponential decrease in the presence of decoherence sounds about as bad as it could reasonably be, and for long times, of course, decoherence reduces the walk to classical behaviour. However, the hitting times are short, only $n = 2$ steps, so $p = 1/n$ only lowers $r(t)$ by a factor of $1/e$. For algorithmic purposes this is insignificant, only a factor of order unity and thus still exponentially better than classical. Note also that the size of the graph (measured in number of nodes) is 2^n , so the decoherence has only a linear effect measured in terms of the size of the graph.

The concurrent hitting time already includes a portion of decoherence, no extra features are produced by the addition of unselective decoherence, but there is still a range of $0 < p = 1/n$ within which the quantum speed up is preserved. Note that in both the

Fig. 10. Hitting probability on a 9-dimensional hypercube for one-shot (left) and concurrent (right), perfect walk (circles), with $p = 0.05$ (dotted), $p = 0.1$ (solid). Classical hitting probability barely visible (dashed).

one-shot and concurrent cases, $p = 1/n$ is a critical damping rate, smoothing out the second peak (shown at around $40 \pm 3n \approx 2$ steps in figure 10).

Decoherence in discrete-time walks has thus provided us with a number of notable common features, such as smoother spreading, enhanced mixing, and a transition from under-damped (quantum) to over-damped (classical) behaviour analogous to classical damping in a harmonic oscillator. We will see in the next section that these features also appear for the continuous-time quantum walk under decoherence.

6. Decoherence in continuous-time walks

Less work has been done on decoherence in continuous-time quantum walks, probably in part because the numerical simulations require more resources (to integrate rather than iterate the dynamics). Analytical calculations for the continuous-time walk are often simpler than for the discrete-time walk due to the lack of a coin, but in the case of decoherence this removes the simple case of decoherence on the coin only that has been so successfully studied in the discrete-time walk. Nonetheless, there are two notable recent analytical results. Fedichkin et al. (2006) obtain the scaling for mixing times for the walk on the cycle for both small and large decoherence rates. They augment this with numerical studies showing a minimum mixing time for intermediate decoherence rates. Alagic and Russell (2005) solve the decoherent walk on the hypercube for all rates of decoherence. These results will be discussed in separate sections below. First, we will set up a general model for decoherence in continuous-time quantum walks analogous to the basic model used for discrete-time walks. Then we will briefly examine the effects of decoherence in the continuous-time quantum walk on the line, obtained numerically, to illustrate the key features we can expect to see.

The pure state evolution of the continuous-time quantum walk given by equation (28)

can be expressed in density matrix form as

$$\frac{d}{dt} \rho(t) = -i [\rho(t), H]; \quad (83)$$

where $[a; b] = ab - ba$ denotes the commutator. We can add a non-unitary decoherence to this in exact analogy to the discrete-time method by writing

$$\rho(t + \Delta t) = (1 - p \Delta t) \rho(t) - i \Delta t [\rho(t), H] + p \Delta t P; \quad (84)$$

where P represents the action of the noise, for example, a set of projectors P_j , such that $P = \sum_j P_j P_j^\dagger$. For uncorrelated noise, taking $\Delta t \rightarrow 0$ this yields

$$\frac{d}{dt} \rho(t) = -i [\rho(t), H] - p \rho(t) + p P; \quad (85)$$

The effect of the extra two terms is to reduce some or all of the off-diagonal elements of $\rho(t)$ at a rate p per unit time.

6.1. Effects in the walk on the line

In contrast to the extensive studies of the discrete-time walk on the line, there are no published analytical treatments of decoherence in a continuous-time quantum walk on the line. We can easily investigate numerically: for uncorrelated noise events at a rate p per unit time, we can unpack equation (85) into

$$\frac{d}{dt} \rho_{x;y}(t) = -i \frac{\rho_{x;y+1} + \rho_{x+1;y} - \rho_{x-1;y} - \rho_{x;y-1}}{4} - p \rho_{x;y}(t) + p \rho_{0;0}(t); \quad (86)$$

where $x, y \in \mathbb{Z}$. (Fedichkin et al. (2006) credit this model as developed by Gurvitz (1997); Gurvitz et al. (2003).) Figure 11 shows the results of evolving a continuous-time quantum walk on the line with hopping rate $v = 0.5$ until $t = 40$, for various decoherence rates. This is to be compared with Figure 1, which shows the same type of study for a discrete-time quantum walk. The continuous-time walk does not produce quite such a nice top hat as the discrete-time walk, partly due to having support on all sites rather than alternate sites, though it would probably be equally useful in practice. There is, however, a striking new effect: unlike with the discrete-time walk, where decoherence rates larger than one have no useful interpretation, there is no reason why p in equations (85) and (86) cannot be made arbitrarily large. In Figure 11, $p = 8000$ is shown: the walk hardly manages to leave the starting point. High values of p can be interpreted as continuous monitoring, which projects the walk into the initial state with high probability. In other words, the walk suffers a quantum Zeno effect (Misra and Sudarshan, 1977), a phenomenon that does not appear in coined quantum walks. One consequence of this is that quantities such as the concurrent hitting time are infinite, since the continuous monitoring will ensure the continuous-time quantum walk never arrives.

