

Control and Representation of n -qubit Quantum Systems

W. E. Baylis, R. Cabrera, C. Rangan

Department of Physics, University of Windsor, Windsor, ON N9B 3P4. Canada

Just as any state of a single qubit or 2-level system can be obtained from any other state by a rotation operator parametrized by three real Euler angles, we show how any state of an n -qubit or 2^n -level system can be obtained from any other by a compact unitary transformation with $2^{n+1} - 1$ real angles, 2^n of which are azimuthal-like and the rest polar-like. The results follow from a modeling of the Hilbert space of n -qubits by a minimal left ideal of an associative algebra. This representation is expected to be useful in the design of new compact control techniques or more efficient algorithms in quantum computing.

The general control of an N -level quantum system is a subject of considerable interest in many fields, including chemical dynamics and quantum computing. A general statement that establishes the controllability basically says that for an N -level system to be completely controllable, it is sufficient that the free-evolution Hamiltonian, along with the interaction Hamiltonian (which could involve a sequence of steps) and all possible commutators among them, form a Lie algebra, which in general is $u(N)$, with N^2 independent real elements [1, 2]. Once quantum controllability is established, it is important to find the optimal method to actually control the system. This involves optimization of both resources and time (for examples, see [3, 4, 5] and references therein).

In this letter, we show that an arbitrary state of an N -level quantum system can be generated from any other state by a compact, rotation-like unitary transformation with $2N - 1$ real parameters. We explicitly demonstrate this controllability for n -qubit systems where $N = 2^n$. We show that a complex algebra of only N independent elements is sufficient to describe an evolution from any given reference state to an arbitrary state of the system. The $N = 2^n$ independent elements of the linear space of the algebra span the N -dimensional Hilbert space, and the $N - 1$ independent elements excluding unity generate polar-like rotations. When combined with the N independent phase angles for each term, which arise from azimuthal-like rotations, there are a total of $2^{n+1} - 1 = 2N - 1$ real control parameters for the system. Thus, it is shown that the minimum number $2N - 1$ of real parameters needed to identify an arbitrary state is also sufficient to create it from any other state by a compact, rotation-like unitary operation. Our results generalize the well-known description of a single-qubit system, any state of which can be specified by the three Euler angles of a rotation that relate the state to a “spin-up” reference state.

Clifford’s geometric algebra has been used to study Lie groups without the use of matrices [6]. The Clifford algebra \mathcal{C}_N of an N -dimensional Euclidean space contains a scalar, N linearly independent vectors or directions, $\binom{N}{2} = N(N - 1)/2$ linearly independent bivectors or

planes, $\binom{N}{3}$ linearly independent trivectors, and so on for a total of 2^N linearly independent elements. Its unimodular even elements, called rotors, form the $\text{Spin}(N)$ group, which is a two-fold cover of the rotation group $\text{SO}(N)$ and is generated by its bivectors. The 2-state spinor of a single qubit can be represented as the projection of a rotor in the Clifford algebra \mathcal{C}_3 of 3-dimensional Euclidean space onto a minimal left ideal. [7, 8, 9, 10]. An equivalent representation has been extended to the Lie algebra of two-qubit systems [11]. This letter shows how this structure can be simply implemented for an n -qubit system, and more generally, for an N -level quantum system.

The qubit or 2-state quantum system is well known in many contexts, including the Bloch sphere for spin-1/2 magnetic resonance [12] and the Feynman-Vernon-Hellwarth model [13], both of which ultimately have the same mathematical structure. The states of a single qubit can be represented by elements of $\text{Spin}(3)$, which is isomorphic to $\text{SU}(2)$, projected onto a minimal left ideal of \mathcal{C}_3 by the projector $P_3 = \frac{1}{2}(1 + \sigma_3)$ with σ_3 a unit vector. Projectors are real idempotent elements that obey $P_3 = P_3^2 = \sigma_3 P_3$. In a matrix representation of \mathcal{C}_3 , the unit vectors σ_j can be represented by the Pauli-spin matrices, $\sigma_0 \equiv 1$ is represented by the unit matrix, and the volume element is $\sigma_1 \sigma_2 \sigma_3 = i1$. The projector acts from the right to reduce the matrix representation of the rotor R to a spinor $\psi = R P_3$ with a single non-vanishing column. Within the minimal left ideal, the basis states of the two-level system can be taken as

