8 August 1996

Abstract

An introductory review of the linear ion trap is given, with particular regard to its use for quantum information processing. The discussion aims to bring together ideas from information theory and experimental ion trapping, to provide a resource to workers unfamiliar with one or the other of these subjects. It is shown that information theory provides valuable concepts for the experimental use of ion traps, especially error correction, and conversely the ion trap provides a valuable link between information theory and physics, with attendant physical insights. Example parameters are given for the case of calcium ions. Passive stabilisation will allow about 200 computing operations on 10 ions; with error correction this can be greatly extended.

1 Introduction

This paper is a contribution to the rapidly developing eld of quantum inform ation theory and experiment. Quantum information is an interdisciplinary subject, in which computer scientists and other experts in the theory of classical information and computing are not necessarily familiar with quantum mechanics, while physicists and other experts in quantum theory are not necessarily familiar with information theory. Furthermore, whereas the eld has enjoyed a rich theoretical treatment, there is a lack of an experimental basis to underpin the ideas. This is especially signi cant to the issue of error correction, or more generally any stabilisation of a quantum computer, which is among the most important unresolved issues in this eld. The aim of this paper is to o er an aid to people from di erent sides of the subject to understand issues in the other. That is to say, the ideas of quantum information and computing will be introduced to experimental physicists, and a particular physical system which might in plement quantum computing will be described in detail for the bene t of theoreticians. I hope to give su cient inform ation to form more or less a blueprint' for the type of quantum inform ation processor which is currently achievable in the lab, highlighting the various experimental problems involved. The discussion is like a review in that it brings together the work of other authors rather than provides much original material. However, an exhaustive review of the wide range of subjects involved is not intended, and as a result it will not be possible to do justice to the e orts of the many people who brought the experimental and theoretical program mes to their present state of accomplishment.

The plan of the article is as follows. In section 2 the concepts of quantum information processing are introduced, especially the Universal'set of quantum logic gates. In section 3 the linear ion trap is considered as a realisable system in which these ideas can be applied. A physical process by which quantum logic gates may be applied in an ion trap is described in detail. Limitations on the size of the processor (number of quantum bits) and speed of operation ('switching rate') are discussed. In sections 4 and 5 the main experimental techniques required to realise the ion trap processor in the lab are discussed; these are laser cooling of the ions, and low-noise generation of the correct dc and radio frequency (rf) voltages for the trap electrodes, as well as a good choice of electrode design. In section 6 we begin to establish de nite values for the experim ental param eters, by considering speci c candidate ions to which the m ethods can be applied. Example values are given for the singly-charged calcium ion. In section 7 experimental lim itations such as unwanted heating of the ion motion are discussed. This leads to an estimate for the maximum number of unitary operations (quantum gates) which could be carried out in the processor before the coherence of the system is destroyed. It is found that for an example case of around 10 ions, a few hundred operations represents a severe experimental challenge. The use of quantum error correction to enhance the perform ance is then discussed. This should allow great increases in the number of operations, while preserving coherent evolution. The conclusion outlines the most important avenues for future investigation.

2 Requirements for Quantum Information Processing

Quantum information theory is concerned with understanding the properties of quantum mechanics from an information theoretic point of view. This turns out to be a very fruitful approach, and leads naturally to the idea of information processing or computing, so that one poses the question \what are the possibilities for, and the limitations of, information processing in a physical system governed by the laws of quantum mechanics?" A great deal of theoretical insight into this question has been gained. For instance, it is possible to identify a sm all set of building blocks' which if they could be realised and many of them combined, a 'universal quantum computer' could be constructed. The computer is 'universal' in the sense that it could simulate, by its computations, the action of any other computer, and so is more or less equal to or better than any other computer [1]. The phrase in ore or less equal' has a technical de nition which will be elaborated in section 3.3. A speci c set of such building blocks is a set of two-state system s (think of a line of spins), and a simple unitary interaction which can be applied at will to any chosen small set of these two-state system s [2, 3]. In this context it is useful to describe the interaction in terms of its propagator $U = \exp(iH t=h)$ rather than its H am iltonian H. Here t is some nite interval of time (one 'clock period' in computing term inology) at the end of which the propagator has had just the e ect desired on the computer. A fler this time the interaction H falls to zero (is turned o). Such a propagator is referred to as a 'gate', by analogy with a logic gate in a classical computer.

To do quantum information processing, these requirements may be summed up as that you need a system (quantum computer' or QC) with a Hilbert space of su cient number D of dimensions, over which you have complete experimental control. That is, you can tell your system to go from any of its states to any other, without uncontrollable error processes such as relaxation and decoherence.

It is usual to consider a H ilbert space whose number of dimensions is a power of 2, is $D = 2^{K}$, in which case we say we have a system of K quantum bits or 'qubits'. Examples of qubits are the spin state of an electron (2 orthogonal states and so a single qubit) the polarization state of a photon (a single qubit), the internal state of an atom having two energy levels of total spin 1 and 2 (8 states and so 3 qubits). W hereas these are all equivalent from the point of view of the properties of H ilbert space, they are very di erent from the point of view of experimental in plementation. The use of the word 'qubit' rather than 'two-state system' emphasizes this equivalence between otherwise very di erence quantum systems. In fact, the idea of a qubit has further signi cance, since it can be shown [4, 5] that the essential properties of any quantum state of an nite set of qubits and back again [6]. The important point is that the average number of qubits required to do this is equal to the von N eum ann entropy of the initial state (\quantum noiseless coding theorem ", also referred to as \quantum data compression" [7]). Therefore the qubit gives a measure of inform ation content in quantum systems, and is thus the correct quantum equivalent of the classical bit.

Having accepted the invention of a new word for the quantum two-state system, there is justiled resistance to the adoption of the terms 'computer' and 'computing' to describe the larger quantum systems with which we are concerned. This is because it is an open question whether a true quantum 'computer' could ever function, since once the physical system has su cient degrees of freedom to be meaningfully called a 'computer', the large-scale interference necessary for parallel quantum computing may always be destroyed in practice, owing to the sensitivity of such interference to decoherence. For this reason, them orem odest term 'inform ation processor' is used here as much as possible. The 'processing' might consist of quite simple manipulations, such as allowing one qubit to interact with another, followed by a measurement of the state of the second qubit. Even such a simple operation has a practical use, since it can be used for error detection at the receiving end of a quantum communication channel, leading to the possibility of secure quantum key distribution for cryptography [8, 9, 10].

Decoherence and dissipation in quantum mechanics is a subject in its own right, and has been discussed since the birth of quantum theory. Recent reviews and references may be found in

[11, 12, 13]. Its impact on quantum computers in particular has been considered [14, 15, 16], and will be taken into account in section 7.

It can be shown [17] that to produce arbitrary unitary transform ations of the state of a set of qubits, which is what one wants for inform ation processing, it is su cient to be able to produce arbitrary rotations in H ilbert space of any individual qubit, is the propagator

$$\exp(i = 2) = \begin{array}{c} \cos(-2) & e^{i} \sin(-2) \\ e^{i} \sin(-2) & \cos(-2) \end{array}$$
(1)

and to be able to carry out the 'controlled-rotation' operation crot = j00ih00j+ j0ih01j+ j10ih10j j11ih11jbetween any pair of qubits. The notation used here is standard, the kets j0i and j1i refer to two orthogonal states of a qubit. This basis is referred to as the 'com putational basis', since this aids in designing useful algorithm s for the QC.From a physical point of view, it is useful to take the com putational basis to be the ground and excited eigenstates of the H am iltonian of the relevent two-level system, though this is by no means required and any basis will serve. States such as j01i are product states j0i = j0i j1i where the rst written ket refers to one qubit, and the second another. For our purposes the qubits will always be distinguishable so we do not need to worry about the sym etry of the states (with respect to exchange of particles) and any related quantum statistics.

As mentioned previously, an operation like crot is a propagator acting on the state of a pair of qubits. In matrix form it is written

$$U_{crot} = \begin{bmatrix} 0 & 1 & 1 \\ B & 1 & C \\ B & 1 & C \\ 0 & 1 & A \end{bmatrix}$$
(2)

in the basis 00i; 01i; 10i; 11i, where matrix elements which are zero have not been written. The appellation controlled rotation comes from the fact that if the rst qubit is in the state 0i, crot has no e ect, whereas if the rst qubit is in the state 1i, crot rotates the state of the second by the Pauli _z operator.

The two operators just described form a universal set, which means that any possible unitary transformation can be carried out on a set of qubits by repeated use of these operators or quantum gates', applied to di erent qubits [17]. Another commonly considered quantum gate is the 'controlled not' or 'exclusive or' (xor) gate

$$U_{XOT} = \begin{bmatrix} 0 & 1 & 1 \\ B & 1 & C \\ C & 0 & 1 \\ C & 0 & 1 \\ 1 & 0 \end{bmatrix}$$
(3)

see also equation (16). This gate has no e ect if the rst qubit is in the state $\mathcal{D}i$, but applies a not operation ($_x$ Pauli spin operator) to the second qubit if the rst is in the state $\mathcal{J}i$. In

the com putational basis, this m eans that the state of the second qubit becom es the xor of the two input qubit values. We have introduced crot before xor in this discussion, going against standard practice, because we shall see later that crot is easier to implement in an ion trap.

It should be emphasized that this model in terms of quantum gates operating on quantum bits is by no means the only way to think about quantum computation, but is the way which is most well understood at present, and is certainly very powerful. O ther models include those based on cellular autom ata, and simulated annealing.