6.2. Effects in the walk on the N -cycle

The time-dependent non-unitary evolution of $\rho(t)$ on a cycle is also given by equation (86), only with $x, y \in \mathbb{Z}^N$ for a cycle of size N . Fedichkin et al. (2006) showed how to

Fig. 11. Probability distribution for a continuous-time quantum walk on the line with $\gamma = 0.5$, at time $t = 40$, for various decoherence rates p give in the key.

solve this for small and large values of decoherence. We will now outline their method. The following substitution

$$R_{x,y} = i^y x_{x,y} \quad (87)$$

converts the differential equations into a set with real coefficients,

$$\frac{d}{dt} R_{x,y} = \frac{1}{4} (R_{x,y+1} + R_{x+1,y} - R_{x-1,y} - R_{x,y-1}) - p(1 - x_{x,y}) R_{x,y} \quad (88)$$

Note that this leaves the diagonal elements of \mathbf{R} identical to the diagonal elements of \mathbf{R} . As a side note, Fedichkin et al. (2006) observe from these equations that if $p = 0$, there is an exact mapping of the quantum walk on a cycle onto a classical random walk on a two-dimensional torus, and if $p \neq 0$, there is still an exact mapping of the quantum walk on a cycle onto some classical dynamics on a directed toric graph. Similar mappings (one-dimensional quantum to two-dimensional classical) also occur in quantum phase transitions in spin chains (see, for example, Sachdev, 1999), and can prove a useful technique for analysing quantum systems, though we will not need to use it explicitly here.

Equation (88) can be expressed as a linear operator equation

$$\frac{d}{dt} \mathbf{R}(t) = (\mathbf{L} + p\mathbf{U}) \mathbf{R}(t) \quad (89)$$

One can think of \mathbf{L} and \mathbf{U} as $N^2 \times N^2$ matrices and $\mathbf{R}(t)$ as a vector of size N^2 (instead of a matrix of size $N \times N$). The indices of $\mathbf{R}(t)$ as a vector become $xN + y$ where x, y are the pair of indices of $\mathbf{R}(t)$ as a matrix, but we will write xy for such indices to reduce complexity in the notation. The formal solution of (89) can be written $\mathbf{R}(t) = e^{t(\mathbf{L} + p\mathbf{U})} \mathbf{R}(0)$. The explicit solution for arbitrary decoherence rates has not been obtained, but one can examine the behaviour of the mixing time under the action of small and large decoherence, using standard perturbation theory methods. When the decoherence rate p is small such that $pN \ll 1$, $p\mathbf{U}$ is treated as a perturbation of \mathbf{L} . The unperturbed linear operator \mathbf{L} (which evolves the pure state quantum walk in density matrix formalism) has

eigenvalues

$$\epsilon_{m,n} = i \sin \frac{(m+n)}{N} \cos \frac{(m-n)}{N} \quad (90)$$

with corresponding eigenvectors

$$V_{m,n} = \frac{1}{N} \exp \frac{2i}{N} (m+n) \quad ; \quad (91)$$

Here m, n are indices $0 \leq m, n < N$ combined like x, y above. With due consideration of the degeneracies in the eigenvalues $\epsilon_{m,n}$ of L (see Fedichkin et al., 2006, for details), the eigenvalue perturbation $\tilde{\epsilon}_{m,n}$ turns out to be

$$\tilde{\epsilon}_{m,n} = \frac{(N-2)}{N} : \quad (92)$$

Thus, the solution is of the form

$$R_{xy}(t) = \frac{x y}{N} + \frac{1}{N^2} \sum_{m,n} (1 - \delta_{m+n, (m \bmod N); 0}) e^{i t (\epsilon_{m,n} + \tilde{\epsilon}_{m,n})} \exp \frac{2i}{N} (m x + n y) \quad (93)$$