$$\begin{aligned} P_3 &= \sigma_3 P_3 \text{ (“spin up”)} \\ \sigma_1 P_3 &= \sigma_{13} P_3 \text{ (“spin down”)} \end{aligned} \quad (1)$$

where $\sigma_{13} = \exp(\pi \sigma_{13}/2)$ is the bivector $\sigma_{13} = \sigma_1 \sigma_3 = -\sigma_3 \sigma_1$ that generates rotations with rotor $R = \exp(\theta \sigma_{13}/2)$ in the plane of σ_1 and σ_3 , and we noted that $\sigma_3^2 = 1 = -\sigma_{13}^2$. A general state is a linear combination

$$\psi = (c_0 + c_1 \sigma_1) P_3 \quad (2)$$

with complex scalar coefficients c_0, c_1 . If the state is normalized: $|c_0|^2 + |c_1|^2 = 1$, we can write $c_0 = e^{i\alpha} \cos \theta/2$

and $c_1 = e^{i\beta} \sin \theta/2$ with real phase angles α, β , and express its spinor by

$$\begin{aligned}\psi &= \left(e^{i\alpha} \cos \frac{\theta}{2} - e^{i\beta} \sigma_{13} \sin \frac{\theta}{2} \right) P_3 \\ &= e^{i\alpha} \left(\cos \frac{\theta}{2} - e^{-i\phi} \sigma_{13} \sin \frac{\theta}{2} \right) P_3, \quad \phi = \alpha - \beta \\ &= e^{-i\phi\sigma_3/2} e^{-\sigma_{13}\theta/2} e^{-i\chi\sigma_3/2} P_3, \quad \chi = \phi + 2\alpha\end{aligned}\quad (3)$$

The left factor multiplying P_3 is here the rotor for a rotation with Euler angles (ϕ, θ, χ) . Its three real parameters are the polar angle θ and two azimuthal angles χ and ϕ . In terms of physical operators, ϕ can be a phase generated by free evolution, θ a phase generated by an applied field, and χ one generated by both free evolution and geometry.

In this paper, we extend this formalism to systems of N states, and represent such states by unitary elements of a compact rotor-like group with $2N - 1$ real parameters (angles), projected onto a minimal left ideal, and, most significant for the control of the system, we show that transformations between arbitrary states are given simply by such rotor-like operators.

The proof involves a simple algebraic representation of the states. In the case of a single qubit, any state is given by a direction in three-dimensional space (on the Bloch sphere) together with an overall complex phase. However as seen in (2), it is more simply represented by a complex associative algebra \mathcal{A}_1 of the left factor with just one spatial dimension times a projector P_3 outside the algebra. Every element of \mathcal{A}_1 for a single qubit is a complex linear combination of $\{1, \mathbf{e}_1\}$ and \mathcal{A}_1 can be identified with the Clifford algebra \mathcal{C}_1 . We show below that an arbitrary state of a system of n qubits can similarly be represented by the minimal projection of a left-factor algebra \mathcal{A}_n of $N = 2^n$ independent elements generated by products of n fundamental ones. The algebra \mathcal{A}_n can be identified as the Clifford algebra \mathcal{C}_n over the complex field, but other algebras are also possible and it may be simpler to use an abelian algebra. In all cases, the left factor can be written as the product of compact rotor-like unitary transformations that can be factored into $N - 1$ polar-like rotors and N azimuthal-like ones. The generators of the polar-like rotations give the basis states of the system and the polar-like angles themselves give the amplitudes of the basis states in the state expansion, whereas the azimuthal-like angles determine the complex phases of the basis-state expansion and are related to the geometric phases that can be found for N -level systems by an iterative procedure recently discussed by Uskov and Rau[14]. The total number of real angular parameters is thus exactly the minimum $2N - 1$ parameters needed to define any state of the system.