A further simplication of the physical construction of a quantum computer is as follows. Instead of seeking a means to carry out crot between any pair of qubits directly, it is su cient to have one special qubit which can undergo crot with any of the others. This special qubit acts as a one-bit bus' to carry quantum information around the computer, making repeated use of the swap operation j0ih00j + j10ih01j + j1ih10j + j11ih11j. To carry out crot between any pair of qubits x and y, one makes use of the bus bit B as follows: crot (x;y) = swap (B;x) crot (B;y) swap (B;x). The operation swap can be built out of three xor's with the order of the bits alternating: swap (B;x) = xor (B;x) xor (x;B) xor (B;x), however in practice this construction is unnecessarily com plicated, since swap can be applied more or less directly in most physical in plem entations.

The use of a bus bit makes the physical construction of a quantum information processor much simpler, and indeed most current proposals use this concept. However, it has the major disadvantage that more than one gate (acting on di erent sets of qubits) cannot be carried out simultaneously (ie in parallel), except single qubit rotations. A coepting this limitation, the minimum requirement for our processor is arbitrary rotations of any single qubit, plus crot and swap between the bus qubit and any of the others. This is the minimum set of computing operations', in the sense that arbitrary transformations can be carried out by means of this small set. However, this establishes neither that arbitrary transformations can be carried out by means of the ciently, nor that they can be carried out without uncorrectable errors, both of which are important additional considerations for a computer. We will return to these issues in the sections 3.3 and 7.1.

A further ingredient for quantum inform ation processing is that the result of the process | here the nal state of the quantum system | must be able to be measured without errors. A basis is chosen (typically the eigenbasis of the system Ham iltonian) and a measurement of all the qubits is carried out in this basis.

To make a modest processor (a few qubits) the easiest approach is probably to use single particles with several internal degrees of freedom. Examples are a spin $J = 2^{K-1}$ 1=2 in a magnetic eld (say J = 7=2 giving 2J + 1 = 8 dimensions and therefore K = 3 qubits); a molecule or con ned particle with 2^{K} accessible vibrational states ('accessible' in this context means the experimenter can cause computing operations among the states at will). This approach will be interesting in the short term. However it is di cult to imagine it being extended in the longer term to enable the realisation of a really interesting processor with hundreds of qubits. A lso, it is not clear how to apply arbitrary operations to a single particle (spin, m olecule) with an evenly spaced ladder of energy levels, owing to level degeneracies in the interaction picture.

There are now several proposed physical system s which m ight one day make a quantum computer [18, 19, 20, 21, 22]. We will concentrate on the system of a line of ions in an ion trap, since it appears to be the most promising at present. However, developments in solid state physics may overtake us, and one should bear this in mind. It is not easy to couple the quantum information out of an ion trap system (ie in the form of qubits, not classical measurements), which is important for quantum communication. In this regard the approach based on strong coupling between an atom and a cavity mode appears more useful, since there a bit of quantum information could in principle be transferred into the polarisation state of a photon which then leaves the system in a chosen direction (a 'ying qubit') [23]. However, such ideas could be applied to trapped ions, making a form of hybrid processor, so the ion trap system remains an interesting candidate even for quantum communication purposes.

3 Ion Trap M ethod

For reviews and references on ion trapping, see for example [24, 25, 26, 27, 28]. The ion trap system which interests us uses a line of N trapped ions. Each ion has two stable orm etastable states, for example two hyper ne components of the electronic ground state (which usually requires an odd isotope), or two Zeem an sublevels of the ground state, separated by applying a m agnetic eld. The ground state and a m etastable electronic exited state (eg a D state for ions of a kaline earth elements) m ight also be used, but this is a poor choice since the laser linew idth and frequency, as well as most of the m incors etc on the optical bench, will have to be very precisely controlled for such an approach to work. There have been optim istic estim ates of the com putational abilities of an ion trap processor, based on the use of such optical transitions, but one should beware of the lack of realism in such estim ates. This will be discussed m ore fully once we have seen exactly how the system is intended to operate.

There are N laser beam pairs, each interacting with one of the ions, (or a single beam which can be directed at will to any chosen ion), see gure 1. Each ion provides one qubit, the two-dimensional H ibert space being spanned by two of the ion's internal energy eigenstates. A further N + 1'th qubit acts as a bus' enabling the crucial crot operations. This qubit is the vibrational motion of the whole ion string in the trap potential. This motion must be quantised, in other words the ion cloud temperature must be reduced well below the 'quantum lim it' de ned by the axial vibrational frequency in the ion trap:

$$k_{\rm B} T = h!_{\rm z}$$
 (4)

The rst major experimental challenge (after making a trap and catching your ions) is to cool the ions down to this quantum regime. Note that the quantum regime for the trapped motion of the ion is not related to the \Lamb-D icke" regime which will be considered below. In brief, it will be shown that one wants to operate well into the quantum regime, but on the border of the Lamb-D icke regime.

So far the quantum regime has only been achieved for a single ion of either M ercury in two dimensions [29] or Beryllium in three dimensions [30]. Both experiments used optical sideband cooling in the resolved sideband (tight trapping) limit. This and other possible cooling techniques will be discussed. Traps for neutral atoms have also attained the motional ground state, most spectacularly in the case of Bose Einstein condensation [31], but also in optical lattices [32]. These systems do not (at present) provide full control of individual atoms and interactions between pairs, so we will not discuss them. How ever, they lend further weight to the impression that it is in atom ic physics and quantum optics, rather than solid state devices, that quantum inform ation processing will be most fruitful in the immediate future.

To get to the quantum regime, it appears to be necessary to use a Paul rather than Penning trap, since rf technology allows tighter con nem ent than does high magnetic eld technology. Therefore only the Paultrap (rftrap) will be considered from now on, although we may perm it ourselves to add a magnetic eld if we wish, for some other reason such as to enhance the stability or split the Zeem an levels. In any case, tighter con nem ent enables a faster 'sw itching-time' for quantum gates such as crot, so the tightest possible trap is the best option.

Note that once more than a single ion is in a three-dimensional rf trap of standard geometry (with the rf voltage between end caps and a ring) matters are complicated since nomore than one ion can be at the centre of the trap potential. Away from the centre, ions undergo rf micromotion and this causes heating if there is more than one ion, due to collisions (C oulom b repulsion) which force the micromotion out of quadrature with the rf eld. To avoid this, one must use a linear or ring geometry. The con nement along the axis is then either due to a static eld from end cap electrodes (linear case), or to repulsion between ions combined with their con nement to a ring shape. In this case, only radial micromotion is present, but this vanishes for all the ions if they lie along the axis at the centre of the radial potential, so rf heating is avoided. The ring case must im ply a sm all micromotion tangential to the ring, since the tangential and radial con nement can't be completely decoupled, but as far as I know this has not yet been found to be a problem.

3.1 A verage m otion

We will model a row of N ions in a trap as a system of N point charges in a harm onic potential well of tight radial con nement, is $|_x;|_y |_z$, see gure 2. The oscillation frequencies $|_x;|_y$ and $|_z$ are parameters which will be obtained from the electrode geometry and potentials in section 5. The total H am iltonian is

$$H = \sum_{i=1}^{N} \frac{1}{2} M + \sum_{x}^{2} \hat{X}_{i}^{2} + \sum_{y}^{2} \hat{Y}_{i}^{2} + \sum_{z}^{2} \hat{Z}_{i}^{2} + \frac{\hat{P}_{i}^{2}}{M^{2}} + \frac{\hat{Y}_{i}^{2}}{M^{2}} + \frac{\hat{Y}_{i}^{2}}{\frac{1}{2}} + \frac$$

For $!_x;!_y$ $!_z$ and at low temperatures, the ions all lie along the z-axis, so we can take $\hat{\mathcal{R}}_i = \hat{\mathcal{R}}_j j' \not \hat{\mathcal{I}}_i = \hat{\mathcal{I}}_j j$ and the radial and axial motion can be separated. The axial motion interests us, so the problem is one-dimensional. A length scale is given by

$$z_{s} = \frac{e^{2}}{4 \quad _{0}M ! _{z}^{2}}$$
(6)

which is of the order of the separation between the ions (typically 10 to 100 m). Solving the classical equations of motion (ie the operators \hat{Z} ; \hat{P}_z become classical variables z; p_z) one obtains the equilibrium positions shown in gure 3. W ith more than two trapped ions, the outer ions tend to push the inner ones closer togther, so the ion positions depend on N (see equation (9)). Remarkably, however, the frequencies of the rst two norm almodes of oscillation about these equilibrium positions are independent of N (for sm all oscillations) [21], and those of higher modes are nearly independent of N. The frequencies of the rst two modes are $!_z$ and $3!_z$, and those of higher modes are given approximately by the list f1; $3; 29=5; 3:051; 3:671; 4:272; 4:864; 5:443; 6:013; 6:576g, which gives the frequency of the highest mode, in units of <math>!_z$, for N = 1 to 10. The near independence of N of the mode frequencies is illustrated by gure 4.

The lowest mode of oscillation corresponds to harmonic motion of the centre of mass of the ion string. In this mode, all the ions move to and fro together. It is important that the frequency of this mode is significantly different from that of any other mode, since this means that experimentally one can excite the centre of mass mode without exciting any of the others.

