On the Degrees-of-Freedom of the K-user Distributed Broadcast Channel

Antonio Bazco-Nogueras, Student Member, IEEE, Paul de Kerret, Member, IEEE, David Gesbert, Fellow, IEEE, and Nicolas Gresset, Senior Member, IEEE

Abstract

In this paper, we consider the network MIMO channel under the so-called distributed Channel State Information (CSI) configuration. In that setting, each Transmitter (TX) shares the common knowledge of all user’s data symbols but has only its own imperfect estimate of the CSI, based on which it designs its transmission coefficients in a decentralized manner. This setting could for example be encountered when the user’s data symbols are cached beforehand at the TXs or in a Cloud-RAN scenario with partial centralization where the CSI sharing between TXs suffers from the delay due to the sharing through the backhaul network. Our first contribution consists in rigorously computing an upper-bound for the DoF through the analysis of a genie-aided setting. Building on this upper-bound, we present a new robust decentralized transmission scheme that achieves the optimal DoF over several important CSI configurations. In strong contrast to the conventional zero-forcing scheme which is known to be limited by the worst estimate across TXs, the proposed scheme is able to leverage the more accurate CSI at few TXs to improve the DoF. Surprisingly, we show that there is a CSI regime in which the optimal DoF only depends on the CSI quality at the best TX, such that sharing the channel estimate to the other TXs does not improve the DoF.

I. INTRODUCTION

A. Limited Channel State Information on the Transmitter Side in Wireless Networks

Channel capacity characterization of multi-user networks is known to be an elusive problem for an important set of scenarios, in particular whenever the Channel State Information at the Transmitter (CSIT) is not perfect. In order to tackle this problem, capacity approximations at high Signal-to-Noise Ratio (SNR), e.g., the Degrees-of-Freedom (DoF) analysis [1], have been used as a first step towards the complete characterization of the system capacity, offering important insights. In particular, the optimal DoF of the $K$ user MISO Broadcast Channel (BC)
with imperfect noisy CSIT was obtained by Davoodi and Jafar in [2] by showing that a scaling of the CSIT error in SNR\(^{-\alpha}\) for \(\alpha \in [0, 1]\) leads to a DoF of \(1 + (K - 1)\alpha\).

A different line of work in the area of BC with limited feedback has been focused on the exploitation of delayed CSIT. This research area was triggered by the seminal work from Maddah-Ali and Tse [3] where it was shown that completely outdated CSIT could still be exploited via a multi-phase protocol involving the retransmission of the interference generated. While the original model assumed completely outdated CSIT, a large number of works have developed generalized schemes for the case of partially outdated [4]–[6], alternating [7], or evolving CSIT [8], to name just a few.

In all the above literature, however, centralized CSIT is typically assumed, i.e., the transmission is optimized at the TX side on the basis of a single imperfect/outdated channel estimate being common at every transmit antenna. Recently, the increasing importance of cooperation of non-collocated TXs (e.g., Unmanned Aerial Device (UAV) aided networks [9]) has lead to an increasing number of works challenging this assumption of centralized CSIT. In [10], [11], methods are developed to reduce the CSIT required to achieve MIMO Interference Alignment (IA). The DoF achieved with delayed and local CSIT in the Interference Channel (IC) is also studied in several works [12]–[14]. The assumption of centralized CSIT has also been challenged in capacity analysis for the Multiple Access Channel [15] and the Relay Channel [16], among others.

B. Network MIMO with Distributed CSIT

In order to account for TX-dependent limited feedback in the network MIMO channel, a Distributed CSIT model—which is here referred to as D-CSIT—has been introduced in [17]. In this model, TX \(j\) receives its own multi-user imperfect estimate \(\hat{H}(j)\) on the basis of which it designs its multi-user transmit coefficients, without additional communications with the other TXs. This configuration where the user’s data symbols are available at all TXs but the CSIT is imperfectly shared has become increasing relevant due to two key features being envisioned for future 5G-and-beyond wireless networks: Caching [18]–[20] and Cloud-Ran/Fog-Ran [21], [22].

