Unitary Dynam ics for Quantum Codewords

A sher Peres

Institute for Theoretical Physics University of California Santa Barbara, CA 93106

A quantum codeword is a redundant representation of a logical qubit by means of several physical qubits. It is constructed in such a way that if one of the physical qubits is perturbed, for example if it gets entangled with an unknown environment, there still is enough information encoded in the other physical qubits to restore the logical qubit, and disentangle it from the environment. The recovery procedure may consist of the detection of an error syndrome, followed by the correction of the error, as in the classical case. However, it can also be performed by means of unitary operations, without having to know the error syndrom e.

Since quantum codewords span only a restricted subspace of the complete physical H ilbert space, the unitary operations that generate quantum dynamics (that is, the computational process) are subject to considerable arbitrariness, sim ilar to the gauge freedom in quantum eld theory. Quantum codewords can thus serve as a toy m odel for investigating the quantization of constrained dynam ical system s.

1. Introduction

In classical communication and computing systems, logical bits, having values 0 or 1, are implemented in a highly redundant way by bistable elements, such as magnetic domains. The bistability is enforced by coupling the bit carriers to a dissipative environment. Errors may then occur, because of thermal uctuations and other hardware imperfections. To take care of these errors, various correction methods have been developed [1], involving the use of redundant bits (that are implemented by additional bistable elements).

In quantum communication and computing, the situation is more complicated: in spite of their name, the logical \qubits" (quantum binary digits) are not restricted to the discrete values 0 and 1. Their value can be represented by any point on the surface of a Poincare sphere. Moreover, any set of qubits can be in an entangled state: none of the individual qubits has a pure quantum state, it is only the state of all the qubits together that is pure [2].

Perm anent address: Technion | Israel Institute of Technology, 32 000 Haifa, Israel

The qubits of a quantum computer are materialized by single quanta, such as trapped ions β]. Their coupling to a dissipative environment (which was the standard stabilizing mechanism for classical bits) is now to be avoided as much as possible, because it readily leads to decoherence, namely to the loss of phase relationships. Yet, disturbances due to the environment cannot be completely eliminated: e.g., even if there are no residual gas molecules in the vacuum of an ion trap, there still are the vacuum uctuations of the quantized electromagnetic eld, which induce spontaneous transitions between the energy levels of the ions. Therefore, error control is an essential part of any quantum communication or computing system.

This goal is much more di cult to achieve than classical error correction, because qubits cannot be read, or copied, or duplicated, without altering their quantum state in an unpredictable way [4]. The feasibility of quantum error correction, which for some time had been in doubt, was rst demonstrated by Shor [5]. As in the classical case, redundancy is an essential element, but this cannot be a simple repetitive redundancy, where each bit has several identical replicas and a majority vote is taken to establish the truth. This is because qubits, contrary to ordinary classical bits, can be entangled, and usually they are. As a trivial example, in the singlet state of two spin- $\frac{1}{2}$ particles, each particle, taken separately, is in a completely random state. Therefore, com paring the states of spin- $\frac{1}{2}$ particles that belong to di erent (redundant) singlets would give no inform ation whatsoever.

All quantum error correction methods [5{9] use several physical qubits for representing one logical qubit. These physical qubits are prepared in a carefully chosen, highly entangled state. None of these qubits, taken alone, carries any information. However, a large enough subset of them may contain a su cient amount of information, encoded in relative phases, for determining and exactly restoring the state of the logical qubit, including its entanglement with the other logical qubits in the quantum computer.

In this article, I review the quantum mechanical principles that make error correction possible. (I shall not discuss how to actually design new codewords; the most e cient techniques involve a combination of classical coding theory and of the theory of nite groups.) Since quantum codewords span only a restricted subspace of the complete physical H ibert space, the unitary operations that generate the quantum dynam ical evolution (that is, the computational process) are subject to considerable arbitrariness. The latter is sim ilar to the gauge freedom in quantum eld theory. Quantum codewords can thus serve as a simple toy model for investigating the quantization of constrained dynam ical systems, such as eld theories with gauge groups.