We can now proceed directly to a quantum mechanical treatment, simply by treating the centre of mass coordinate z_{cm} as a harmonic oscillator. The classical result that the centre of mass normal mode has frequency $!_z$ remains valid even though the ion wavefunctions may now overlap, since all the internal interactions among the ions cancel when one calculates the centre of mass motion. Since we have an oscillator of mass NM and frequency $!_z$, the energy eigenfunctions are

$${}_{n}(z_{cm}) = \frac{N M !_{z}}{h2^{2n} (n !)^{2}} H_{n} z_{cm} q \overline{N M !_{z}} = h e^{N M !_{z} z_{cm}^{2} = 2h}$$
(7)

The spatial extent of the Gaussian ground state probability distribution is indicated by its standard deviation

$$z_{\rm cm} = \frac{q}{h=2N M !_z}$$
 (8)

Since we wish a di erent laser beam to be able to address each of the ions, we require z_{cm} to be small compared to the separation between ions. The closest ions are those at the centre of the line. A num erical solution of (5) yields the following form ula for the separation of the central ions:

$$z_{min}$$
 ' 2:0 $z_s N^{-0.57}$: (9)

This form ula is plotted for N 10 in gure 3. An approximate analytical treatment for N 1 does not predict a power-law dependence of z_{min} on N, but rather $z_{min} / z_s (\log (N) = N^2)^{1=3}$ [34]. However, (9) is more accurate for N < 10 and remains accurate for the range of N which interests us (up to, say, N = 1000). Setting $z_{cm} = z_{min}$ yields

$$\frac{!_{z}}{M} = \frac{32N^{1:86}}{h^{3}} = \frac{e^{2}}{4} \int_{0}^{1:2} \prime 2:4 = 10^{21} N^{1:86} H z=u$$
(10)

where u is the atom ic m ass unit 1:66057 10^{27} kg. This condition is easily fulled in practice, with $!_z$ no greater than a GHz, and M between 9 and 200 u. Therefore it is legitimate to picture the ions as strung out in a line, each sitting in a small wavepacket centred at its classical equilibrium position, not overlapping the others. Note that (10) does not guarantee that the ions are su ciently separated to be addressed by di erent laser beam s, only that their wavefunctions do not overlap.

In the above it was assumed that the radial con nement was su cient to cause the ions to lie along the z-axis, rather than form a zigzag or helix about it. The onset of such zigzag modes has been studied numerically [33] and analytically [34]. They occur when the ions approach su ciently closely that the local potential minimum at the position of an ion on the z axis becomes a saddle point. For a string of ions uniform ly spaced by z (which is not the case in our harmonic trap), the transition from a line to a zigzag occurs when [35] $!_r^2$ 42072 ($z_s = z$) $^3!_z^2$, where we have taken the case $!_x = !_y$ $!_r$. Setting $z = z_{min}$, this leads to the condition

$$\frac{!_{r}}{!_{z}} > 0.73N^{0.86}$$
(11)

for the prevention of zigzig m odes. For N 1, an approximate analytic treatment yields the condition [34]

$$\frac{!_{r}}{!_{z}} > 0.77 \frac{N}{\text{bgN}}:$$
(12)

These num erical and approximate analytic formulae are within 10% agreement for 3 < N < 2000.

3.2 Principle of operation

The principle of operation of an ion trap 'inform ation processor' was described by C irac and Zoller [21], and the most important elements of such a system were rst realised in the laboratory by M onroe et al [36]. W hereas the transition operators given by C irac and Zoller were calculated for standing-wave excitation of allowed single-photon transitions, experimentally M onroe et al em ployed travelling-wave excitation of two-photon R am an transitions (cf gures 1 and 8). The basic form of the operators is independent of the type of excitation used, how ever. The m ethod

m ay be understood by reference to gure 5, which shows the relevant energy levels for one of the ions in the trap. We consider three of the ion's internal energy eigenstates $f_1;M_1i; f_2;M_2i$ and $f_{aux};M_{aux}i$, and various excitations of the centre of mass motion. The ion's internal energy levels are separated in frequency by $!_0$ and $!_{aux}$ as indicated on gure 5. Note that all these levels are low -lying, separated from the ground state only by hyper ne and Zeem an interactions (see gure 8), so their natural lifetim e against spontaneous emission of rf photons is essentially in nite. Figure 5 shows the lowest-lying excitations of the second, third and fourth norm al modes as well as the rst, to act as a rem inder of the location of the closest extraneous levels whose excitation we wish to avoid. The energy eigenstates of the vibrational modes. O nly the ground state $j_1; 0; 0; ::: i$ where the n_i are the excitations of the cantre of mass $j_1; 0; 0; :: i$ will be involved in the operations we wish to invoke. This centre of mass vibrational degree of freedom is often referred to som ewhat loosely as a 'phonon'. The 'com putational basis' consists of the states

It will now be shown how to carry out crot between any single ion's internal state and the bus (phonon) bit, then how to carry out arbitrary rotations of the internal state of an ion, then how to carry out swap between any ion and the bus bit. Recalling the discussion in section 2, these three operations form a universal set and so allow arbitrary transform ations of the stored qubits in the processor.

The auxillary states jaux; ii $f_{aux}; M_{aux}$ i j;0;0;:::i (i = 0;1) are available as a kind of Shelf' by m eans of which useful state-selective transform ations can be carried out among the computational basis states. If one applies radiation at the frequency $!_{aux} + !_z$, then inspection of gure 5 will reveal that only transitions between j;11 and jaux;01 will take place (assuming that unwanted levels such as j1;21 are unoccupied)¹. If one applies a 2 pulse at this frequency then the state j1;11 is rotated through 2 radians, and therefore simply changes sign. In the computational basis, the e ect is equal to that of the crot operator described in section 2, see equation (2).

A 2 pulse at frequency $!_0$ $!_{aux}$ $!_z$ also produces a controlled rotation, only now the m inus sign appears on the second element down the diagnonal of the unitary m atrix, rather than the fourth, causing a sign change of the component \mathfrak{P} ; li rather than \mathfrak{I} ; li. This case w ill be called c. rot, the negation symbol: referring to the fact that here the second qubit is rotated if the rst is in the state \mathfrak{P} ir rather than \mathfrak{I} :

¹C irac and Zoller originally proposed to produce the selective e ect of this crot operation by m eans of a chosen laser polarisation rather than frequency. However, experimentally frequencies can be discriminated m ore precisely than polarisations, which explains why M onroe et. al. chose to use a frequency-rather than polarisation-selective m ethod.

To rotate an ion's internal state without a exting the centre of mass motion, one applies radiation of frequency $!_0$. If such radiation has phase with respect to some de ned origin of phase, and duration su cient to make a p pulse, then the e ext in the computational basis is

$$V^{p}() \qquad \begin{array}{c} \cos(p = 2) & ie^{i} \sin(p = 2) & 1 & 0 \\ ie^{i} \sin(p = 2) & \cos(p = 2) & 0 & 1 \\ & & & & \\ \end{array}$$
(14)

where we have followed the notation of [21], but used p instead of k to avoid confusion with the wave vector. Note that to apply such rotations successfully, it is necessary to have the phase of the radiation under experimental control. That means under control at the position of the ion, not just in some stable reference cavity. This constitutes a severe experimental constraint which makes computational basis states separated by radio frequencies highly advantageous compared to states separated by optical frequencies. On the other hand, in order to have the right phase experimentally, note that one need not worry about the continuous precession at frequency $!_0$ caused by the internal H am iltanian of each ion. The laser eld keeps step with this precession, as becomes obvious when one uses the interaction picture, which we have done in plicitly in writing equation (14). Problem s arise when di erent ions have di erent internal energies, due to residual electric and magnetic elds in the apparatus, but such problem s are sum ountable.

The centre of mass motion acts as the bus' qubit described in section 2. To carry out xor (B;x), between the bus' and the internal state of a single trapped ion, M onroe et. al. applied rst a =2 pulse at frequency $!_0$,

$$V^{1=2} (=2) = \frac{1}{p-2} \qquad \begin{array}{c} 1 & 1 & 1 & 0 \\ 1 & 1 & 1 & 0 & 1 \\ 1 & 1 & 0 & 1 \\ \end{array} \qquad (15)$$

followed by crot as described in the paragraph after equation (13), followed by a second =2 pulse at $!_0$ with phase displaced by with respect to the rst, ie V $^{1=2}$ (=2)². A straightforward calculation shows that this sequence produces exactly

$$\operatorname{xor}(\operatorname{cm};\operatorname{ion}) = \begin{pmatrix} 0 & 1 & 0 & 0 & 0 \\ B & 0 & 0 & 0 & 1 \\ B & 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \end{pmatrix}$$
(16)

By symmetry, to obtain xor (ion, cm), one m ight in agine using a similar sequence, but with the =2 pulses applied at frequency $!_z$ so as to a ect the vibrational state without a ecting the internal state. However, the vibrational degree of freedom is not really a two-level system, so this will not work (indeed, it will cause unwanted multiple excitations of the vibrational motion). To perform crot, we made use of a transition at frequency $!_{aux} + !_z$. Note that this relied on the fact that there was no population in the state jaux;11 (which would have

 $^{^{2}}$ In fact M onroe et. al. state that they used V $^{1=2}$ (=2) for the st pulse, and V $^{1=2}$ (=2) for the third, producing xor with an additional a rotation of the om state.

become coupled to $j_1;2i$ which is outside the computational H ibert space). This illustrates the general method by which the vibrational state is in uenced: one uses radiation at a frequency o set from an internal resonance of the ion by $!_z$, thus coupling levels of vibrational quantum number di ering by 1. To avoid coupling higher-lying vibrational states, one of the possible initial states must be unoccupied when such a transition is invoked.