The probability distribution of the continuous-time quantum walk is given by the diagonal terms (considering $R(t)$ as an $N \times N$ matrix again) $P(x; t; p) = R_{xx}(t)$, that is

$$P(x; t; p) = \frac{1}{N} + \frac{1}{N^2} \sum_{(m,n)} (1 - \delta_{m+n, (m \bmod N); 0}) e^{i t (\epsilon_{m,n} + \tilde{\epsilon}_{m,n})} e^{p \frac{N-1}{N} t} + (1 - \delta_{m,n}) e^{p \frac{N-2}{N} t} \exp i t \sin \frac{(m+n)}{N} \cos \frac{(m-n)}{N} \exp \frac{2i}{N} (m+n)x \quad (94)$$

Fedichkin et al. (2006) then calculate an upper bound on the mixing time $M(\epsilon)$. Defining

$$M_x(t) = \frac{1}{N} \sum_{m=0}^{N-1} e^{i t \sin(2\pi m/N)} \frac{1}{N} x; \quad (95)$$

where $\frac{1}{N} = \exp(2\pi i/N)$, and noting that

$$M_x^2(t) = \frac{1}{N^2} \sum_{m,n=0}^{N-1} e^{i t (\epsilon_{m,n} + \tilde{\epsilon}_{m,n})} \frac{1}{N} (m+n)x; \quad M_{2x}(t) = \frac{1}{N} \sum_{m=0}^{N-1} e^{i t (\epsilon_{m,m} + \tilde{\epsilon}_{m,m})} \frac{1}{N} 2m x \quad (96)$$

and that $M_x(t) \leq 1$, we can simplify equation (94) as follows,

$$P(x; t; p) = \frac{1}{N} e^{p \frac{N-2}{N} t} M_x^2(t) + \frac{e^{tp=N}}{N} M_{2x}(t) + \frac{2(N \bmod 2)}{N} e^{p \frac{N-2}{N} t} \left(1 + \frac{e^{tp=N}}{N} (1 - 2\delta_N) \right) : \quad (97)$$

Adding a now-trivial summation over x gives us the total variational distance required to obtain the mixing time:

$$\sum_{x=0}^{N-1} P(x; t; p) = \frac{1}{N} e^{p \frac{N-2}{N} t} (N + e^{tp=N} - 1) : \quad (98)$$

Since $e^{-tp} \ll 1$, the above equation shows that the mixing condition is $N e^{-p \frac{N-2}{N} t}$. This gives the mixing time bound of

$$M(\epsilon) < \frac{1}{p} \log \frac{N}{\epsilon} + \frac{2}{N-2} : \quad (99)$$

Some comments on this result are in order. First of all, this is the mixing time for the instantaneous probability distribution, so it should be compared with the discrete-time results in figure 8. Just as for the discrete-time walk, the first key effect of decoherence is to cause the continuous-time quantum walk to mix. On the face of it, $M(\epsilon)$ appears to scale as $\log(N)$, which would imply an exponential speed up over classical mixing times of $O(N^2)$. However, this formula is only valid for $pN \ll 1$, the $1/p$ scaling thus ensures that $M(\epsilon) \sim N$ for the range of validity of the result. What this result tells us is that decoherence causes the continuous-time quantum walk to mix with the dominant effect a scaling of $1/p$, and only weak (logarithmic) dependence on N and ϵ . It does not tell us anything about the optimal decoherence rate that might give a minimum mixing time, nor what value that minimum mixing time might take.

We can calculate the time-averaged mixing time from the results for $P(x;t;p)$ above, and compare it with the discrete-time and classical values. Again, we will obtain a result only valid in restricted ranges of parameters. Working with equation (97), and assuming $N \gg 1$ for simplicity, we obtain

$$\overline{P(x;T;p)} = \frac{1}{N} \int_0^T e^{-pt} + \frac{1}{N} \int_0^T dt = \frac{1}{N} \left(1 - e^{-pT} \right) \quad (100)$$

Summing over x to obtain the total variational distance trivially multiplies by N . Comparing this to as before gives

$$\frac{N}{pT} (1 - e^{-pT}) \quad (101)$$

Assuming $pT \ll 1$ (which is consistent with our other assumptions, $N \gg 1$ and $pN \ll 1$, it requires $T \ll N$) gives

$$\overline{M}(\epsilon) = \frac{N}{p}; \quad (102)$$

which is similar to the scaling found numerically for the discrete-time quantum walk. In particular, the scaling with N and ϵ is no longer logarithmic, as a consequence of the time-averaging. The scaling with p is still inverse, indicating that, in general, pure continuous-time quantum walks on cycles do not mix to within ϵ of uniform, even when time-averaged distributions are considered, as already noted in x3.3.