2. Encoding and decoding

In the following, I shall usually consider codewords that represent a single logical qubit. It is also possible, and perhaps it may be more e cient, to encode several qubits into larger codewords. However, no new physical principles are involved in this, and the simple case of a single qubit is su cient for illustrating these principles.

The quantum state of a single logical qubit will be denoted as

$$= j0i + jli; \qquad (1)$$

where the coe cients and are complex numbers. The symbols jui and jui represent any two orthogonal quantum states, such as \up" and \down" for a spin, or the ground state and an excited state of a trapped ion.

In a quantum computer, there are many logical qubits, typically in a collective, highly entangled state, and any particular qubit has no de nite state. I shall still use the same symbol for representing the state of the entire computer, and Eq. (1) could now be written as

$$= ji j j i + ji j l i;$$
 (2)

where one particular qubit has been singled out for the discussion, and the sym bols j i and j i represent the collective states of all the other qubits, that are correlated with jDi and jLi, respectively. However, to sim plify the notation and improve readability, I shall still write the computer state as in Eq. (1). In the following, D irac's ket notation will in general not be used for generic state vectors (such as , ,) and the sign will som etimes be om itted, when the meaning is clear. Kets will be used only for denoting basis vectors such as jDi and jLi, and their direct products. The latter will be labelled by binary numbers, such as

In order to encode the qubit in Eq. (1), we intoduce an auxiliary system, called ancila,¹ initially in a state j000 :::i. The ancilla is made of n qubits, and we can use the mutually orthogonal vectors jai, with $a = 0, 1, ..., 2^n$ 1 (the number a being written in binary notation) as a basis for its quantum states. These labels are called syndrom es, because, as we shall see, the presence of an ancilla state with a ≤ 0 m ay serve to identify an error in the encoded state that represents .

 ${\tt E}\,{\tt ncoding}$ is a unitary transform ation, ${\tt E}$, perform ed on a physical qubit and its ancilla together:

$$\dot{\mathbf{z}}_{1} = 0\mathbf{i} + \mathbf{E} \dot{\mathbf{z}}_{1} \dot{\mathbf{z}}_{0} \mathbf{i}$$
 (4)

where jzi m eans either j0i or j1i. This unitary transform ation is executed by a quantum circuit (an array of quantum gates). However, from the theorist's point of view, it is also convenient to consider jzi $j_a = 0i$ and $j_{c0}i$ as two di erent representations of the same qubit jzi: its logical representation, and its physical representation. The rst one is convenient for discussing matters of principle, such as quantum algorithms, while the physical representation is the one where qubits are actually materialized by distinct physical systems (and the latter are the ones that may be subject to independent errors).²

¹This is the Latin word for housem aid.

²These two di erent representations are analogous to the use of norm alm odes vs. local coordinates for describing the sm all oscillations of a mechanical system [10]. One description is mathematically simple, the other one is related to directly accessible quantities.

3. Error correction

If there are 2^n syndrom es (including the null syndrom e for no error), it is possible to identify and correct up to 2^n 1 di erent errors that a ect the physical qubits, with the help of a suitable decoding method, as explained below. Let $J_a i$, with $a = 0, \ldots, 2^n$ 1, be a complete set of orthonorm al vectors describing the physical qubits of which the codewords are made: $j_{0}i$ and $j_{1}oi$ are the two error free states that represent j i and j and j and $j_a i$ are the results of errors (a ecting one physical qubits in the codeword, or several ones, this does not matter at this stage). These $J_a i$ are de ned in such a way that $j_a i$ and $j_{1a}i$ result from the same errors in the physical qubits of $j_{0}oi$ and $j_{1}oi$ (for example, the third qubit is ipped). We thus have two complete orthonorm al bases, j_{2i} is and $J_a i$. These two bases uniquely de ne a unitary transform ation E, such that