The Hilbert space of an n -qubit system is spanned by tensor products of n single-qubit states. A complete basis of states is $\{|\ell\rangle = \mathbf{b}(\ell)\psi_0, \ell = 0, \dots, N - 1\}$, where the

reference state $\psi_0 = P = P_3 \otimes P_3 \otimes \dots \otimes P_3$ is a primitive projector, and $\mathbf{b}(\ell)$ are the hermitian operators

$$\mathbf{b}(\ell) = \sigma_1^{\lambda_n} \otimes \sigma_1^{\lambda_{n-1}} \otimes \sigma_1^{\lambda_{n-2}} \otimes \dots \otimes \sigma_1^{\lambda_1}, \quad (4)$$

where each λ_j , $j = 1, 2, \dots, n$ is 0 or 1, with 0 corresponding here to “spin up” and 1 to “spin down”. To be explicit, we take λ_j to be the bits in the binary expression of ℓ . In particular, $\mathbf{b}(0) = 1$ because the binary number 0 has all bits $\lambda_k = 0$. Thus, we denote a general state ψ by

$$\psi = \sum_{\ell=0}^{N-1} |\ell\rangle c_\ell = \sum_{\ell=0}^{N-1} c_\ell \mathbf{b}(\ell) \psi_0. \quad (5)$$

The $\mathbf{b}(\ell)$, $\ell \in [0, n] \cap \mathbb{Z}$, form a closed abelian group with $[\mathbf{b}(\ell)]^2 = 1$. The inner product of states ψ and ψ' is given algebraically by $\langle \psi' | \psi \rangle = N \langle \psi \psi'^{\dagger} \rangle_0$, where $\langle x \rangle_0$ is the scalar part of x , that is, the part that is scalar in each factor of its tensor product. It is easily verified that the basis states $|\ell\rangle$ are orthonormal. Since ψ is assumed to be normalized, $\langle \psi | \psi \rangle = \sum_{\ell=0}^{N-1} |c_\ell|^2 = 1$. A direct power-series expansion verifies that

$$\exp(-i\mathbf{b}\theta/2) = \cos \frac{\theta}{2} - i\mathbf{b} \sin \frac{\theta}{2}, \quad (6)$$

and a product of $N - 1$ such compact unitary factors for some set of $N - 1$ real “polar angles” θ_ℓ gives

$$\prod_{\ell=1}^{N-1} \exp\left[-\frac{i}{2} \mathbf{b}(\ell) \theta_\ell\right] = \exp\left[-\frac{i}{2} \sum_{\ell=1}^{N-1} \mathbf{b}(\ell) \theta_\ell\right] = \sum_{\ell=0}^{N-1} c_\ell \mathbf{b}(\ell) \quad (7)$$

with complex coefficients normalized so that

$$\sum_{\ell=0}^{N-1} |c_\ell|^2 = 1. \quad (8)$$

The expression (7) is similar to the state expansion (5), but the phases are not necessarily the same. To adjust the phases, we include N “azimuthal angles” in rotations generated by

$$\mathbf{z}(\ell) = \sigma_3^{\lambda_n} \otimes \sigma_3^{\lambda_{n-1}} \otimes \sigma_3^{\lambda_{n-2}} \otimes \dots \otimes \sigma_3^{\lambda_1}, \quad \ell \in [0, n] \cap \mathbb{Z}. \quad (9)$$

The operators $\mathbf{z}(\ell)$ are analogous to the $\mathbf{b}(\ell)$ but with σ_3 replacing σ_1 . Each $\mathbf{z}(\ell)$ either commutes or anticommutes with any given $\mathbf{b}(\ell')$ and is projected to unity by $\psi_0 = P$. Thus, a product of rotors