The transition at frequency $!_0$ $!_z$ is indicated on gure 5. A moment's rejection allows one to convince oneself that as long as there is no population in the jl;1i state (nor in extraneous states such as j);2i), application of this radiation will only cause transitions between jl;0i and j);1i, and hence a swap operation is available between the bus qubit and any other. Applying a p pulse at phase and frequency $!_0$ $!_z$, we obtain the operation

$$U^{P}() = \begin{bmatrix} 0 & 1 & 0 & 0 & 1 \\ B & 0 & \cos(p = 2) & ie^{i} \sin(p = 2) & C \\ 0 & ie^{i} \sin(p = 2) & \cos(p = 2) & A \\ 0 & 0 & 0 & 0 \end{bmatrix}$$
(17)

where the nal column of crosses indicates that an initial state jl;11 is carried out of the computational basis by $U^{p}()$. The case p = 1, that is a pulse, produces a swap operation with an additional i phase factor, which we will write $U^{1}(0) = swap_{(i)}$. Applying $U^{1}(0)$ to ion x, followed by c.rot to ion y (ie using the frequency $!_{0} : !_{aux} : !_{z}$), followed by $U^{1}(0)$ once again to ion x, has the e ect of a crot operation between x and y. That is, crot (x;y) = swap_{(i)} (B;x) : crot (B;y) : swap_{i} (B;x), as long as the initial state of x and the bus is not jl;11. To apply the method, one uses the bus as a Work bit' which is arranged always to return to state jDi before operations such as $U^{p}()$ are applied, so the quantum inform ation processing can go forward without problem .³

So far we have described operations on the ion trap by means of p pulses. A complimentary technique is that of adiabatic passage, in which a quantum system is guided from one state to another by a strongly perturbing H am iltonian applied slow ly. For example, instead of sw apping one ion's internal state with the bus qubit, and then sw apping the bus with another ion, one could swap the internal state of two ions Via' the bus but without ever exciting the rst vibrational level. The details are described for a related system in [22]. This method has experimental advantageous in being insensitive to features such as the tim ing and interaction strength. Both p pulses and adiabatic passage will probably have their uses in a practical QC.

The laser pulses described provide the universal set of quantum logic gates' for the linear ion trap. To complete the operation of our processor or QC, we require that the nal state of the quantum information processor can be measured with high accuracy. This is possible for trapped ions by means of the electron shelving' or quantum jumps' technique [24, 26, 28]. That is, one may measure whether a given ion is in state $f_1;M_1$ i or $f_2;M_2$ i by illuminating it with

³Indeed, the bus m ay even be measured at those times when it should be in the ground state jDi, producing a slight stabilisation or error detection, see section 7.1. In the ion trap, however, one can only thus measure the vibrational state by rst swapping it with the internal state of a prepared ion.

radiation resonant with a transition from F_1 ; M_1 i to some high-lying level, whose linewidth is small enough so that transitions from F_2 ; M_2 i are not excited. If uorescence is produced (which may be detected with high e ciency), the ion state has collapsed to F_1 ; M_1 i, if none is produced, the ion state has collapsed to F_2 ; M_2 i.

3.3 E cient gate sequences

It was shown in the previous section that crot can be applied to any pair of qubits, and arbitrary rotations of single qubits can be carried out. Hence, as explained in section 2, any arbitrary sequence of unitary transform ations of the quantum processor can be brought about. However, the most e cient m ethods will not blindly adopt a simple repetition of crot's and rotations to solve any problem. There may be much more e cient m ethods, by using other possible pulse sequences. Cirac and Zoller emphasize this by demonstrating how to apply a cⁿ rot operation, in which the _z operator is applied to one ion's internal state only if n other ions are in the state jli, using a number of pulses equal to 2 (n 2) + 3. This is e cient in that the number rises only linearly with n, and the multiplying factor is small (ie 2 rather than 48 as in [37]).

E ciency in computer science has a rigorous de nition. W ithout going into details, the essential point is that if the number of elementary computational steps (here, quantum gates) required to complete an algorithm rises exponentially with the size of the input to the algorithm, then the algorithm is ine cient. The de nitions can be made rigorous, which we will not attempt to do, but essentially each algorithm addresses not one instance of a problem, such as to \ nd the square of 2357", but a whole class of problem s, such as, \given an integer x, nd its square". The size of the input' to the algorithm is measured by the amount of information required to specify x, which is the number of digits in the binary expression of x, ie $\log_2(x)$. A computation is ine cient if the number of steps is exponential in $\log(x)$, ie is proportional to x. Sim ilarly, a quantum gate involving n qubits is ine cient if the number of physical operations, such as laser pulses, required to implement it is exponential in n (eg increases as 2^n). The strict de nition of the universal computer mentioned in section 2 also involves this e ciency aspect: when a universal computer simulates the action of another, the num ber of operations in the simulation algorithm must not rise exponentially with the amount of information required to de ne the simulated computer.

A lthough we emphasised in section 2 that a small set of gates is 'universal' in that all unitary transform ations can be composed by them, this does not necessarily imply that they can be used to build the particular transform ations we may want in an e cient way. In this sense, the word 'universal' is misleading.

So far, networks of quantum gates have been designed for the most part without regard to the exact physical process which might underlie them. However, in such an approach it is not obvious which gates to call 'elementary', since a physical system like the ion trap may be particularly am enable to some transform ations. We have already seen an example in the sw ap gate in the ion trap, which can be carried out without recourse to a sequence of xor gates. This implies that a thorough understanding of a particular system like the ion trap may lead to progress in nding e cient networks. The important insight in C irac and Zoller's construction of the cⁿ rot gate is that the method makes use of pulses at frequency $!_{aux} + !_z$. In other words, during the implementation of this gate the ions are deliberately carried out of the computational H ilbert space. A Iternatively, one could regard the Shelf' level F_{aux} ; M _{aux} i j; 0; 0; ::: i as within the computational H ilbert space, in which case we have more than one qubit available per ion. Later, in section 7.1, we will consider using vibrational modes in addition to the lowest one in order to have more than one bus' qubit.

3.4 Switching Rate

The previous section showed how the ion trap information processor worked, by invoking radiation of prescribed frequency and duration in the form of p pulses. The 'switching rate' of the processor is limited by the duration of these pulses.

Let be the Rabi frequency for resonant excitation of the internal transition at frequency $!_0$ for a free ion. This will be determined by the linestrength of the transition and the laser power available. For a two-level atom one has $^2 = 6$ I=hck³ where is the linewidth of the transition, I is the intensity of the travelling wave exciting the transition, and k is the wavevector. W hen considering excitations of the internal state alone of an ion in a trap, ie n = 0 where n is the vibrational quantum number, this 'free ion' Rabi frequency still applies. However, when changes in the vibrational state are involved, is transitions at frequency $!_0$ $!_z$ producing n = 1, an additional scaling factor $z_{cm} k_z$ appears, where z_{cm} is the extent of the ground state vibrational wave function given in equation (8), and $k_z = k \cos($) is the wavevector component along the z direction. U sing (8), we have

$$z_{cm} k_z = \frac{hk^2 \cos^2()^{!}}{2N M !_z} \frac{p_{m}}{N}$$
 (18)

where is the Lamb-D icke parameter for a single trapped ion. In the case of weak excitation, the e ective R abi frequency for the vibrational-state-changing transitions is \overline{p} N, a result which can be interpreted as arising from conservation of momentum. The factor N appears because the whole ion string moves en masse and therefore has an elective mass N M (M ossbauer elect). The Lamb-D icke parameter can also be written in terms of the recoil energy (energy of recoil of an ion after emission of a single photon)

$$E_{R} = \frac{(hk)^{2}}{2M}; \qquad (19)$$

giving $\cos() (\mathbf{F}_{\mathbf{R}} = h!_z)^{1=2}$.

We can now obtain a measure of the switching rate R by taking it as the inverse of the time to bring about a 2 pulse on a vibrational-state-changing transition, ie

$$R' \frac{p}{2N} (N)$$
(20)

Outside the Lamb-Dicke limit (is for $> N_{p}$ the ion-radiation interaction is more or less equivalent to that of a free ion, so the factor = N is replaced by 1.

It was remarked in the previous section that to maintain phase control between (and during) computing operations, there is a strong advantage in having the transition frequencies $!_0;!_{aux}$ in the rf to m icrowave rather than optical region of the electrom agnetic spectrum. However, if the relevant transitions are driven directly by m icrowave radiation, with a frequency of the order of the vibrational frequency $!_z$, then the Lamb-D icke parameter is extremely small (of order $(h!_z=2M \ c^2)^{1=2}$, so vibrational-state-changing transitions are alm ost in possible to drive. O ne way to avoid this would be to make the trap extremely weak, but this has the disadvantage of making the system sensitive to purturbations and lowering the switching rate. Instead, it is better to drive the microwave transitions by R am an scattering at optical frequencies. This combines the advantage of a large photon momentum and hence strong driving of vibrational-state-changing transition need be accurately controlled. The R am an technique was adopted for these reasons by M onroe et. al. [36]. The sam e reasoning leads to the advantage of R am an scattering for precise laser-m anipulation of free atom s [38, 39]. A clear theoretical analysis is provided by [40].

The maximum switching rate is dictated by the three frequencies ;! $_z$ and $E_R = h$ in a subtle way. If only low laser power is available, ! $_z$, then the R abi frequency limits the switching rate and the best choice for ! $_z$ is that which makes N, ie

$${}^{2} \quad \frac{\cos^{2}\left(\right) E_{R}}{h!_{z}} \, \prime \, N \tag{21}$$

Therefore the recoil energy, given by the choice of ion and transition, dictates the choice of trap strength, for a given number of ions. Typical recoil energies for an ion are in the region $E_R = 2 h$ (10{200) kHz, and traps with this degree of con nem ent are now standard. In this situation, increasing the number of ions does not a left the switching rate, but reduces the required trap con nem ent, making the system more sensitive to perturbations.

If higher R abi frequencies are available, one's intuition suggests that $!_z$ becomes the limit on the switching rate, since must be less than $!_z$ or the power broadening will no longer allow the dimensional levels to be discriminated. However, at high $!_z$ one has 1 (Lamb-Dicke regime) so the switching rate on n = 1 transitions cannot reach $!_z$ if $< !_z$. Placing the ad hoc limit $< !_z=10$ in equation (20), one obtains

$$R < \frac{1}{20} - \frac{E_R !_z}{hN} =$$
 (22)

The switching rate is thus limited by the geometric average of $!_z$ and $E_R = h$, and the processor slows down when more ions are involved. For example, to achieve a switching at the recoil frequency, is $R = E_R = 2$ h, with N = 10 ions, (22) implies $!_z = 1000E_R = h$ and $= 100E_R = h$. To keep the ions in a straight line, equation (11) requires $!_r > 5300E_R = h$ which is very hard to achieve experimentally.