We now turn to the analogous calculation for large decoherence rates. When the decoherence rate p is large, that is, when $p \gg 1$, the quantum walk is experiencing a quantum Zeno effect that suppresses most of the transitions. We can therefore neglect all but the first off-diagonal terms in the matrix $R(t)$ from equation (88). Retaining only matrix elements that are of order $1/p$ produces a truncated set of differential equations for the

elements along the major and the two adjacent minor diagonals:

$$R_{x,x}^0 = \frac{1}{4} (R_{x,x+1} + R_{x+1,x} - R_{x-1,x} - R_{x,x-1}); \quad (103)$$

$$R_{x,x+1}^0 = \frac{1}{4} (R_{x+1,x+1} - R_{x,x}) - pR_{x,x+1}; \quad (104)$$

$$R_{x,x-1}^0 = \frac{1}{4} (R_{x,x} - R_{x-1,x-1}) - pR_{x,x-1}. \quad (105)$$

To facilitate our subsequent analysis, we define

$$a_x = R_{x,x}; \quad d_x = R_{x,x+1} + R_{x+1,x}. \quad (106)$$

Then, we observe that

$$a_x^0 = \frac{(d_x - d_{x-1})}{4}; \quad d_x^0 = \frac{(a_{x+1} - a_x)}{2} - pd_x. \quad (107)$$

The solution of differential equation at large p has the form

$$a_x = \frac{1}{N} \sum_{y=0}^{N-1} \exp \left[-\frac{\sin^2 \frac{y}{N} t}{2p} \right] e^{ixy}. \quad (108)$$

Based on the above analysis, the full solution for $R(t)$ is given by

$$R_{x,y}(t) = \begin{cases} a_x & \text{if } x = y \\ d_x/2 & \text{if } |x - y| = 1 \\ 0 & \text{otherwise} \end{cases} \quad (109)$$

The total variation distance between the uniform distribution and the probability distribution of the decoherent quantum walk is given by

$$\sum_{x=0}^{N-1} a_x(t) - \frac{1}{N} = \sum_{x=0}^{N-1} \frac{1}{N} \sum_{y=0}^{N-1} \exp \left[-\frac{\sin^2 \frac{y}{N} t}{2p} \right] \exp \left[\frac{2ixy}{N} \right] - \frac{1}{N}; \quad (110)$$

which simplifies to

$$\sum_{x=0}^{N-1} a_x(t) - \frac{1}{N} = \frac{1}{N} \sum_{x=0}^{N-1} \sum_{y=1}^{N-1} \exp \left[-\frac{\sin^2 \frac{y}{N} t}{2p} \right] \cos \frac{2yx}{N}; \quad (111)$$

A lower bound on the mixing time for large decoherence rate p can be derived as follows. Note that

$$\sum_{x=0}^{N-1} a_x(t) - \frac{1}{N} \geq a_0(t) - \frac{1}{N} = \frac{1}{N} \sum_{y=1}^{N-1} \exp \left[-\frac{\sin^2 \frac{y}{N} t}{2p} \right]; \quad (112)$$

$$\geq \frac{2}{N} \exp \left[-\frac{\sin^2 \frac{1}{N} t}{2p} \right]; \quad (113)$$

where the first inequality uses the term $x = 0$ only and the second inequality uses the term $y = 1; N - 1$. This expression is monotone in t , and is a lower bound on the total

Fig. 12. The quantum to classical transition of mixing time in a continuous-time decoherent quantum walk on C_N , for $N = 5; 10; 15; 20; 25; 30; 35$. (From Fedichkin et al. (2006).)

variation distance. It reaches $\frac{1}{2}$ at time T_{lower} , when

$$T_{\text{lower}} = \frac{2p}{\sin^2 \frac{\pi}{N}} \ln \frac{2}{N}, \quad \frac{2pN^2}{2} \ln \frac{2}{N}; \quad (114)$$

for large $N \rightarrow \infty$.

An upper bound on the mixing time for large decoherence rate p can also be derived (details in Fedichkin et al. (2006))

$$T_{\text{upper}} = \frac{pN^2}{2} \ln \frac{2}{N} : \quad (115)$$

For large decoherence rates $p \rightarrow \infty$, the mixing times are bounded as

$$\frac{pN^2}{2} \ln \frac{2}{N} < M(\gamma) < \frac{pN^2}{2} \ln \frac{2}{N} : \quad (116)$$

These bounds show that $M(\gamma)$ is linearly proportional to the decoherence rate p , but is quadratically dependent on N , and logarithmically dependent on γ .

The change in the form of the scaling with p from reciprocal for small p to linear for large p suggests there is a minimum mixing time at some intermediate decoherence rate. Fedichkin et al. (2006) confirmed this numerically, reproduced in Figure 12.

