We demonstrate a scheme, based on a cascade of lithium niobate intensity and phase modulators driven by specially tailored radio frequency waveforms to generate an optical frequency comb with very high spectral flatness. In this work we demonstrate a 10 GHz comb with ~40 lines with spectral power variation below 1-dB and ~60 lines in total. The number of lines that can be generated is limited by the power handling capability of the phase modulator, and this can be scaled without compromising the spectral flatness. Furthermore, the spectral phase of the generated combs in our scheme is almost purely quadratic which, as we will demonstrate, allows for very high quality pulse compression using only single mode fiber.

Strong sinusoidal phase modulation of a continuous wave (CW) laser creates multiple sidebands leading to generation of a frequency comb [1]. Advantages of this technique include the ability to create high repetition rate combs with optical frequency stability equal to that of the source laser and convenient tuning of the repetition rate and optical center frequency. Therefore, such combs are a source of choice for some applications in optical communications [2], RF photonics [3] and optical arbitrary waveform generation (OAWG) [4]. However, by phase modulation alone, the spectral flatness of the comb is quite poor. The amplitudes of successive comb lines follow successive Bessel function dependences on drive voltage; for drive voltages large enough to generate a significant number of comb lines, the line to line amplitude variation can be quite large.

From an application point of view, a flat frequency comb is generally desired. For example, if the comb is used as a multi-wavelength source, it is desirable to have equal power in different wavelengths. For applications such as RF photonic filtering requiring a specific spectral shape (for example, [5]), apodization is much easier with minimal excess loss if we start off with a flat comb. Also, for time domain applications where a short pulse is needed, abrupt line to line variations result in poor pulse quality; hence a flat comb enables generation of cleaner pulses. In recent years there has been substantial research activity aimed at generating flatter combs (e.g. [6]-[10]). The schemes used include using an intensity modulator in series with the phase modulator [6], using two phase modulators with a chirped fiber Bragg grating [7], using a dual-drive Mach-Zehnder modulator [8, 9], or using an optimization procedure to calculate the RF drive waveform to the phase modulator [10]. Though all of these schemes improve the flatness significantly compared to phase-only modulation, they still provide either limited flatness over the bandwidth of interest or limited number of lines over which flatness can be maintained. For
example, in [7] the comb shows 7-dB power variation over the ~60 lines which constitute the flat region of the spectrum, while references [8] and [9] report 11 spectral lines, with 1.1dB and 1.9dB power variation, respectively. In this work we will demonstrate a scheme which can produce very flat combs over large bandwidths, limited only by the RF power handling capability of the phase modulator. We achieve this using a cascade of two intensity modulators and two phase modulators driven by tailored RF sinusoids. An attractive feature of this scheme is that it is backed by a strong theoretical argument as to why it works. In particular, we report a 10 GHz comb with ~40 lines in a 1-dB bandwidth and ~60 lines in total. The number of lines can be scaled with increasing RF drive power without sacrificing the spectral flatness. Also, the spectral phase of the comb generated in our experiment is almost purely quadratic, which allows for generation of high quality pulses via compression in a simple dispersive fiber or chirped fiber Bragg grating.

Our research draws on the interesting theoretical work of V. Torres-Company and coworkers [11], which proposed a novel way of understanding the spectral flatness achieved in previous schemes such as [6] and [7]. The idea is that if a flat topped pulse is subjected to a strong, periodic, quadratically varying temporal phase, it undergoes time-to-frequency mapping [12, 13], resulting in a comb whose shape mimics the time domain intensity of the input waveform. Since a flat topped pulse is used, the frequency comb would be flat. Generating a periodic quadratic temporal phase though is hard; however, a sinusoidal temporal phase can be approximated by a quadratic function around its peak or its valley and to a first order provides a means to generate the required quadratic temporal phase. Generating a flat topped pulse is easier; one convenient approach is to use an intensity modulator driven with a sinusoid with an amplitude equal to the $V\pi$ of the modulator and a DC bias corresponding to a phase shift of
\(-\pi / 2\) (i.e. the envelope of the output field after the intensity modulator goes as
\((1 + \exp(j \pi / 2) \cdot \exp(j \pi / 2 \cdot \cos \omega_{rf} t))\). Putting these two aspects together, an
IM-PM cascade with sinusoidal drives should generate a reasonably flat comb. Fig 1(a) shows
this scheme, and Fig 1(b) shows the spectrum simulated assuming the intensity modulator
generates a flat-topped pulse as described above and the phase modulator is driven with a
sinusoidal voltage whose amplitude ‘V’ is given by \(V/\sqrt{\pi} \sim 6.4\) (i.e. the effect of the phase
modulator can be written as a multiplication by \(-\exp(j \cdot 6.4 \pi \cdot \cos \omega_{rf} t)\)). The number of
lines largely depends on the ratio of the phase modulator drive voltage its \(V\pi\). In all our
simulations we choose this close to what we can achieve experimentally to allow for easier
comparison between simulation and experiment. In Fig. 1(b) we see a flat central section to the
spectra, but towards the edges there are pronounced “bat ears.” This can be understood better in
the time domain. Figure 1(c) (blue, solid) shows the time domain signal, and 1(c) (red, solid)
shows the sinusoidal temporal phase. In the central part, the time domain is very flat and the
phase is almost quadratic leading to good spectral flatness in this section. As we move away
from the center and the phase starts deviating from a quadratic, the flatness is degraded. The
strong peaks or bat-ears occur at the spectral extrema, where the instantaneous frequency, i.e.,
the time derivate of the temporal phase, is at a minimum or maximum. The bat-ears may be
explained on the basis of the relatively long time for which the instantaneous frequency function
dwells at the frequency extrema.