р N. There is another problem with increasing $!_z$ in order to increase R.W hen $!_z$ is large, so the transitions which do not change the vibrational state (n = 0) are much more strongly driven by the laser than those that do (n =1, equation (20)). This increases the unwanted o -resonant driving of n = 0 transitions when n =1 transitions are invoked to perform quantum gates between an ion and the phonon bus'. In principle it should be possible to run an ion trap processor at rates of order $!_z$ by relaxing the condition $< !_z$ and allowing o -resonant transitions, but the simple analysis given in section 3.2 is then no longer valid. One can no longer use a two-level model for each transition of the ion/centre-ofm ass system. The a.c. Stark e ect (light shift) will be all-im portant, and di erent com putational basis states will become mixed by the ion { light interaction. The optical B loch equations remain solvable (num erically if not analytically), and a detailed analysis should still enable useful elementary com puting operations to be identied. Such an analysis is a possible avenue for future work.

4 Cooling

To make the quantum inform ation processor described in the previous sections, the main initial requirements of an experimental system are cooling to the quantum regime, equation (4), and connement to the border of the Lamb-Dicke regime, equation (21). The ions must be separated by at least several times the laser wavelength (equation (9)), but this is automatically the case, for small numbers of trapped ions, since with current technology the ions are always separated by many times the width of their vibrational ground state wavefunction (inequality (10)), which is itself approximately equal to the laser wavelength given that the Lamb-Dicke parameter is of order 1.

Surveys of cooling m ethods in ion traps are given in [27, 28]. To cool to the quantum regime, there are two possible approaches. Either one m ay cool to the ground state in the Lam b-D icke regime 1, then adiabatically open the trap to 1, or one m ay apply cooling to a trap already at 1. The advantage of the form er approach is that one does not require cooling below the recoil limit $k_B T_R = E_R$. The advantage of the latter is that strong con nem ent is not necessary, but to attain the quantum regime with 1 requires sub-recoil cooling.

Cooling to the quantum regime has so far been demonstrated for trapped ions by means of sideband cooling in the Lamb-Dicke limit [29, 30]. This is described in section 4.1 below. However, it may be interesting to pursue other approaches, as discussed in sections 4.2 and 4.3.

The physics of sideband cooling is very closely related to that involved in inform ation processing in the ion trap. This is no coincidence, and a similar link will probably be found in all physical implementations of quantum information processing. The relationship is su ciently close that one may say that once the goal of laser cooling to the motional ground state is achieved in any given experimental ion trap, a primitive form of quantum information processing can proceed immediately, since all the required experimental components will be in place. Conversely, quantum error correction (see section 7.1) is a special type of booling'.

4.1 Sideband Cooling

Sideband cooling is just another name for the simplest type of laser cooling, is radiation pressure or D oppler cooling. The name comes from how the process looks in the Lamb-D icke lim it 1.

There are several signi cant frequencies or energies. First, we have the vibrational frequency in the ion trap potential, $!_z$. Next, we have the radiative width of the transition used to do the cooling, . Either a single photon transition is used, in which case is its natural width (or possibly its broadened width if another laser is used to broaden a very narrow level as in [29]), or a stim ulated R am an transition is used, in which case is some combination of the inverse of the duration of the R am an pulses, and the time for optical pumping out of one of the states linked by the R am an transition. B asically, the physics in the R am an case and single-photon case is very similar. The R am an method is a way of providing a very narrow transition when one is not already available. It also combines the advantages of precise frequency control (in the rf regim e) with large photon recoil (optical regim e), which perm its fast cooling, for the same e reason that the switching rate for inform ation processing is faster (section 3.4). One could instead use an rf or microw ave transition, but then the cooling would be a lot slower and m ay not compete well enough with heating processes.

Laser cooling of atom s is often done quite happily using strong, resonant transitions. Indeed, such transitions are eagerly sought out. W hy the talk of narrow transitions in the previous paragraph? It is because simple D oppler cooling leads to the well-known D oppler cooling lim it $k_B T_D$ ' h =2, assuming the recoil energy is small compared to h (this applies in a trap as well as to free atom s). However, we want to get to the quantum limit (equation (4)), so we require

This equation is a further constraint on the performance of the trap. It says the cooling transition must be narrow enough, or the trap con nem ent tight enough, to resolve them otional sidebands in the Lamb-D icke spectrum.

In the resolved sideband lim it, radiation pressure cooling is called sideband cooling. A nice way of understanding it is to consider it as a form of optical pumping towards the state of lowest vibrational quantum number [27], see gure 6. Note that the recoil after spontaneous emission

produces heating. The average change in the vibrational energy per spontaneous emission is equal to the recoil energy $h!_{z}hni = E_{R}$ (a particularly clear derivation of this fact may be found in [41]). For a single trapped ion illum inated by low-intensity light, the cooling is governed by the following equation [42, 41]:

$$\frac{d}{dt}hHi = \frac{I_0}{h!_L} R_n^X P_n^X (E_f E_n + E_R) h_n je^{ik R} j_f i^2 g(!_L (E_f E_n)=h)$$
(24)

where I is the intensity of the incident radiation (a single travelling wave), $_0$ is the resonant photon scattering cross section ($_0 = 2$ $^2 = (2)^3 = k^2$ for a two-level atom), h!_L = hck is the laser photon energy, P_n is the occupation probability of the n'th energy level of the vibrational motion, of energy E_n = h!_z (n + 1=2) and wavefunction $_n$ (equation (7)), and g(!) is the lineshape function. For a two-level atom,

$$g(!) = \frac{{}^{2}=4}{(! \; !_{0})^{2} + \; ^{2}=4}$$
(25)

The quantity dHH i=dt is the rate of change of the m ean total energy of the ion, averaged over an absorption/spontaneous emission cycle. Since the ion's internal energy is left unchanged, this is the rate of change of the m ean kinetic energy. Equation (24) has a simple physical interpretation as a sum of energy changes associated with radiative transitions up and down the ladder of vibrational energy levels. At the lowest attainable temperature, dHH i=dt = 0 and one possible solution of equation (24) is the therm all distribution

$$P_n = (1 \ s) \dot{s}^n$$
 (26)

where s is the Boltzm ann factor $s = \exp(h_z = k_B T)$, and the probability distribution has been properly norm alised.

At su ciently low tem peratures, all but the lowest energy levels can be ignored in equation (24). Using k $R = \langle \hat{a} + \hat{a} \rangle$ where $\hat{a} j_n i = \frac{p}{n} j_{n-1} i$, and expanding in powers of the Lam b-D icke parameter, it is a simple matter to obtain

$$\frac{d}{dt} hH i' I_{0} \frac{E_{R}}{h!_{L}} (hni[g(!_{L} !_{z}) g(!_{L} + !_{z})] + [g(!_{L}) + g(!_{L} !_{z})])$$
(27)

where $hni = {}^{P} nP_{n}$ is the ion's mean vibrational quantum number. Now assume $!_{z}$ (inequality (23)) and let the incident radiation be tuned to the rst sideband below resonance, $!_{L} = !_{0} \quad !_{z}$, then the cooling limit dhH i=dt = 0 leads to a mean vibrational quantum number [43, 42].

mi'
$$\frac{5^2}{16! z^2}$$
: (28)

Note that since hni is proportional to $(=!_z)^2$, the experimental constraint (23) will ensure achievement of the quantum limit hni 1. This also justiles our ignoring higher energy levels in deducing (28).

The above assumed a single direction of propagation for the cooling laser, which will only result in cooling along one direction, so our calculation has been one-dimensional. Taking into account the fact that spontaneous photons are emitted into all directions, they do not heat any given dimension quite as much as we assumed, and the factor 5 in equation (28) is replaced by (1 + 4) where ' 2=5 depends on the dipole radiation emission pattern [44]. However, this corresponds to an experiment in which the motion in the other dimensions is heated, which we wish to avoid. To cool all three dimensions, one can either introduce three laser beam s, or use a single beam propagating at an oblique angle to all the principle axes of the trapping potential, and tune it separately to resonance with the three sideband frequencies $!_{L}$ $!_{x,y,z}$. For this one must have all three frequencies distinct, is $!_{x} \notin !_{y}$.

It is commonly in agined that sideband cooling is not possible if the recoil energy is greater than the phonon energy $h!_z$, since then the cooling which results from photon absorption is undone by the recoil from photon emission, and dhH i=dt > 0. However, one can always tune to the next lower sideband, $!_L = !_0 \quad 2!_z$, and good cooling is regained, as a thorough analysis of (24) will show. Therefore it is not necessary to be well into the Lam b-D icke regime in order to attain the quantum lim it by sideband cooling.

Note also, that both equations (27) and (28) are signi cant in order to nd the minimum temperature one will obtain in the lab. This is because there will always be heating mechanisms present, such as a coupling between the stored ions and therm al voltages in the electrodes (see section 7), so it is the cooling rate, equation (27), not just the minimum possible temperature, which is important.

4.2 Sisyphus cooling

The constraint (23) means that sideband cooling will either be slow and therefore not compete well with heating processes, or will require the use of R am an transitions. We can avoid $!_z$ and nevertheless use laser cooling to get close to the quantum regime, by the use of Sisyphus' cooling [45, 46]. This makes use of optical pumping and optical dipole forces (forces associated with a position-dependent a.c. Stark shift of the atom ic energy levels) in a laser standing wave, on an atom with at least three internal states. When the dipole force is caused by a position-dependent polarisation of the standing wave, the cooling is referred to as 'polarisation gradient cooling'. Theoretical analyses [45, 46, 47] have so far concluded that the lowest temperatures attainable by this method correspond to a mean vibrational quantum number hni' 1, ie just on the border of the regime we require. However, the cooling rate is important as well as the theoretical minimum temperature, and for this reason Sisyphus cooling may be attractive for cooling a whole string of ions [48], as required for the inform ation processor, since it is relatively fast. A nal stage of sideband cooling or som ething sim ilar would then be required to get well into the quantum regime.