$$E (jzi jai) = J_a i;$$
(5)

and

$$E^{Y} Z_{a} i = j z i j a i;$$
 (6)

where a runs from 0 to 2^n 1. Thus, E is the encoding m atrix, and E^Y is the decoding m atrix. If the original and corrupted codewords are chosen in such a way that E is a real orthogonal matrix (not a complex unitary one), then E^Y is the transposed matrix, and therefore E and E^Y are implemented by the same quantum circuit, executed in two opposite directions. (If E is complex, the encoding and decoding circuits must also have opposite phase shifts.)

The 2^n 1 \standard errors" $\not \mathbb{Z}_0 i!$ $\not \mathbb{Z}_a i$ are not the only ones that can be corrected by the E^y decoding. Any error of type

$$z_0 i! \quad U \quad z_0 i = \sum_{a}^{X} c_a \quad z_a i; \tag{7}$$

is also corrected, since

$$E^{Y} \stackrel{X}{\underset{a}{}} c_{a} \not z_{a} i = \dot{z} i \qquad \overset{X}{\underset{a}{}} c_{a} \dot{z}_{a} i; \qquad (8)$$

is a direct product of jzi with the ancilla in som e irrelevant corrupted state. Note that no know ledge of the syndrom e is needed in order to correct the error [11]. Error correction is a logical operation that can be performed autom atically, without having to execute quantum m easurements. We know that the error is corrected, even if we don't know the nature of that error.

It is essential that the result on the right hand side of (8) be a direct product. Only if the new ancilla state is the same for jzi = jli and jzi = jli, and therefore also for the complete computer state in Eq. (2), is it possible to coherently detach the ancilla from the rest of the computer, and replace it by a fresh ancilla (or restore it to its original state

ja = 0i by a dissipative process involving still another, extraneous, physical system).³ This means, in the graphical form alism of quantum circuits, that the \w ires" corresponding to the old ancilla stop, and new \w ires" enter into the circuit, with a standard quantum state for the new ancilla.

There are many plausible scenarios for the emergence of coherent superpositions of corrupted states, as in (8). For example, in an ion trap, a residual gas molecule, whose wave function is spread over a domain much larger than the inter-ion spacing, can be scattered by all the ions, as by a diraction grating, and then all the ions are left in a collective recoil state (namely, a coherent superposition of states where one of the ions recoiled and the other ones did not). Furtherm ore, mixtures of errors of type (8) are also corrigible. Indeed, if

$$= \sum_{j=ab}^{X} p_{j} c_{ja} \mathcal{I}_{a} ih \mathbb{Z}_{b} j c_{jb};$$
(9)

with $p_j > 0$ and $p_j = 1$, then

$$E^{y} E = jzihzj \qquad \begin{array}{c} X & X \\ p_{j} & p_{j} \\ j & ab \end{array} c_{ja} jaihbjc_{jb}; \qquad (10)$$

again is a direct product of the logical qubit and the corrupted ancilla.

These m ixtures include the case where a physical qubit in the codew ord gets entangled with an unknown environment, which is the typical source of error. Let be the initial, unknown state of the environment, and let its interaction with a physical qubit cause the following unitary evolution:

where the new environment states ; ; , and , are also unknown, except for unitarity constraints. Now assume that the physical qubit, that has become entangled with the environment in such a way, was originally part of a codeword,

$$f_{z_0}i = f_{z_0}i \quad f_{0}i + f_{z_1}i \quad f_{1}i;$$
 (12)