In order to obtain flat spectra, since we need both a nice flat-topped pulse as well as a
good quadratic temporal phase (for which the instantaneous frequency would be a linear without
extrema). Accordingly, we propose two modifications to the above method. A first improvement
would be to make the flat-topped pulse sharper, which will reduce the fraction of the waveform
seeing a significant departure from quadratic temporal phase. This can be achieved using two intensity modulators in series driven with the same parameters as described previously. Figure 1(c) (black, dashed) shows the new time domain waveform, and Fig. 1(d) shows the comb generator setup. The input to the phase modulator is unchanged. Figure 1(e) shows the simulated output spectrum. The flatness is improved compared to Fig. 1(b), with less power in the bat-ears and with the contrast between the peaks and the flat central region reduced from ~5-dB to ~3-dB.

To further improve the flatness we focus on the temporal phase. Since the bat ears happen due to deviation from quadratic phase, we attempt to generate a phase profile that better approximates a quadratic. One approach is to achieve Fourier synthesis of the RF quadratic waveform from harmonics of the initial sinusoid. Here we show that it is possible to make significant progress by using only the first and second RF harmonic (obtained using a X2 multiplier) in order to eliminate the first non quadratic term. Now the expansion for the cosine around its maximum up to the first undesirable term is,

\[
\cos(\omega_{rf}t) = 1 - \frac{(\omega_{rf}t)^2}{2!} + \frac{(\omega_{rf}t)^4}{4!} - \ldots
\]  

So we have

\[
\cos(\omega_{rf}t) - \frac{1}{16} \cos(2\omega_{rf}t) = \frac{15}{16} - 0.75 \frac{(\omega_{rf}t)^2}{2!} + 0 + \ldots
\]  

From eqn (2) we see that by using the first and 2\textsuperscript{nd} harmonics with a suitable ratio and phase shift between them, the 4\textsuperscript{th} order term (which is the first non-ideal term) can be made zero. In a general sense, since all the higher order terms still exist it is still not a pure quadratic. However, in our case since the cascade of the intensity modulator creates a flatter waveform with a sharper decay, in the region of the flat topped pulse, the remaining high order terms are less of an issue.
The absence of the first undesirable term (namely the 4\textsuperscript{th} order term) enables a significant performance improvement.

Figure 2(a) shows our experimental scheme incorporating both the improvements we discussed. A variable attenuator is used to achieve the correct ratio between the harmonics (~24dB) and RF phase shifters allow for accurate phase relations (180 degrees) and delay matches between different modulators. Figure 2(b) shows the simulated spectrum, which we see is now significantly flattened, with the power variation before the spectrum falls of on either side reduced to less than ±0.5 dB (<±10%).