4.3 Statistical mechanical cooling methods

So far, all the cooling techniques described have been based on laser cooling. However, for trapped neutral atoms the technique of forced evaporative cooling has been shown to be extrem ely powerful, enabling the tem perature in a weakly interacting atom ic vapour to be brought well into the quantum regime of a trap, which for a cloud of Bosons leads to Bose E instein condensation [31].

In forced evaporative cooling, one starts with a large number of trapped particles in them al equilibrium. Those of higher energy are forced to leave the trap, and those remaining rethermalise towards a lower equilibrium temperature. The technique relies on an ability to remove selectively particles of higher than average energy. One way to do this is to reduce the depth of the trap, allowing the faster particles to y out. Clearly this approach will only work if the thermal energy is located more in some particles than in others, which is true for a gas of weakly interacting particles, but not for a crystalised system such as a cold string of trapped ions. However, evaporation may be useful in an ion trap as a rst stage of cooling, to bring about crystalisation. A lso, it is conceivable that a Bose condensate of neutral atom s may one day be su ciently easy to produce in the vicinity of an ion trap that it may be used as a cold reservoir to cool the ions through collisions. The use of one species to cool another is referred to as Sym pathetic cooling'.

5 rf requirem ents

We now turn to the design of the ion trap itself. The electrode structure of the trap consists of a two-dimensional regulation plus an axial static potential. Concentrating on the twodimensional quadrupole, consider inst the most simple case, in which the point in the centre of the electrode structure remains at zero potential, and we om it any axial connement. The potential on one pair of diagonally opposed electrodes is $(U = V \cos_V t)=2$, and that on the other pair has equal magnitude and opposite sign to this. Here $_V$ is the frequency of the applied voltage, the subscript is necessary to distinguish it from the Rabi frequency of a driven atom is transition introduced in previous sections. The potential as a function of position in the x-y plane is $(x;y;t) = (U = V \cos_V t)(x^2 = y^2)=2r_0^2$ where r_0 is a measure of the electrode separation⁴ For the case of cylindrical electrodes, r_0 is the distance from the axis to the surface of the electrodes [49]. The trapping e ect in the radial direction is stable as long as $_V$ is not too small, and is strong as long as $_V$ is not too large. This may be parametrised in terms of the standard parameters

$$a = \frac{4eU}{M r_0^2 r_V^2};$$
 (29)

⁴In practice it is advantageous to avoid exact cylindrical sym etry in order to have all three vibrational frequencies distinct, but this will unnecessarily com plicate the present discussion.

$$q = \frac{2eV}{M r_0^2 r_V^2};$$
 (30)

where e is the charge on a trapped ion. For present purposes, a zero dc potential di erence U = 0 m ay be used, so a = 0. The radial con nem ent is then stable as long as q is less than about 0:9 [24, 28]. The radial m icrom otion has a velocity am plitude of q_V =2 for an ion at average distance from the z-axis. The average m otion on a time scale slow com pared to $1 = _V$, the so-called secular motion, can be m odelled in term s of the pseudopotential $\frac{1}{2}M$! $_r^2(x^2 + y^2) = w$ ith radial vibrational frequency

$$!_{r} = \frac{q}{a^{2} + q^{2} = 2} \frac{v}{2} = \frac{q}{2} \frac{v}{2} \qquad (a = 0):$$
(31)

Choosing $q = 1 = \frac{p}{2}$ so as to be comfortably in the zone of stability of the trap, we obtain $!_r = v = 4$. From this the Lamb-D icke parameter for the radial connemt is obtained as

$$r = -\frac{2^{p} \overline{2} E_{R} k^{2} r_{0}^{2}}{eV}^{! 1=4}$$
(32)

where k is the wavevector and E_R the recoil energy as de ned in equation (19), and we have neglected the cos() term for simplicity. The signi cance of equation (32) is that, for a given ion and wavevector, the Lamb-D icke parameter of the radial con nement is dictated primarily by the choice of electrode size (r_0) and rf voltage amplitude V. The required rf frequency v is dictated by $V=r_0^2$ through equation (30) and the stability condition q' $1=\frac{1}{2}$.

Note that for inform ation processing, we wish the Lamb-D icke parameter for the axialm otion to be around 1, assuming there is only a small number of ions in the trap. We also wish the ions to adopt the shape of a linear string, so the radial con nement must be tighter than the axial con nement (equation (11,12)). Taken together these two considerations in ply that the Lamb-D icke parameter for the radialm otion should be much less than 1.

Let us now add to the linear trap an axial dc potential, so that the ions are con ned in all three dimensions, and with no axial micromotion. The most obvious way to do this is to add positively charged electrodes to either end of the linear trap, but this introduces a di culty in correctly balancing the rfpotential so that there is no residual axial rf component. An ingenious way around this is to split the linear electrodes of the radial quadrupole eld and impose a potential di erence between their two ends, as described in [49], see gure 1. In either case, the dc potential near the centre of the trap will take the form of a harm onic saddle point potential

$$_{dc}(\mathbf{x};\mathbf{y};\mathbf{z}) = \frac{U_{z}}{z_{0}^{2}}^{h} \mathbf{z}^{2} \quad \frac{1}{2} \quad \mathbf{x}^{2} + \mathbf{y}^{2} \quad (33)$$

where U_z is the potential on each electrode, and z_0 is a parameter which is measure of the electrode separation (its exact value depending on the geometry). From this equation we obtain the vibrational frequency for the axial harm onic motion of a trapped ion:

$$!_{z} = \frac{5}{\frac{2eU_{z}}{M z_{0}^{2}}}$$
(34)

This is also the frequency of the lowest mode of vibration of a string of trapped ions (centre of m ass mode), as discussed in section 3.1. The Lamb-D icke parameter of the axial con nem ent is

$$z = -\frac{E_{R}k^{2}z_{0}^{2}}{4eU_{z}}!^{1=4}$$
(35)

Owing to Eamshaw's theorem, it is in possible to apply an axial dc potential without in uencing the radial con nement. The dc potential $_{dc}(x;y;z)$ has the elect of expelling the ions in the radial direction. In the presence of both static axial and uctuating radial electric potentials, the secular (is slow) radial motion is still harm onic, but the vibrational frequency is no longer $!_r$ but

$$!_{r}^{0} = !_{r}^{2} \frac{1}{2}!_{z}^{2}$$
(36)

However, as long as $!_r$ $!_z$, which is the case we are interested in, then $!_r^0 ' !_r$ so the previous discussion of the radial con nem ent remains approximately valid, and in particular the stability condition q < 0.9 is not greatly changed.

The depth of the trap (and hence the ease of catching ions) is given approximately by the smaller of eU_z and eV=11.

6 Candidate Ions

Table 1 gives a list of ions which are suitable for inform ation processing. The list consists of ions whose electronic structure is su ciently simple to allow laser cooling without the need for too m any di erent laser frequencies. The list is not intended to be exhaustive, but contains m ost ions which have been laser cooled in the laboratory.

For inform ation processing, a large recoil energy is attractive from the point of view of allowing a faster switching rate (equation (22)), but makes the Lamb-Dicke regime harder to achieve (equations (32), (35)). The choice of rfrather than optical transitions for information processing appears so advantageous as to be forced upon us. Since we require at least three long-lived low – lying internal states of the ion (the states jDi; jLi and jauxi), this im plies that the existence of hyper ne structure (ie a non-zero nuclear spin isotope), while com plicating the cooling process, may be advantageous. Indeed, for alkali-like ions, (such as singly charged ions from group 2 of the periodic table) a non-zero nuclear spin is required, since for zero nuclear spin the total angular momentum of the ground state is only 1=2, yielding only two long-lived states (the Zeem an components jJ; M i = jL=2; 1=2i) which is not su cient. M ost even isotopes have zero nuclear spin. The other major consideration is the di culty in generating the light required for cooling and inform ation processing.

Examining qure 7 and table 1 it is seen that ⁹Be is an attractive choice, in that it allows the fastest switching rate, requires only one laser wavelength for cooling, and the hyper ne splitting frequency of 125 G H z is accesible to electroptic m odulators. How ever, the wavelength of 313 nm requires the use of a dye laser (frequency doubled) which is disadvantageous. The next m ost prom ising candidate appears to be ⁴³Ca. It requires two laser wavelengths for cooling, 397 (or 393) nm and 866 (or 850) nm (qure 8), but both can be produced by diode lasers (one frequency doubled) which makes this ion very attractive (strontium has similar advantages). D ide lasers can be made very stable in both frequency and power. If more laser power is needed than is possible with diode lasers, then a titanium -sapphire laser can be used, which is also advantageous com pared with dye lasers. The hyper ne splitting of 326 G H z is accessible to electrooptic m odulators, though less easily than the sm aller splitting in beryllium. The obvious di culty in working with ⁴³C a is that it is a rare isotope, having a natural abundance of only 0:14% or 1 part in 700, making an isotopically enriched sample that much more expensive. However, one could carry out prelim inary experiments using the 97% abundant 40 Ca, in order to bring the trapping and cooling techniques up to perform ance, and the swap operation could be tested since it does not make use of the auxilliary state F_{aux} ; M_{aux}i.

For a group 2 ion, the internal states required for inform ation processing, discussed in section 32 and illustrated in gure 5, will be taken from the ground state hyper nem anifold. For ⁴³Ca, for example, one m ight take $F_1 = 4$; $M_1 = 4i$; $F_2 = 3$; $M_2 = 3i$ and $F_{aux} = 4$; $M_{aux} = 2i$. This choice is highlighted in gure 8. The degeneracy between the rst and auxilliary levels is lifted by an imposed magnetic eld of order 0.1 m T.