That codew ord, together with its environm ent, thus evolve as

 Z_0 ! $Z^0 = X_{z0}$ jDi + jLi + X_{z1} jDi + jLi ; (13)

where I have om itted most of the ket signs, for brevity. This can be written as

$$Z^{0} = \overset{h}{X_{z0}} \overset{fi}{\text{pi} + X_{z1}} \overset{i}{\text{pi}} \frac{+}{2} + \overset{h}{X_{z0}} \overset{fi}{\text{pi}} X_{z1} \overset{i}{\text{pi}} \frac{-}{2} + \overset{i}{X_{z0}} \overset{fi}{\text{pi}} X_{z1} \overset{i}{\text{pi}} \frac{-}{2} + \overset{i}{X_{z0}} \overset{fi}{\text{pi}} X_{z1} \overset{fi}{\text{pi}} \frac{-}{2} + \overset{i}{X_{z0}} \overset{fi}{\text{pi}} X_{z1} \overset{fi}{\text{pi}} \frac{-}{2} :$$
(14)

³The introduction of a dissipative process in the quantum computer, which essentially is an analog device with a continuous evolution, brings it a step closer to a conventional digital computer!

$$Z_{0} = X_{z0} \quad \text{pi} + X_{z1} \quad \text{ji};$$

$$Z_{r} = X_{z0} \quad \text{pi} \quad X_{z1} \quad \text{ji};$$

$$Z_{s} = X_{z0} \quad \text{ji} + X_{z1} \quad \text{pi};$$

$$Z_{t} = X_{z0} \quad \text{ji} \quad X_{z1} \quad \text{pi};$$
(15)

correspond, respectively, to a correct codeword, to a phase error (jli! jli), a bit error (jli \$ jli), which is the only classical type of error, and to a combined phase and bit error. If these three types of errors can be corrected, we can also correct any type of entanglem ent with the environm ent, as we shall soon see.

For this to be possible, it is necessary that the eight vectors in Eq. (15) be mutually orthogonal (recall that the index z m eans 0 or 1).⁴ The simplest way of achieving this is to construct the codewords j_0 i and j_0 i in such a way that the following scalar products hold:

hX _{zy}; X _{z⁰y⁰}
$$i = \frac{1}{2}$$
 _{zz⁰ yy⁰}: (16)

(There are 10 such scalar products, since each index in this equation m ay take the values 0 and 1.) If these conditions are satilled, the decoding of Z^{0} by E^{y} gives, by virtue of Eq. (6),

$$E^{Y}Z^{0} = jzi$$
 $ja = 0i$ $\frac{+}{2} + jzi$ $\frac{-}{2} + jzi$ $\frac{+}{2} + jzi$ (17)

The expression in parentheses is an entangled state of the ancilla and the unknown environm ent. We cannot know it explicitly, but this is not necessary: it is su cient to know that it is the same state for $j_{2i} = j_{1i}$ or $j_{2i} = j_{1i}$, or any linear combination thereof, as in Eq. (1). We merely have to discard the old ancilla and bring in a new one.

How to construct codewords that actually satisfy Eq. (16), when any one of their physical qubits is singled out, is a di cult problem, best handled by a combination of classical codeword theory [1] and nite group theory. I shall not enter into this subject here. I only mention that in order to correct an arbitrary error in any one of its qubits, a codeword must have at least ve qubits: each one contributes three distinct vectors, like Z_r, Z_s , and Z_t in Eq. (15), and these, together with the error free vector Z_0 , make 16 vectors for each logical qubit value, and therefore $32 = 2^5$ in the total. Longer codewords can correct more than one erroneous qubit. For example, Steane's linear code [7], with 7 qubits, can correct not only any error in a single physical qubit, but also a phase error, jli ! jli, in one of them, and a bit error, jli \$ jli, in another one (check! $1 + 7 = 3 + 7 = 6 = 2^{7 \ 1}$). A well designed codeword is one where the orthogonal basis J_{a} is corresponds to the most plausible physical sources of errors.