Through caching, the user’s data symbols are pre-fetched at the TX nodes before the transmission occurs. This availability of the data symbols is exploited in wireless networks to reduce interference through joint precoding [23]. An efficient interference reduction however requires the accurate and timely knowledge of the multi-user channel. Thus, the obtaining and sharing of this information becomes a key limitation.

In the Cloud-RAN paradigm, the centralization of the processing of all nodes is envisioned so as to gain full benefits of the cooperation. This centralization is however limited by its cost and by its delay, such that partial centralization is considered a promising solution for these limitations. In particular, the direct links between the nodes can be used to reduce the delay in the CSIT sharing. This distributed CSIT acquisition would then lead to CSIT configurations where all the TXs would not share the same channel estimate, i.e., a D-CSIT configuration.

In [24] the finite-SNR performance of regularized Zero-Forcing (ZF) under D-CSIT has been computed in the large system limit and heuristic robust precoding schemes have been provided in [25], [26] for practical cellular networks. In terms of DoF, it was shown in a previous work [17] that using a conventional ZF precoder (regularized
or not) leads to a severe DoF degradation caused by the lack of a consistent CSI shared by the cooperating TXs. Exploiting the fact that there is a single interfered user in the two-user case, it was shown that exploiting the CSIT at a single TX was sufficient to completely suppress the interference, thus recovering from the DoF loss due to the D-CSIT setting. Interestingly, this result was extended in [27] to the Generalized DoF (GDoF) [28], where it was shown that the 2-user case centralized GDoF is recovered for any path-loss topology and CSIT allocation.

Obtaining a robust transmission scheme for an arbitrary number of users has remained an open problem for several years due to the fact that all these approach do not extend well to more than 2-users. tackling this challenging problem is the focus of this work.

C. Main Contributions

Our main contributions read as follows:

- We compute the DoF of the genie-aided setting where all TXs are given the knowledge of all the channel estimates at all TXs, the so-called centralized upper-bound.
- We then show the surprising result that this bound is actually tight for a range of D-CSIT configurations, coined the weak CSIT regime and which will be defined rigorously further down. Interestingly, the optimal DoF for such D-CSIT settings only depends on the CSIT quality at the most informed TXs. It is hence not necessary to share the instantaneous CSIT among the TXs to achieve the genie-aided centralized DoF.
- Building on the fundamental principles of the previous scheme, we derive a robust transmission scheme adapted to any CSIT configuration and any number of users.

As a byproduct of our approaches, two building elements of our robust transmission schemes are interesting by themselves and could prove useful to obtain other results. First, we present a non-trivial extension of the Active-Passive precoding scheme introduced in [17]. Specifically, we highlight how multiple passive TXs are essential to multi-stream transmissions. Second, we translate to the distributed CSIT setting the idea introduced by Maddah-Ali and Tse in [3] consisting in estimating and retransmitting the interference generated. Interestingly, and in contrast to [3], the interference terms are estimated before they even take place and are retransmitted in the same time slot. This principle could be applied in other configurations where some TXs are more informed than others.

**Notations:** We denote the probability density function of a variable $X$ as $f_X(x)$. For a conditional probability density function, the simplified notation $f_{X|Y}(x|y)$ stands for $f_{X|Y}(X=x|Y=y)$. We use $\doteq$ to denote exponential equality, i.e., we write $f(P) \doteq P^x$ to denote $\lim_{P \rightarrow \infty} \frac{\log f(P)}{\log P} = x$. The exponential inequalities $\leq$ and $\geq$ are defined in the same way. We use the conventional Landau notation, i.e., $f(x) = O(g(x))$ stands for $\lim_{x \rightarrow \infty} \frac{|f(x)|}{|g(x)|} = a$, with $0 < a < \infty$, and $f(x) = o(g(x))$ stands for $\lim_{x \rightarrow \infty} \frac{|f(x)|}{|g(x)|} = 0$. We also use the shorthand notation $\mathcal{K} \triangleq \{1, \ldots, K\}$. Given a matrix $A$, the sub-matrix obtained by taking from $A$ the rows $\{r_i, \ldots, r_j\}$ and the columns $\{c_i, \ldots, c_j\}$ is denoted by $A_{r_i:r_j,c_i:c_j}$. 
II. SYSTEM MODEL