6.1 Example: the ${}^{43}Ca^+$ ion

To estim ate laser power requirements, we will calculate the intensity required to saturate the $4S_{1=2}$ { $4P_{3=2}$ transition in C a⁺ (for laser cooling purposes) and that required for R am an transitions in the ground state via a quasi-resonance with this transition (for information processing purposes). Using a two-level model for the allowed electric dipole transition, the saturation intensity (de ned as the intensity giving a Rabi frequency equal to the FW HM linewidth divided by $\frac{1}{2}$) is $I_s = 4$ $^2hc = 6$ $^3 = 48$ mW /cm² (using = 2 23 MHz, = 397 nm). To initiate laser cooling, this intensity must be available in a laser beam wide enough to intersect a signi cant proportion of a hot' ion's trajectory in the trap. Taking a beam diam eter of 1 mm, the required laser power is of order 0.5 mW, which is a large overestim ate in practice.

Ram an transitions from flito jlivia a near-resonance with an excited state jei can be modelled as transitions in an elective two-level system, in which the elective Rabi frequency of the

Raman transition is

$$_{e} = \frac{0 \ 1}{2};$$
 (37)

where $_0$ and $_1$ are the R abi frequencies of the single-photon transitions from levels [) i and jli to jei, and $_0$; $_1$ is the detuning from resonance of both of these transitions. A ssum ing level jei only decays to levels [) i and jli, the single photon R abi frequencies can be obtained from the laser intensity I and the linewidth of the excited state, leading to $_{\rm e}$ ' I 2 =8I_S. During a R am an transition, the average population of the excited state jei is 2_0 =4 2 , and to produce, for example, a 2 pulse, the pulse duration is 2 = $_{\rm e}$. Therefore the probability of an unwanted spontaneous emm ision process duration such an operation is

$$p_{em} = ---:$$
 (38)

An interesting possibility, which has not yet been tried in an ion trap, is to use the Argon ion laser line at 488 nm to drive Raman transitions. In this case, we have ' 6 10^6 , so p_{em} ' 5 10^7 , allowing a million computing operations before spontaneous emission is a problem. The laser intensity required to obtain h $_{e} = E_{R}$ is then

$$I = 8I_{S} - \frac{E_{R}}{h} / 2.9 \quad 10^{9} W / m^{2}:$$
(39)

To address a single ion, the laser is focussed to a tight spot of diam eter of order 10 $\,$ m , so the required power is modest, of order 0:3 W .

Finally, to con ne Ca to the Lamb-Dicke regime of the 393 nm radiation, we require $!_z =$ $E_{R} = h' 2$ 29 kHz. This is a reasonable choice for information processing, bearing in mind the remarks made in section 3.4 about o -resonant transitions. Choosing an axial electrode 4 mm, the voltage required on the axial electrodes is U_z 0:12 volts. This separation of surprisingly low value arises from the fact that we have assumed the ions can be cooled to the ground state of the axialm otion, which here corresponds to a tem perature sm all com pared to the recoil limit $E_R = k_R'$ 1:4 K. It shows that contact potentials will certainly be a problem, and one must be able to compensate them by seperately controlling the voltage on each electrode. To make the radial con nem ent 10 times stronger than this axial con nem ent we require an alternating voltage on the radial quadrupole electrodes of frequency $\sqrt{2}$ 1:2 M H z (equation (31)) and amplitude V ' 9 volts (equation (30)), assuming a distance of 1 m m from the axis to the radial electrode surfaces.

7 Perform ance lim itations

Having begun in section 3.2 with an idealised treatment, in which we assumed operations could be carried out in an ion trap with arbitrary precision, the discussion has become in section 6

more realistic. It now remains to discuss the limitations on the performance of the ion trap system for information processing purposes.

Two important gures of merit for a quantum information processor are the number of stored qubits, which so far in this paper has been the number of trapped ions N, and the number Q of elementary operations which can be carried out before dissipation or decoherence causes a signi cant best of quantum information. To rst approximation, we may quantify dissipation or decoherence by a simple rate $_{d}$, in which case Q = R = $_{d}$, where the switching rate R is given in section 3.4. If we model decoherence rate for any individual ion, then we must take $_{d} = N$ since the quantum computation is likely to produce entangled states in which the o -diagonal elements of the density matrix decay at this enhanced rate [11, 12, 15, 16]. However, decoherence of a many-ion state in an ion trap is not yet su ciently well understood to tell whether such a model applies [51]. Two possible therm al reservoirs a ecting the ion trap are electrical resistance in the electrodes, and therm al radiation.

The major problems in an ion trap are spontaneous transitions in the vibrational motion, ie heating (a random walk up and down the ladder of vibrational energy levels), therm al radiation (driving internal rf transitions in the ions), and experimental instabilities such as in the laser beam power, rf voltages and mechanical vibrations, and uctuating external magnetic elds [36]. The instabilities contribute to the heating, and also imply that a laser pulse is never of exactly the right frequency and duration to produce the intended quantum gate. A decoherence rate' gure of a few kH z was quoted by M onroe et. al. [36], consistent with the heating rate of 1000 vibrational quanta per second quoted in their earlier work [30]. W ith the switching rate of order 20 kH z, they obtained Q ' 10 with N = 1. A heating rate of 6 quanta per second was reported by D iedrich et. al. [29].

A useful model of the motion of a trapped ion is a series LC circuit which is shunted by the capacitance of the trap electrodes [52, 51]. The inductance in the model is given by 1' $M z_0^2 = N e^2$ where z_0 is of the order of the axial electrode separation. A resistance r is due to losses in the electrodes and other conductors in the circuit. This resistance both damps and heats the ionic motion with time constant l=r, leading to a heating rate in vibrational quanta per second [51]:

heat
$$\frac{r k_B T}{l h!_z}$$
 $\frac{r N e^2 k_B T}{M z_0^2 h!_z}$ (40)

For example, substituting the parameters from section 6.1, and using r = 0.1 ohm, T = 300 K, we obtain $_{heat} = 5 \text{ s}^{1}$. It should be born in m ind that one can only consider equation (40) to apply once other sources of electrical noise, such as rfpickup, have been reduced su ciently, so one cannot hope to improve the perform ance merely by increasing the electrode separation z_0 and voltage U_z .

It is a simple matter to combine equations (20), (34), (37) and (40) in order to obtain $Q = R = _{heat}$ as a function of the experimental parameters. However, this does not bring much insight

and it is better to think in terms of the switching rate and decoherence rate. Taking N = 10 ions with $!_z = E_R = h = 2$ 29 kHz, as suggested in the previous section, the switching rate is about 1 kHz, and Q 200 using the value just quoted for _{heat}. These parameters indicate what will probably be achievable in the next few years.

It is not hard to show that the in uence of spontaneous emission of photons by the ions in the trap is much less important than the severe experimental problems just mentioned. Spontaneous emission takes place during the application of a laser pulse, due to the unavoidable weak excitation of an excited state of the relevant ion, as noted in the previous section. (It was already remarked that spontaneous emission between laser pulses is negligible, owing to the adoption of the ground state hyper nemanifold for computing). Taking the probability p_{em} from equation (38), the number of operations that can be carried out before spontaneous emmission plays a signi cant role is Q ' 1= p_{em} which can be of the order of 10⁶, as remarked after equation (38).

The conclusion is that for the moment the limitations of the ion trap are associated with the vibrational degrees of freedom, and with experimental instabilities. It is here that experimental and theoretical work must concentrate if progress is to be made. It remains misleading at present to talk of quantum 'computations' taking place in the lab.

7.1 Error correction

Although it is important to build an information processor with as much precision and stability as possible, in the longer term the aim of signi cant computations is almost certainly unrealisable without som ething which goes beyond such passive' stabilisation. It was initially thought that anything like active stabilisation of a quantum computer would be impossible, since it would rely on a means of monitoring the quantum state of the computer, which would irreversibly destroy the computation. However, the union of inform ation theory with quantum mechanics has lead to another powerful concept, that of quantum error correction [53, 54, 55]. The essential idea is that K qubits of quantum information in the quantum computer can be stored (encoded) in a carefully chosen way among N > K two-state system s. The computation is carried out in this specially chosen 2^{K} -dimensional subspace of the total H ilbert space (2^N dimensions) of the enlarged computer. The important feature is that the encoding is chosen so that the most likely errors, for example caused by heating of the vibrational degrees of freedom of the ion trap, cause the computer's state to go out of the special subspace. Such departures can be detected by well-chosen measurements on the computer, without upsetting the evolution of the quantum computation. Furtherm ore, a good encoding enables the most likely errors to be corrected, once they are detected, by the application of one or more extra quantum gates or dissipative m easurem ents.

Quantum error correction is more powerful than the more simple watchdog e ect' idea which preceded it [56]. The watchdog' or 'quantum Zeno e ect' relies on rapid repeated measurements

of the state of a system in order to prevent unwanted changes caused by the in uence of som e error' Ham iltonian H_e . It is successful if many measurements can be applied within a time t su ciently small that 1 f_h jexp($iH_et=h$) j ij / t². In the midst of a computation one does not necessarily know what quantum state j i any part of a QC should be in, so the watchdog method cannot be applied directly, and a more subtle approach is required [57]. However, it may not be possible to make measurements rapidly enough, and it is not clear whether the method can be applied during the application of a quantum gate, in which the quantum system is required to go through a prescribed evolution.