The error correction m ethod proposed above, in Eq. (6), is conceptually simple, but it has the disadvantage of leaving the logical qubit jzi in a \bare" state, vulnerable to new

⁴There is a slight risk of confusion here, because the same symbol 0 refers to the bit-value 0, and to the error free state of a codeword. I see no way of circum venting this di culty without causing further confusion.

errors that would be not be detected. It is therefore necessary to re-encode that qubit in m ediately, with another ancilla (or with the sam e ancilla, reset to $j_a = 0$ i by interaction with still another system). A more complicated but safer m ethod is to bring in a second ancilla, in a standard state $j_b = 0$ i, and have it interact with the complete codeword in such a way that

$$\mathbf{z}_{a}$$
i $\mathbf{p} = 0$ i! \mathbf{z}_{0} i $\mathbf{p} = a$ i: (18)

This is also a unitary transform ation, which can be implemented by a quantum circuit. Note that now the unitary matrix that performs that error recovery is of order 2^{2n+1} , instead of 2^{n+1} .

Naturally, errors can also occur in the encoding and decoding process. More sophisticated methods can however be designed, that allow fault tolerant computation. An adaptive strategy is used, with several alternative paths for error correction. Most paths fail, because new errors are created; however, these errors can be detected, and there is a high probability that one of the paths will eventually lead to the correct result. As a consequence, the error correction circuits are able to correct old errors faster than they introduce new ones. There is then a high probability for keeping the number of errors sm all enough, so that the correction machinery can successfully deal with them [12].

4. Constrained dynam ics

A quantum codeword is a redundant representation of a logical qubit by means of several physical qubits. Since quantum codewords span only a restricted subspace of the complete physical H ibert space, the unitary operations that generate quantum dynamics (that is, the computational process) are subject to considerable arbitrariness. This is most easily seen with the logical representation, jzi $j_a = 0i$. A unitary transform ation, 1 g, where g acts solely on the ancilla's states, generates

(1 g)
$$\dot{z}$$
i \dot{z} = 0i = \dot{z} i $c_a \dot{z}$ i: (19)

This is a corrupted, but corrigible codeword. In the physical representation, this harm less unitary transform ation becomes

$$G = E (1 g) E^{Y}$$
: (20)

The unitary matrices G are a representation (usually a reducible one) of the Un group. C onsecutive applications of various transform ations of this type merely convert one corrigible error into another corrigible error. These transform ations do not mix the two com plementary subspaces that represent the logical 0 and 1.

On the other hand, a genuine unitary transform ation (one that is actually needed for the computation) is, in the logical representation, ! = (u = 1). It is encoded into

$$U = E (u \ 1) E^{y};$$
 (21)

for the physical representation. Thus, in sum m ary, all the \legal" unitary transform ations are of type E (u g) E y , for codewords that represent a single logical qubit.

For unitary transform ations involving two logical qubits, the encoded representation, including the possibility of corrigible errors, is likewise

$$U_{12} = (E_1 \quad E_2) [u_{12} \quad (g_1 \quad g_2)] (E_1^{Y} \quad E_2^{Y}); \qquad (22)$$

where u_{12} acts on the two logical qubits, and g_1 and g_2 act on their respective ancillas. (I am assuming here that each logical qubit is encoded separately, and that block coding is not used.) It is obvious that in unitary transform ations of that type, the logical steps are not a exted by the occurrence or evolution of corrigible errors.

A mong these unitary transform ations, there is a subgroup leaving the zero-syndrom e ancilla invariant (such a subgroup is called the little group of the invariant state):

$$g \dot{a} = 0 \dot{i} = \dot{a} = 0 \dot{i}$$
 (23)

Let us now focus our attention on these transform ations, that do not induce errors in correct codewords. They only modify corrupted codewords, while keeping them corrigible. W e m ay imagine, if we wish, that error free codewords are stabilized by erecting around them a high potential barrier: conceptually, we add to the H am iltonian a potential term, equal to zero for the legal codeword states, and to a large positive number for erroneous states. This artice is similar to, but much simpler than, the use of the quantum Zeno e ect, that was proposed by several authors as a way of reducing errors. It is actually not di cult to devise quantum circuits that act like a potential barrier (the only serious di culty is that such a circuit must activate high frequency interactions with extraneous qubits, and the latter may them selves be subject to errors, and induce new ones).