The effects of decoherence on continuous-time quantum walks on cycles is thus similar to the effects on discrete-time walks on cycles, as described in §5.5. In fact, the proofs in Richter (2006b) are sufficiently general—they apply equally to the continuous-time walk as to the discrete-time walk. This fills in the gap between small and large decoherence rates, and proves that continuous-time walks, with $O(\log(1/\epsilon))$ decoherence or measurement events, mix in time $O(N \log(1/\epsilon))$ on the cycle (and the d -dimensional torus).

6.3. Effects in the walk on the hypercube

The hypercube is an attractive subject for analytical calculations of quantum walks because, under certain conditions, it offers two routes to simplify the analysis. If the walk has the appropriate symmetry, it is constrained to a subspace that maps to a walk on a line segment with positions corresponding to the Hamming weight of the node labels (with position dependent transition rates). Alternatively, the continuous-time walk can be factored in Fourier space into independent walks on each qubit of the labels of the locations, as explained in §3.4. Furthermore, both mixing properties for spreading over the whole graph, and hitting properties for traversing to opposite corners are non-trivial on the hypercube. We thus have a large number of comparisons to make between discrete and continuous-time quantum walks, and classical random walks. Alagic and Russell (2005) provide a complete solution to the dynamics of the continuous-time quantum walk on the hypercube subject to decoherence. We will sketch their method of solution, then discuss their results.

Alagic and Russell give their quantum walk an energy k (this is equivalent to an arbitrary hopping rate $\gamma = k/n$ instead of the choice of $\gamma = 1/n$ for a graph with vertices of degree n). We consider the continuous quantum walk on the n -dimensional hypercube with energy k and decoherence rate p , starting from the initial wave function $\psi_0 = \prod_i |i\rangle^n$, corresponding to the corner with Hamming weight zero. The decoherence operators in equation (85) project the walker onto one of the vertices of the hypercube chosen uniformly at random. It is useful to write these projectors explicitly in terms of single qubit projectors P_0 and P_1 onto $|i\rangle$ and $|j\rangle$, respectively. We have

$$P = \frac{1}{n} \sum_{j=1}^n [P_0^j + P_1^j] \quad (117)$$

where $P_0^j = \mathbb{1} \otimes \dots \otimes P_0 \otimes \dots \otimes \mathbb{1}$ with the non-identity projector appearing in the j th place and similarly for P_1^j .

We now show that, with the model of decoherence described above, each dimension still behaves independently. Recall equation (41) showing that the adjacency matrix for the hypercube decomposes into a sum of tensor products each acting only on a single qubit. Since the noise operators P_j also have this structure, provided $\psi(0)$ starts out in a state that is also decomposable (such as the all-zero vertex), the subsequent evolution will maintain this structure and will remain decomposable as a system of n non-interacting qubits. Since the qubits are now in mixed states ρ_j , the superoperator acting on them is equivalent to a 4×4 matrix

$$\begin{aligned} J &= \frac{t}{n} [(\mathbb{1} \otimes \dots \otimes \sigma_x) (\sigma_x \otimes \dots \otimes \mathbb{1}) p (\mathbb{1} \otimes \dots \otimes \mathbb{1}) + p (\mathbb{1} \otimes \dots \otimes \mathbb{1}) + p (\sigma_z \otimes \dots \otimes \sigma_z)] \\ &= \frac{t}{n} \begin{pmatrix} \mathbb{B} & \mathbb{C} \\ \mathbb{A} & \mathbb{D} \end{pmatrix} : \end{aligned} \quad (118)$$

Notice that for $p = 0$, $e^{Jt} = e^{-it\sigma_x} \otimes \dots \otimes e^{-it\sigma_x}$, which is exactly the superoperator

formulation of the dynamics of the non-decohering walk. So far we have shown that the walk with decoherence is still equivalent to n non-interacting single-qubit systems. We now analyse the behaviour of a single-qubit system under the superoperator e^J . The structure of this single particle walk will allow us to then immediately draw conclusions about the entire system.