$$\begin{aligned}R &= \prod_{\ell=0}^{N-1} \exp\left[-\frac{i}{2} \mathbf{z}(\ell) \phi_\ell\right] \prod_{\ell'=0}^{N-1} \exp\left[-\frac{i}{2} \mathbf{b}(\ell') \theta_{\ell'}\right] \\ &= \exp\left[-\frac{i}{2} \sum_{\ell=0}^{N-1} \mathbf{z}(\ell) \phi_\ell\right] \exp\left[-\frac{i}{2} \sum_{\ell'=1}^{N-1} \mathbf{b}(\ell') \theta_{\ell'}\right]\end{aligned}\quad (10)$$

when projected onto the minimal left ideal by ψ_0 gives a unique state $\psi = R\psi_0$ (5) with arbitrary phase factors. Again in terms of physical operators, the θ 's are phases that arise due to applied fields and ϕ 's arise mainly due to free evolution, but sometimes due to geometry.

The N basis-state operators $\mathbf{b}(\ell)$ are not unique. We can alternatively choose elements generating the Clifford algebra $\mathcal{C}\ell_n$ with

$$\begin{aligned} \mathbf{e}_1 &= 1 \otimes \cdots \otimes 1 \otimes 1 \otimes \sigma_1 = \mathbf{b}(1) \mathbf{z}(0) \\ \mathbf{e}_2 &= 1 \otimes \cdots \otimes 1 \otimes \sigma_1 \otimes \sigma_3 = \mathbf{b}(2) \mathbf{z}(1) \\ \mathbf{e}_m &= \mathbf{b}(2^{m-1}) \mathbf{z}(2^{m-1} - 1). \end{aligned} \quad (11)$$

These anticommute and square to $+1$: $\mathbf{e}_j \mathbf{e}_k + \mathbf{e}_k \mathbf{e}_j = 2\delta_{jk}$. Many other bases are possible in the form $\mathfrak{B}(\ell)P = \mathbf{b}(\ell)\mathbf{z}(L_\ell)$ for the expansion (5). Since $\mathbf{z}(L_\ell)\psi_0 = \psi_0$, the basis states are actually the same, but the difference in operators is important since given any set $\{\mathfrak{B}(\ell)\}$, one can find linear combinations $\sum_{\ell=0}^{N-1} c_\ell \mathfrak{B}(\ell)$ that are singular, that is noninvertible, and such nonunitary cannot be expressed as a rotor. Such cases do not cause problems since other operator sets can be found in which the linear combinations are not singular.

The strength of our approach is evident from the example of the two-qubit or four-level system rewritten in standard matrix form (although the algebra does not require matrices). Four-level systems have been previously studied in the context of coupled qubits [15, 16, 17, 18], spin 3/2 fermions [19], and controllability [20, 21]. The general state is (5) with $N = 4$ and

$$\begin{aligned} \psi_0 &= P = P_3 \otimes P_3 = \frac{1}{4} \sum_{\ell=0}^3 \mathbf{z}(\ell) = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \\ \mathbf{b}(0) &= \mathbf{z}(0) = 1 \otimes 1 = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \\ \mathbf{b}(1) &= 1 \otimes \sigma_1 = \begin{pmatrix} 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{pmatrix} \\ \mathbf{b}(2) &= \begin{pmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \end{pmatrix}, \quad \mathbf{b}(3) = \begin{pmatrix} 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \end{pmatrix}. \end{aligned}$$

The matrices for $\mathbf{z}(\ell)$ are diagonal and are similarly obtained. Each $\mathbf{b}(\ell)$ and $\mathbf{z}(\ell)$ is its own inverse, but linear combinations are not necessarily invertible as we demon-

strate below. However, the state ψ is arbitrary:

$$\sum_{\ell=0}^3 c_\ell \mathbf{b}(\ell) \psi_0 = \begin{pmatrix} c_0 & c_1 & c_2 & c_3 \\ c_1 & c_0 & c_3 & c_2 \\ c_2 & c_3 & c_0 & c_1 \\ c_3 & c_2 & c_1 & c_0 \end{pmatrix} \psi_0 = \begin{pmatrix} c_0 & 0 & 0 & 0 \\ c_1 & 0 & 0 & 0 \\ c_2 & 0 & 0 & 0 \\ c_3 & 0 & 0 & 0 \end{pmatrix} \psi_0. \quad (12)$$