By contrast with the Zeno e ect, quantum error correction allows a nite error term in the system 's density matrix to accumulate, and corrects it afterwards. This is particularly im portant to the operation of quantum gates. For example, a gate between two qubits involves a four-dimensional logical Hilbert space. To allow error correction, we must ensure that at no point is the whole action of this gate concentrated into a four-dimensional physical Hilbert space. This can be done as follows. Suppose each qubit in the QC is encoded into two physical two-state systems. A gate U (a;b) between two such encoded qubits a;b can then be applied in four steps U (a;b) = $u(a_2;b_1)$ $u(ab_2)$ $u(ab_2)$ $u(ab_1)$, where the operators u are gates between a pair of two-state systems, and $fa_1;a_2q;fb_1;b_2q$ are the sets of two-state systems storing qubits a and b. The important point is that error correction can be applied between the four u operations. At no stage is any quantum information stored in a physical Hilbert space only just large enough to hold it, neither is any gate U carried out in a single step. The proper combination of these features so as to allow stabilisation has been dubbed Yault tolerance' [60].

Quantum error correction was initially discussed with a generalm odel of error processes in the quantum computer, in order to show that alm ost any in aginable error process might in principle be corrected by such techniques [58, 59, 53, 54]. Subsequently, a technique speci cally adapted to the vibrational noise in an ion trap was proposed [61]. In this proposal, the H ilbert space is enlarged by making use of four internal states in each ion to store each qubit in the quantum computation. This enables a two-qubit gate to be carried out in four steps as outlined above. Next, we require a method of detecting and correcting the most likely errors in the vibrational state. This is done by using the rst (n = 0) and fourth (n = 3) vibrational states, $i_{0}; 0; 0; 0; \dots$ and β ;0;0;:::i, instead of the rst two, to store the bus' qubit. The vibrational quantum number n is measured whenever it should be 0, by swapping the phonon state with the state of additional ions introduced for the purpose, and probing them . If n is found to be 1, then corrective m easures are applied based on the assumption that a single jump upwards from n = 0occured, the details are given in [61]. If n is found to be 2 or 4, then corrective m easures are applied based on the assumption that a single jump down or up from n = 3 occurred. If n is found to be 0 as it should be, a corrective measure is still required to allow for the di erence between such conditional evolution and the unitary evolution without jumps. This procedure enables single jumps up or down the ladder of vibrational levels to be corrected. Since these will be the most likely errors (at a su cient degree of isolation from the environment), the e ect overall is to stabilise the QC. In this case the gure of merit Q is roughly squared (where Q counts the possible number of logical gates U, not subgates u), a rem arkable enhancem ent.

The above procedure makes allowance for the fact that errors cause the vibrational state to explore a H ilbert space of more than two dimensions, so in the language of quantum information, the bus size is larger than a single qubit, though the bus is still only used to store a single logical qubit. The bus could be made larger still by using higher excitations of the fundamental normal mode, or by using higher-order normal modes. This should allow more powerful error correction, and hence further increases in Q. The basic theory of error correction gives hope that such increases in Q can be dramatic [53, 54, 60].

E mor correction should not be regarded as a device merely of interest to quantum computers. Rather, it is a powerful method of enforcing coherent evolution on a quantum system which would otherwise be dissipative. Such a capability may be useful for quite general situations in which stability is important, for example in low-noise electronic circuits, and frequency and mass standards. This may prove to be an area in which quantum information theory has provided a useful tool for other branches of physics.

8 Conclusion

In conclusion, let us sum m arise them ain avenues for future work involving the ion trap quantum inform ation processor.

One of the basic aims of quantum information theory is to link abstract ideas on the nature information with the laws of physics. The ion trap provides a means of establishing this link in a complete and concrete way. This will set the theory on a more m basis.

An important task in the theory of quantum computation is that of identifying e cient multiplequbit quantum gates. So far, it has been assumed that the e cient gates are those that can be divided into a set of su ciently few two-qubit gates. However, a system like the ion trap may allow particular unitary transform tions to be carried out e ciently without dividing them into many two-qubit operations. An investigation of this should be fruitful.

The principle of operation of the ion trap which we have described m ade use of various approxim ations whose in uence on long quantum computations has yet to be analysed. For example, any given laser pulse on an ion will involve o -resonant stimulation of transitions other than the speci c transition the pulse is designed to drive. Such e ects m ay be unwanted, but their in uence is unitary and accurately predictable. It would be interesting to investigate whether these e ects can be taken into account in designing the sequence of laser pulses, so that they do not need to be corrected, or whether we are forced to regard them as errors.

Quantum computation will certainly require error correction if it is ever to be useful for computational purposes. The ion trap provides a guide to the speci c type of error correction which is likely to be required in the future. The basic tools of error correction are now fairly well understood, but there is much work to be done in bringing them to bear on the ion trap. In additition, these ideas m ay o er signi cant advantages for other uses of the ion trap, such as frequency and m ass standards; this should be explored.

Error correction only works once the level of noise in the trap is brought su ciently low by careful construction and isolation. Experimental ion trap systems must be made much more stable than they are at present before they can take advantage of error correction of multiple errors among many qubits. This is not just a question of technology, but also of a better understanding of the noise processes, especially the in uence of electrical noise in the electrodes providing axial con nem ent. The most immediate experimental challenge is to coola many-ion crystal to the motional ground state.

I would like to add helpful conversations with R. Thompson, D. Segal, D. Stacey and especially J. Brochard. The author is supported by the Royal Society.

Figure 1: Experimental arrangement. A line of three ions sits between cylindrical electrodes, here seen sideways on. Pairs of laser beam sexcite Ram an transitions, which impart momentum changes to the ions along the axial direction of the trap. The double-ended arrow indicates the direction of the resulting oscillations, it can be regarded as a pictorial representation of the fourth 'qubit' in the system (see text, section 3.2). The electrodes are split in order to allow a constant voltage to be applied between their ends, so that an axial potential minimum occurs in the region where the long electrode segments overlap. Radial con nem ent is provided by alternating voltages, see text (section 5).

Figure 2: Schematic illustration showing an anisotropic harmonic potential with the positions of three trapped ions indicated.

Figure 3: Equilibrium positions for a line of point charges in a quadratic potential, as a function of the number of charges N. The positions are in units of z_0 (equation (6)). The curve is equation (9).

Figure 4: Norm almode frequencies for a line of point charges in a quadratic potential, as a function of the number of charges N. The frequencies are in units of $!_z$.

Figure 5: Energy levels and transitions in a single ion signi cant for information processing with a line of trapped ions. The labels F;M indicate di erent internal states of the ion. Each internal state has an associated set of vibrational levels for each of the vibrationalm odes. Here, just the pst few levels of the lowest mode (spacing $!_z$), the rst pair of levels of the next mode (spacing $3!_z$) and the lowest levels of two furtherm odes are shown. The full arrows indicate transitions at frequencies $!_0 = !_z$ and $!_{aux} + !_z$, which are used in the swap_(i) and crot operations described in the text. Note that radiation at a given frequency couples not only the levels at the two ends of the relevant arrow on the diagram, but also other pairs of levels with the same di erence of vibrational quantum number. The gure shows $!_{aux}$ to be of the same order as $!_0$, because this is what typically occurs when alkali-like ions are used. The vibrational frequency is smaller, $!_0 ' = 100!_z$.

Figure 6: Sideband cooling. A laser excites transitions in which the vibrational quantum number of a con ned ion falls by 1 (or a higher integer). Spontaneous transitions bring the ion's internal state back to the ground state, with the vibrational quantum number changing by

1 or 0.0 n average the vibrational quantum number is reduced, until the vibrational ground state is reached. The internal ground and excited states are jui and jei, and the gure shows the di erent vibrational levels spread out horizontally for clarity. When both jui and jei are long-lived (for example they may be the computational basis states, cf gures 5 and 8), the jui; in 1 i transition is driven by a -pulse, (U^1 (0) operator), and the spontaneous transition is a Ram an transition via an unstable excited state (optical pumping). Note that

such experimental techniques are identical to those required for information processing and error correction. To cool a crystal of several ions, it is su cient for the laser to interact with only one ion since the Coulomb coupling between ions causes rapid thermalisation of their motional state. However, the coupling between di erent normal modes is weaker, so these may need to be cooled separately by tuning the laser to the various normal mode sideband frequencies.

Figure 7: The recoil energies and main (typically S{P) transition wavelengths for ions which may be amenable to quantum information processing (cf table 1). A high recoil energy is advantageous for a high switching rate, but tends to be associated with a short wavelength. A rough rule is that the shorter the wavelength, the more complicated and therefore less stable is the laser system. The starred symbols are singly-ionised ions from group 1, in which a metastable manifold is used for computing, making them unattractive in the long term.

Figure 8: Low -lying energy levels of the ${}^{43}Ca^+$ ion, of electronic structure $1s^22s^22p^63s^23p^6nl$. The hyper ne structure is shown (nuclear spin I = 7=2), and the Zeem an sublevels and transition wavelengths. The levels are labelled by the value of the total angular momentum F, and a possible choice of computational and auxilliary levels is shown by the thickened Zeem an sublevels in the ground state manifold. An example R am an transition is shown, for use both in sideband cooling and for the operation of quantum gates. The dashed transitions are forbidden by the electric dipole radiation selection rules in LS coupling, and so are weak. The 3dD levels are an unwanted complication; they must be depopulated by optical pumping during laser cooling. The level separations and lifetim es are taken from references [50].

Table 1: List of candidate ions for inform ation processing. Only singly-charged ions are considered, although some ions of higher charge m ay also be interesting. For each element, only the most abundant isotope, and those having non-zero nuclear spin are shown. Unstable isotopes are not shown, although most elements in the list (allbut M g, In and Li) have further isotopes of half-life longer than one week. The hyper ne splittings are for the ground state in all but the inert-gas-like ions (Li, Na); they are taken from G.W erth in [26]. The S{D wavelength is only shown when the D level lies below the P level. The recoil energy is based on the S{P wavelength. For Li, Na the S,P,D labels do not apply; the transitions are from the m etastable triplet state.