This comb generation scheme based on a tailored RF drive also offers a second interesting aspect. In the large phase modulation limit, a waveform with a pure quadratic temporal phase corresponds to a spectrum with pure quadratic phase. This in turn corresponds to a pulse with a linear chirp, which can be compressed with high quality to the bandwidth limit using the dispersion of an appropriate length of standard single mode fiber, SMF (for the bandwidths involved, the effect of the dispersion slope of the fiber is small). The improved compressibility of combs utilizing tailored RF drive to the phase modulator has also been demonstrated in [14]. However, ref. [14] does not consider the effect of the RF drive waveform on comb flatness and is limited to a single intensity modulator used under a different bias condition that does not generate the flat-topped intensity profiles of interest here. The key contribution of our paper is generation of flat combs, which requires both improved quadratic drive for the phase modulator and an intensity modulator pair with drive and bias conditions prescribed previously. Pulse compression using just the dispersion of SMF has also been demonstrated in comb generation experiments using only a phase modulator [1] or dual drive Mach-Zehnder modulator [8, 9] without separate intensity modulator and with pure sinusoidal
phase. However, as demonstrated in [14], pulse quality is degraded with pure sinusoidal phase modulator drive, as a result of significant departures from the quadratic spectral phase needed for high quality by SMF. In the above experiments, the involved bandwidths are smaller reducing the effect of the non ideal compensation. Pulse compression of a comb generated via intensity modulation at the fundamental RF frequency cascaded with pure phase modulation at the RF second harmonic has also been reported; however, in that case a line-by-line pulse shaper was required to compensate very rapid spectral phase variations, which increases system complexity. Figure 2(c) (blue, solid) shows our simulated spectral phase together with a quadratic fit (red, dashed). We see that the fit is very good, with slight deviation only at the edges of the spectrum where the comb has little energy (compare to Fig. 2(b)). Hence, as we will show with our experiments, very high quality pulse generation is possible using only linear propagation in SMF as the means for compression. This is in contrast when the phase modulator is driven with a pure sinusoid in which case, as shown in fig 2(d), the deviation of the spectral phase from a quadratic is significantly more.

Our experimental setup is shown in Fig. 2(a), with the minor difference that we use two phase modulators in series. This is a common technique used (e.g., [7]) to overcome the RF power handling limit of the phase modulators. In our case the maximum RF power is 1W per modulator; driving two phase modulators identically in series allows effectively a 3-dB increase in the amount of RF drive power to 2W, which doubles the number of obtained spectral lines. Note that the maximum power corresponds essentially to that of the first harmonic RF drive, since the power of our 2\textsuperscript{nd} harmonic drive signal is 24dB down. The drive parameters to the phase modulator in the simulations corresponds to what we experimentally achieve here with a cascade of the two phase modulators. The IM we use has a $V_\pi$ of \~8V, the phase modulator has a
Vπ of ~3V. The repetition rate of the RF oscillator is 10GHz. The net optical loss of the whole apparatus is ~15dB (this includes the mainly the modulator losses; with low loss modulators this number can be significantly improved). Figures 3(a) and 3(b) show the obtained output comb spectra, corresponding to point at (1) in Fig 2(a), in linear and log scale, respectively. We observe a very flat spectral profile with 38 lines in a 1-dB bandwidth, with an impressive 36 lines within a 0.5dB bandwidth (<± 5%). The total number of lines (above the noise floor) is ~ 60.

We then measured the spectral phase of this comb using a frequency comb characterization technique based on a linear implementation of spectral shearing interferometry, described in detail in [15]. This technique involves intensity modulating the comb source with a small RF signal at half the repetition frequency of the comb. The sidebands created from adjacent lines interfere, leading to an amplitude variation dependent on the phase difference between adjacent lines. The spectral phase then can be obtained by summing up the measured phase differences. The measured phase indicated that pulse compression could be accomplished using ~850m of SMF. (the compression scheme is shown in fig 3(c)). Fig 3(d) (blue, solid) shows the measured intensity autocorrelation of the output pulse. The theoretical intensity autocorrelation (red, dashed) taking into account the measured comb spectrum and assuming flat phase is also plotted. We see excellent agreement, indicating high quality pulse compression to a bandwidth-limited pulse. The obtained pulse has an intensity autocorrelation FWHM of ~2.8ps, which corresponds to an intensity FWHM of ~2.1ps assuming the sinc^2 intensity profile appropriate for the nearly flat-topped spectrum.

In summary, we have demonstrated a new scheme for generating very flat optical frequency combs using cascaded intensity and phase modulators driven by tailored RF sinusoids. The number of lines achievable in the comb is only limited by the RF power handling capability
of the phase modulators and can be scaled without compromising spectral flatness by driving more PMs in series or using lower $V_\pi$ devices. In this work we demonstrated a 10 GHz comb with 38 lines in a 1-dB bandwidth and around 60 lines in total. Another attractive aspect of our scheme is the ability to achieve very high quality compression (in our experiments resulting in an \textasciitilde2.1 ps bandwidth-limited pulse) simply through propagation in standard single-mode fiber. This scheme provides an attractive option to generate flat wide bandwidth combs for various applications.