In terms of compact unitary factors

$$\psi = \exp \left[-\frac{i}{2} \sum_{\ell=0}^3 \phi_\ell \mathbf{z}(\ell) \right] \exp \left[-\frac{i}{2} \sum_{\ell'=1}^3 \theta_{\ell'} \mathbf{b}(\ell') \right] \psi_0.$$

We can relate the angles $\theta_{\ell'}$, ϕ_ℓ to the complex coefficients c_ℓ by explicit expansions (6) while noting relations such as $\mathbf{b}(1)\mathbf{b}(2) = \mathbf{b}(3)$:

$$\begin{aligned} &\exp \left[-\frac{i}{2} \sum_{b'=1}^3 \theta_{b'} \mathbf{b}(b') \right] \\ &= \left[\cos \frac{\theta_1}{2} \cos \frac{\theta_2}{2} \cos \frac{\theta_3}{2} + i \sin \frac{\theta_1}{2} \sin \frac{\theta_2}{2} \sin \frac{\theta_3}{2} \right] \mathbf{b}(0) \\ &\quad - i \left[\sin \frac{\theta_1}{2} \cos \frac{\theta_2}{2} \cos \frac{\theta_3}{2} - i \cos \frac{\theta_1}{2} \sin \frac{\theta_2}{2} \sin \frac{\theta_3}{2} \right] \mathbf{b}(1) + \cdots \end{aligned}$$

with the $\mathbf{b}(2)$ and $\mathbf{b}(3)$ coefficients obtained from that for $\mathbf{b}(1)$ by cyclic permutation. This, plus the normalization condition (8) is sufficient to relate the three polar angles θ_j , $j = 1, 2, 3$, to the magnitudes of the complex coefficients c_ℓ . The pattern of commuting and anticommuting pairs $\mathbf{z}(\ell)\mathbf{b}(\ell')$ plus the relation $\mathbf{z}(\ell)P = P$, implies

$$\exp \left[-\frac{i}{2} \sum_{\ell'=0}^3 \phi_{\ell'} \mathbf{z}(\ell') \right] \mathbf{b}(\ell) P = \mathbf{b}(\ell) \exp \left(-\frac{i}{2} \alpha_\ell \right) P$$

with

$$\begin{aligned} \alpha_0 &= \phi_0 + \phi_1 + \phi_2 + \phi_3 \\ \alpha_1 &= \phi_0 - \phi_1 + \phi_2 - \phi_3 \\ \alpha_2 &= \phi_0 + \phi_1 - \phi_2 - \phi_3 \\ \alpha_3 &= \phi_0 - \phi_1 - \phi_2 + \phi_3 \end{aligned}$$

and this is enough to relate the complex phases of the c_ℓ to the four azimuthal angles ϕ_k , $k = 0, 1, 2, 3$.

As mentioned above, for any choice of basis operators $\mathfrak{B}(\ell)$, there exist some states for which the linear combination $\sum_\ell c_\ell \mathfrak{B}(\ell)$ is singular, that is, has no inverse. For the basis operators $\mathbf{b}(\ell)$, for example, the problem arises with the entangled states $\psi_\pm = \frac{1}{\sqrt{2}} (\mathbf{b}(0) \pm \mathbf{b}(3)) \psi_0$. It is seen by inspection that the matrix $\sum_{\ell=0}^3 c_\ell \mathbf{b}(\ell)$ given in (12) has a vanishing determinant when $c_3 = \pm c_0$ and $c_1 = 0 = c_2$. The problem is resolved by using different basis operators. Thus, if we adopt the $\mathcal{C}\ell_2$ basis with phases that make all basis elements antihermitian, we get the expansion

$$\sum_{\ell=0}^3 c_\ell \mathfrak{B}(\ell) = \begin{pmatrix} c_0 & ic_1 & ic_2 & -c_3 \\ ic_1 & c_0 & c_3 & -ic_2 \\ ic_2 & -c_3 & c_0 & ic_1 \\ c_3 & -ic_2 & ic_1 & c_0 \end{pmatrix}, \quad (13)$$

which is unitary for the choice $c_0 = c_3 = 1/\sqrt{2}$ and $c_1 = 0 = c_2$.