The eigenvalues of J are 0 , $\frac{pt}{n}$, $\frac{pt-i}{2n}$ and $\frac{pt+i}{2n}$. Here $\gamma = \frac{p}{16k^2} \frac{1}{p^2}$ is a complex constant that will later turn out to be important in determining the behaviour of the system as a function of the rate of decoherence p and the energy k . The matrix exponential of J in this spectral basis can be computed by inspection. To see how our superoperator acts on a density matrix ρ_0 , we may change ρ_0 to the spectral basis, apply the diagonal superoperator to yield $\rho(t)$, and finally change $\rho(t)$ back to the computational basis. At that point we can apply the usual projectors ρ_0 and ρ_1 to determine the probabilities of measuring 0 or 1 as a function of time. The result (details in Alogoskoufis and Russell, 2005) is

$$\begin{aligned} P[0] &= \frac{1}{2} + \frac{1}{2} e^{\frac{pt}{2n}} \cos \frac{t}{2n} + \frac{p}{2} \sin \frac{t}{2n} \\ P[1] &= \frac{1}{2} - \frac{1}{2} e^{\frac{pt}{2n}} \cos \frac{t}{2n} + \frac{p}{2} \sin \frac{t}{2n} : \end{aligned} \quad (119)$$

All the properties of the decohering walk can be deduced from these equations. Just as was observed in the mixing behaviour of cycles, the decoherence exhibits three distinctive regimes analogous to underdamping, critical damping and overdamping in a damped oscillator. We will now describe the properties of these regimes.

The underdamping regime occurs for $p < 4k$. To determine the mixing times, we solve $P[0] = P[1] = \frac{1}{2}$, giving exact instantaneous mixing times at

$$M_{\text{inst}} = \frac{n(2 - c \arccos(\frac{p^2 - 8k^2}{16k^2} - 1))}{p \frac{1}{16k^2} \frac{1}{p^2}} \quad (120)$$

for all $c \in \mathbb{Z}$, $c > 0$. At these times, the total variational distance between the walk distribution and the uniform distribution is zero, but the walk "unmixes" again as time progresses. This corresponds to the result in Moore and Russell (2002) for pure state quantum walks, and extends it to regions with small decoherence rates. These mixing times scaling linearly with n represent a quantum improvement over the classical random walk mixing time of $(n \log n)$, with the caveat that the classical mixing time is not instantaneous, so strictly speaking we are not comparing like with like, in the quantum case one must sample at exactly the right moment in time. Note that these periodic mixing times decay with p and disappear altogether when $p = 4k$, so the quantum advantage tails off before the critical damping point is reached. Richter (2006b) offers a weak bound of $O(n^{3/2} \log(1/\epsilon))$ for the mixing time at around the critical damping point, which is slower than classical.

By examining the local maximum of $P[1]$, we can determine that the walk has approxi-

mate instantaneous hitting times to the opposite corner $(1; \dots; 1)$ at times

$$H_{\text{one-shot}}(r) = \frac{2^{-n} (2c+1)}{16k^2 - p^2} \quad (121)$$

for all $c \in \mathbb{Z}$, $c \geq 0$. However, the probability $r(p; c)$ of measuring an exact hit decays exponentially,

$$r(p; c) = \frac{1}{2} + \frac{1}{2} e^{-\frac{2^{-n} (2c+1)}{16k^2 - p^2}} : \quad (122)$$

When no decoherence is present, the walk hits at $H_{\text{one-shot}}(1) = \frac{n(2c+1)}{2k}$; and it does so exactly, i.e. $r(c) = 1$. This corresponds to the result of Kempe (2003b, 2005) for the discrete-time quantum walk, see §5.6, thus both discrete-time and continuous-time quantum walks on the hypercube exhibit exponentially faster hitting times than classical random walks. The difference is that the continuous-time quantum walk hits exactly, while the discrete-time quantum walk hits with a probability that is less than one, see Kempe (2003b, 2005) for details.

For a fixed $p \leq 4k$, Alogoskoufis and Russell (2005) show that the walk behaves much like the classical walk on the hypercube, the measurement distribution of the walk converges to the uniform distribution in time $M(n) = (n \log n)$, just as in the classical case.

As $p \rightarrow 1$, the walk suffers from the quantum Zeno effect. Informally stated, the rate of decoherence is so large that the walk is continuously being reset to the initial wave function ψ_0 by measurement. By inspection of equations (119), it is clear that $P[0] \rightarrow 1$ and $P[1] \rightarrow 0$ as $p \rightarrow 1$.

This concludes our overview of decoherence in continuous-time walks. We have observed some of the same effects of enhanced mixing and smoother spreading, and also shown that where the decoherence doesn't directly help, the quantum speed up is at least robust under small amounts of decoherence.