In the logical basis, a \legal" (error free) state, \dot{z}_i $\dot{z}_i = 0i$, which is invariant under the little group of $\dot{z}_i = 0i$, is recognized as being orthogonal to all $\dot{z}_i^{0}i$ $\dot{z}_i \in 0i$. This can be written as an orthogonality relation

hC;
$$i = 0;$$
 (24)

where C is any linear combination of the various jz^0i jaiw ith a \notin 0. There are 2 (2^n 1) linearly independent C, that span the \illegal" subspace (including incorrigible errors). Let us normalize them by hC; C i = . After a legal unitary evolution, U still is a legal state, and therefore

hC ; U
$$i = 0$$
: (25)

It follows that

$$UC = \stackrel{X}{=} A \quad (U)C ; \qquad (26)$$

where the matrices A (U) are a unitary representation of U. (If all legal U are considered, that representation will not, in general, be irreducible.)

It is also possible to construct H erm it in operators that express the same constraints. Recall that the codewords are de ned in a H ilbert space with 2^{n+1} dimensions. Now consider

$$M = \overset{X}{j} L \quad iM \quad hC \quad j;$$
 (27)

where M is any matrix of order $2(2^n \ 1)$. Any legal state obeys M = 0. Another constraint (for the same codeword) could be N = 0, where

...

$$N = jC iN hC j;$$
(28)

and N is any other Herm itian matrix. It is easily shown that

$$[M; N] = iP;$$
 (29)

where P is still another Herm it is operator of the same type, and satis es P = 0 for all legal states. Finally, we note that if there are many logical qubits in the quantum computer, its state obeys the nonlocal spacelike" constraint equation

$$M_1 N_2 = 0;$$
 (30)

where the various operators refer to di erent codewords.

These equations are not completely trivial. They are like those appearing in a quantum eld theory with a gauge group. For example, the canonical momenta of the free electrom agnetic eld are ${}^{k} = E {}^{k}$, where E is the electric eld vector. They satisfy the constraint $\mathcal{Q}_{k} {}^{k} = 0$. This cannot hold as an operator equation, because $\mathcal{Q}_{k} {}^{k}$ does not commute with some other eld operators. However, a legal state vector (one without \longitudinal photons") obeys the constraint $\mathcal{Q}_{k} {}^{k} = 0$. The situation becomes more complicated for theories with non-A belian gauge groups, such as general relativity: singular Schwinger terms appear, and the factor ordering problem cannot be discussed without regularization.⁵

An important problem in quantum eld theory (or, in general, in quantum mechanics with constrained dynamical variables) is to properly de ne a Herm itian scalar product. Should we include in it the spurious particles that are generated by the gauge freedom, such as longitudinal photons? W hen we consider codewords, the situation becomes simple and clear, as we shall now see.

Consider indeed two di erent logical states of a quantum codeword, say

$$= E \qquad \begin{array}{c} X \\ c_{a} jai; \end{array} \qquad (31)$$

and

$$= E \qquad \begin{array}{c} X \\ c_a jai: \end{array} \tag{32}$$

⁵For a recent review, see ref. [13].

On the left hand side, there is the physical representation of the codeword, and, in the parenthesis on the right hand side, its logical representation. Note that, irrespective of the logical state (or), the ancilla has the same state c_a jai, because that state represents the syndrom e of the error, and the latter, caused by an interaction with the environment, is independent of the logical state of the qubit, as may be seen in Eq. (15). It then readily follows from the unitarity of E that the scalar products,

$$h; i = h; i;$$
 (33)

are the same for any two non-orthogonal states of a logical qubit, and for their representation by codewords, even by corrupted ones. Further work is in progress, in order to exploit the analogies of quantum codeword dynamics with gauge eld theory.

A cknow ledgm ents