The method can be applied to arbitrary 2^n -level systems. The relation of the tensor-product basis states, interpreted as giving spin orientations of separate spin-1/2 systems, to the eigenstates of the system depends on the Hamiltonian. For example, for $n = 2$, the Hamiltonian

$$H = E_0 + \gamma_1 \mathbf{s}_1 \cdot \mathbf{B} \otimes 1 + 1 \otimes \gamma_2 \mathbf{s}_2 \cdot \mathbf{B} + 2\lambda \mathbf{s}_1 \cdot \mathbf{s}_2, \quad (14)$$

where \mathbf{B} is the external magnetic field, γ_j are the gyromagnetic ratios, and 2λ is the spin-spin coupling constant, has the matrix form

$$\begin{pmatrix} \hbar\omega_{0++} + \frac{\lambda}{2} & 0 & 0 & 0 \\ 0 & \hbar\omega_{0+-} - \frac{\lambda}{2} & \lambda & 0 \\ 0 & \lambda & \hbar\omega_{0-+} - \frac{\lambda}{2} & 0 \\ 0 & 0 & 0 & \hbar\omega_{0--} + \frac{\lambda}{2} \end{pmatrix}, \quad (15)$$

where $\omega_{0\pm\pm} \equiv \omega_0 \pm \omega_1 \pm \omega_2$. States $\psi_0 = P$ and $\psi_3 = \mathbf{b}(3)\psi_0 = \sigma_3 \otimes \sigma_3 P$ are eigenstates, but linear combinations of $\psi_1 = \mathbf{b}(1)P$ and $\psi_2 = \mathbf{b}(2)P$ form the other eigenstates. In the 2-D basis $\{\psi_1, \psi_2\}$,

$$H = \hbar\omega_0 - \lambda/2 + \begin{pmatrix} \Delta & \lambda \\ \lambda & -\Delta \end{pmatrix} \quad (16)$$

with $\Delta = \hbar(\omega_1 - \omega_2)$ and the eigenenergies are $\hbar\omega_0 - \lambda/2 \pm \sqrt{\Delta^2 + \lambda^2}$. Since we have a total of four independent energy parameters, we expect to be able to represent an arbitrary 4-level system with these coupled qubits.

More generally, however, there is no need to associate the tensor-product states literally with independent spins on spin- $\frac{1}{2}$ particles. Tensor products of Pauli spin matrices are simply a way to specify matrix representations of orthogonal states and operators on them. A complete set of $2^n \times 2^n$ matrices is always given by tensor products of n spin matrices σ_μ . Nothing inherent in our treatment restricts it to systems of n -qubits. Any set of N levels can be similarly handled. In the same vein, the reference state ψ_0 need not be one with maximum total spin component along the z axis. Formally, we can transform the reference state multiplying our spinors ψ by a transformation rotor from the right. This shows that the transformation between any two states of the system can be represented by a unitary rotor with $N - 1$ polar-like angles and N azimuthal ones. For $N > 1$, this is fewer than the N^2 real parameters required to specify a unitary transformation on the system in general, but this reduction simply reflects the fact that only a small subset of the possible unitary transformations are required to transform between arbitrary states. For most practical problems in quantum control, it is only necessary to transform a few given states to others (for example, making a quantum gate), and therefore our representation can be expected to lead to more compact control schemes.

In summary, we have demonstrated that evolution of an arbitrary n -qubit or $N = 2^n$ -level quantum state into another state can be described by a complex algebra of only N independent elements. This compact unitary transformation consists of $2^{n+1} - 1$ real angles, 2^n of which are azimuthal-like and $2^n - 1$ that are polar-like. These results are expected to lead to optimal schemes for coherent control and quantum computing.

It is pleasure to acknowledge helpful discussions with Prof. A.R.P. Rau and Dr. D. B. Uskov of Louisiana State University. WEB and CR gratefully acknowledge support of the research by the Natural Science and Engineering Research Council of Canada.