7. Quantum walks in physical systems

As well as the potential for algorithmic applications that has been in the background of most of our discussion of decoherence in quantum walks in this review, physical systems can be made to perform a quantum walk, and this process is of interest in its own right as an example of precise coherent control. Indeed, the first suggested application of a quantum walk in a physical system was to test decoherence rates in a single trapped ion. Travaglione and Milburn (2002) describe how a coined quantum walk can be performed using the vibration modes of the trapped ion coupled to an internal state of the ion for the quantum coin. They note that a cycle of size $N = 4$ performed in this way should exhibit periodic behaviour, see §2.3. Sanders et al. (2003) suggest a quantum walk using the phase of the electromagnetic field in a cavity as the position (so the walk is again on a cycle) with the role of the coin played by an atom, also in the cavity, which couples to the cavity field depending on its internal state. Since the cavity field cannot be in a state localised at a point in phase space, the positions must be approximated by small regions that do not overlap. Sanders et al. provide a detailed analysis of the experimental parameters necessary to maintain distinct positions during the quantum walk. Dur et al.

(2002) propose a quantum walk on the line using an atom hopping between traps in an optical lattice. The role of the coin is again played by the internal state of the atom. One of the potential sources of error in this system is imperfect transitions between lattice sites, so, along with analysing errors due to imperfect Hadamard operations, Dur et al. also consider the effects of imperfect shift operations. Their work is numerical, but shows that imperfect shifts, or spontaneous tunnelling, smear out the distribution without necessarily reducing the quantum features. This analysis is typical of the extra factors that need to be considered in experimental systems. Since the quantum walk takes place in a subspace of the full quantum system, many of the potential sources of decoherence take the system outside of the subspace of the quantum walk, so the resulting decohered dynamics is not a classical random walk. All of these proposals are within current experimental capabilities but, to date, none has been carried out.

The above examples are all of discrete-time coined quantum walks. Solenov and Fedichkin (2006a,b) analyse a ring of quantum dots in which the electrons in the dots perform a continuous-time quantum walk. They apply similar perturbation theory techniques to analyse the effects of decoherence as were described in §6.2.

There are a number of ways in which photons can be made to follow a quantum walk dynamics, and while some have been implemented, all have used high light intensities that admit a classical wave description. The earliest example, which predates the algorithmic discussions of quantum walks, is from Bouwmester et al. (1999), who present the twin peaked distribution of a quantum walk on the line without identifying it as such. Knight et al. (2003) discuss this experiment, arguing that quantum walks on the line are actually not quantum at all. Kendon and Sanders (2004) explain how what Bouwmester et al. (1999) have done can be regarded as a quantum walk and suggest an enhanced experiment, in which monitoring the individual photon "walkers" reduces the dynamics to a classical random walk, to distinguish a classical "wave walk" from a quantum walk.

A quantum walk experiment carried out by Ryan et al. (2005) uses a 3 qubit NMR system to perform a quantum walk on a cycle of size $N = 4$. This is actually a quantum computation of a quantum walk, since the three qubits are used to represent the binary number labelling the vertex (two qubits), and the qubit coin. This is distinctly different from the physical systems described above, see Kendon (2006b) for more discussion on this point. Ryan et al. also apply decoherence artificially to the qubits, to observe that the quantum walk degrades into the classical walk.

8. Quantum walks on directed graphs

Providing a quantum walk dynamics on undirected graphs is straightforward since the adjacency matrix of an undirected graph is symmetric, hence it can be turned into a unitary (with added coin) or Hermitian operator for any such graph. In contrast, determining whether a directed graph allows a unitary dynamics that respects the graph structure is a hard problem, to which a general answer is not known. Aharonov, D et al. (2001) give a useful definition of how a quantum walk dynamics should respect the structure of a graph, though other approaches are possible, see, for example, Montanaro (2007).

Severini (2003, 2006) provides some necessary conditions, by studying the pattern of a unitary matrix, defined as $U_{ij}^{(P)} = 1$ if $U_{ij} \notin 0$ and $U_{ij}^{(P)} = 0$ if $U_{ij} = 0$. If $A = U^{(P)}$ for some U , then a quantum walk can naturally be applied to the graph with adjacency matrix A . The situation is simpler for some restricted types of graphs, such as line graphs. A line graph $L^{(G)}$ is obtained from graph G by making each edge in G a vertex in $L^{(G)}$, and edges for each pair of edges in G that are adjacent. If x, y, z are vertices in G connected by directed edges (xy) and (yz) which can be traversed only from x to y to z , then the vertices in $L^{(G)}$ correspond to all $(xy) \in G$, and the edges in $L^{(G)}$ correspond to all $((xy)(yz))$ where (xy) and (yz) are edges in G . This definition can be applied recursively to generate a family of line graphs from a single initial graph G , and Pakonski et al. (2003) provide conditions under which line graphs can be quantised.