A. Transmission Model

We study a communication system where $K$ TXs jointly serve $K$ users (RXs) over a Network (Broadcast) MIMO channel. We consider that each node (TX or RX) is equipped with a single-antenna. The assumption of single-antenna TX is done for ease of exposition, and the extension to a multiple-antenna setting with every node having $M > 1$ antennas is straightforward. The signal received at RX $i$ is written as

$$y_i = h_i^H x + z_i,$$

where $h_i^H \in \mathbb{C}^{1 \times K}$ is the channel vector towards RX $i$, $x \in \mathbb{C}^{K \times 1}$ is the transmitted multi-user signal, and $z_i \in \mathbb{C}$ is the additive noise at RX $i$, being independent of the channel and the transmitted signal, and distributed as $\mathcal{N}_C(0, 1)$. We further define the channel matrix $H \triangleq [h_1, \ldots, h_K]^H \in \mathbb{C}^{K \times K}$ and the channel coefficient from TX $k$ to RX $i$ as $H_{i,k}$. The channel is assumed to be drawn from a continuous distribution with density such that all the channel matrices and all their sub-matrices are full rank with probability one. Furthermore, the channel coefficients are assumed to change after one channel use and be independent from one channel use to another.

We will differentiate in this work between the private data symbols, destined to be decoded at a particular user, and the common data symbols, broadcast and destined to be decoded at all users. Note that the term private is used only in contrast to common and does not refer to any privacy/secrecy constraint, but to the fact that only one user will decode the symbol.

B. Distributed CSIT Model

The D-CSIT setting differs from the conventional centralized one in that each TX receives a possibly different (global) CSI, based on which it designs its own transmission parameters without any additional communication with the other TXs. Specifically, TX $j$ receives the imperfect multi-user channel estimate $\hat{H}^{(j)} = [\hat{h}_1^{(j)}, \ldots, \hat{h}_K^{(j)}]^H \in \mathbb{C}^{K \times K}$ where $(\hat{h}_i^{(j)})^H$ refers to the estimate at TX $j$ of the channel from all TXs towards RX $i$. TX $j$ then designs its transmit coefficients solely as a function of $\hat{H}^{(j)}$ and the statistics of the channel. This scenario can be seen as a multi-agent cooperative decision with common goal, where each node knows the structure of the system but not the information that the others own [29].

Remark 1. It is critical to this work to understand well how the distributed CSIT setting differs from the many different heterogeneous CSIT configurations studied in the literature. Indeed, a heterogeneous CSIT configuration typically refers to a centralized CSIT setting (i.e., with a common channel estimate at all TXs), where each element of the channel is known with a different quality owing to specific feedback mechanisms [30]–[33]. In contrast, the distributed setting considered here has as many different channel estimates as TXs, where each TX does not have access to the CSIT knowledge at the other TXs.

This D-CSIT setting is illustrated in Fig. 1. We model the CSI uncertainty at TX $j$ as

$$\hat{H}^{(j)} = H + \bar{P}^{-\alpha^{(j)}} \Delta^{(j)},$$

(2)
Fig. 1: Network MIMO with Distributed CSIT. The accuracy of the channel estimate at TX $j$ is modeled through the CSIT scaling coefficient $\alpha^{(j)}$.

where $\bar{P} \triangleq \sqrt{P}$ and $P$ is the nominal SNR parameter. $\Delta^{(j)} \in \mathbb{C}^{K \times K}$ is a random variable with zero mean and bounded covariance matrix. The scalar $\alpha^{(j)}$ is called the CSIT scaling coefficient at TX $j$ and takes its value in $[0,1]$, where $\alpha^{(j)} = 0$ is generally seen to correspond to a CSIT being useless in terms of DoF, whilst $\alpha^{(j)} = 1$ is equivalent in terms of DoF to a perfect CSIT [2], [34]. For later use, we also denote the $i$-th row of $\Delta^{(j)}$ as $(\delta^{(j)}_{i})^H$, such that it holds

$$
\hat{h}^{(j)}_{i} = h_{i} + \bar{P}^{-\alpha^{(j)}} \delta^{(j)}_{i}.
$$

(3)

We restrict in this work the D-CSIT model to the case of homogeneous CSIT quality within a given TX, i.e., every channel coefficient is known at TX $j$ with the same CSIT quality $\alpha^{(j)}$. This limitation it not inherent to the D-CSIT model and is solely done here for simplicity. How to deal with different CSIT qualities for the different channel coefficients is the topic of undergoing research and is out of the scope of this work.