Starting with an undirected graph, a corresponding directed graph can be constructed by a mapping due to Watrous (2001), similar to the line graph definition above, only each undirected edge is treated as a pair of directed edges. The resulting directed graph is always the pattern of a unitary matrix. The corresponding dynamics, using an associated unitary matrix as the step operator, corresponds exactly to the coined quantum walk dynamics (with a Grover coin) on the original undirected graph (Watrous, 2002).

Directed graphs that are not the pattern of a unitary matrix may still admit a quantum walk dynamics. Montanaro (2007) defines "reversibility" for a directed graph, and proves this allows for a unitary quantum walk in which the coin selects between different sets of cycles in the graph, rather than different paths from each vertex. For irreversible graphs, Montanaro suggests splitting the graph into subgraphs that are reversible, on which the quantum walk dynamics can be unitary, combined with a non-unitary step (a partial measurement) to switch between subgraphs in an irreversible way that nonetheless preserves coherence within each reversible subgraph. If one is willing to allow some transitions that are between vertices not connected by edges, the method of Szegedy (2004a) also provides a quantum Markov process on directed graphs.

This brief section only touches on the range of problems in the realm of directed graphs, reflecting the limited work done in this area. For example, no study of decoherence in quantum walks on directed graphs has been done, nor consideration of the class of graphs that might be the pattern of a CPMAP (rather than of a unitary matrix).

9. Summary and outlook

We have seen in our broad-ranging review of decoherence in quantum walks that the effects are both non-trivial and have potential algorithmic applications. As the decoherence rate is increased, for moderate timescales the quantum features persist, usually to a point of "critical damping" after which the behaviour resembles that of a classical system. In the quantum region before the critical damping point, the useful algorithmic properties, such as spreading and mixing, are often better than the pure quantum dynamics. Indeed, for cycles and tori, some element of non-unitary evolution is essential for efficient mixing behaviour. Our tentative conclusion is thus that decoherence is a useful enhancement, and non-unitary dynamics are a promising avenue of enquiry in the quest for practical applications for quantum computing. The incomplete nature of our conclusions are

in part a reflection of our limited knowledge of the conditions under which a quantum speed up can be obtained.

The idea that the addition of classical randomness can enhance a useful algorithmic property also occurs in other settings, both quantum and classical. An example from the field of quantum information may be found in Kraus et al. (2005); Renner et al. (2005), where the security of a quantum secret key is increased by adding a small amount of randomness to the key during the privacy amplification stage of the protocol. This can be understood in two ways. The goal is to reduce the amount of information available to an eavesdropper to a trivial level. The added randomness reduces the *effective* size of the secret key, but it reduces even more the information that the eavesdropper has. This works for both classical and quantum keys. From a quantum perspective, the randomness takes the form of entanglement with an environment that the eavesdropper does not have access to. Since the total amount of entanglement is limited, this reduces the entanglement of the key with the eavesdropper, and thus reduces the information available to the eavesdropper. The interpretation of this in the context of quantum walks is of course rather different, but the common theme is that the decoherence or randomness induces a more uniform distribution, in this case in the form of a smoother "top-hat" distribution in the walk on the line, and faster mixing times on finite graphs. Some further insight is provided in Kendon and Malyer (2006), where the entanglement between the coin and the position is used to gauge the impact of the added randomness. The optimal decoherence rate turns out to just remove all the quantum entanglement, and can be thought of as removing the "extra" quantum correlations that would otherwise keep the distribution away from uniform.

As will have become clear to the reader by now, there are many gaps in the analysis of decoherence in quantum walks, and, more importantly, many gaps in our understanding of what might make a useful quantum walk algorithm. Some of these shortcomings will only be accessible to serious study when (if) we have a larger (that is, larger than we can simulate classically) quantum computer available to test the performance of actual algorithms. In the meantime, there is still much useful progress that can be made, in particular in understanding the role of symmetry in the properties of quantum walks. Many of the examples studied so far turn out on closer inspection to be exceptional cases, a slight change in the symmetry of the dynamics or initial state can reverse the interesting quantum properties. The role of decoherence as a "memory eraser" to eliminate the dependence on the initial state, while still retaining the interesting quantum properties, is thus one of its most appealing features. My hope in offering this review is that it will be a useful summary of the current state of research in a field that has seen significant recent activity and advances, and that it will facilitate and spur further efforts in this area.

I gratefully thank my colleagues for many useful and stimulating discussions of quantum walks, especially Dorit Aharonov, Andris Ambainis, Todd Brun, Ivens Carneiro², Hilary Carteret, Andrew Childs, Richard Cleve, Jochen Endrejat, Ed Farhi, Will Flanagan,

² It is with much sadness we learned of the death of Ivens Carneiro in a traffic accident in April 2006.