Given that one TX has the same CSIT quality ($\alpha^{(j)}$) for any link, we can order them without loss of generality such that

$$
1 \geq \alpha^{(1)} \geq \alpha^{(2)} \geq \cdots \geq \alpha^{(K)} \geq 0.
$$

(4)

The multi-user distributed CSIT configuration is represented through the multi-TX CSIT scaling vector $\alpha \in \mathbb{R}^{K}$ defined as

$$
\alpha \triangleq \left[ \alpha^{(1)}, \ldots, \alpha^{(K)} \right]^T.
$$

(5)

We assume that all the TXs are aware of the statistical information $\alpha$. In addition, we consider that the channel realizations and the estimation noise are mutually independent. We assume that all channel realizations $H_{i,k}$ and
estimation noise variables $\Delta_{i,j,k}^{(j)}$ satisfy the Bounded Density assumption introduced in \cite{2}. As our proof in the distributed CSIT setting builds on the centralized result, we will also use this assumption to prove the upper-bound. We recall it in the following for the sake of completeness.

Definition 1 (Bounded Density Coefficients \cite{2}). A set of random variables, $\mathcal{A}$, is said to satisfy the bounded density assumption if there exists a finite positive constant $f_{\text{max}}$,

$$0 < f_{\text{max}} < \infty,$$

such that for all finite cardinality disjoint subsets $\mathcal{A}_1, \mathcal{A}_2$ of $\mathcal{A}$, $\mathcal{A}_1 \subseteq \mathcal{A}, \mathcal{A}_2 \subseteq \mathcal{A}, \mathcal{A}_1 \cap \mathcal{A} = \emptyset,$ $|\mathcal{A}_1| < \infty, |\mathcal{A}_2| < \infty$, the conditional probability density functions exist and are bounded as follows

$$\forall \mathcal{A}_1, \mathcal{A}_2, \ f_{\mathcal{A}_1|\mathcal{A}_2}(\mathcal{A}_1|\mathcal{A}_2) \leq f_{|\mathcal{A}_1|}{\text{max}}. \tag{7}$$

C. CSIR Model

In this work, we focus on the impact of the imperfect CSI on the TX side as the CSI acquisition is widely acknowledged to be more challenging on the TX side than on the RX side in Frequency Division Duplexing (FDD), due to the need to feedback to the TX the CSI that has been estimated at the RX. Therefore, we consider that the RX has perfect knowledge of its own channel. Furthermore, as in the important literature on delayed CSIT \cite{3}–\cite{8}, to name just a few, we assume that the RX has been able to obtain perfect knowledge of the multi-user channel, i.e., also the channel to the other users. This assumption is key to the approach used in this work.

However, it is also important to note that this assumption can be weakened in our work as it is sufficient for the users to obtain the multi-user CSIT up to the best CSIT quality across the TXs (not necessarily the same estimate, but of the same quality). Furthermore, the estimate should be made available at the RX for the decoding, such that its latency constraint stems from the constraint of the user’s data, not from the time coherency of the channel.

D. Degrees-of-Freedom Analysis

We assume that every user $i \in \mathcal{K}$ wishes to receive message $W_i \in \mathcal{W}_i$. After $n$ channel uses, the rate $R_i(P)$ is achievable for RX $i$ if $R_i(P) = \log_2 \left( \frac{|W_i|}{n} \right)$ and the probability of wrong decoding goes to zero as $n$ goes to infinity. The sum capacity $C(P)$ is defined as the supremum of the sum of all achievable rates \cite{35}. The optimal sum DoF in the D-CSIT setting with CSIT scaling coefficients $\alpha \in \mathbb{R}^K$ is defined by

$$\text{DoF}^{\text{DCSI}}(\alpha) \triangleq \lim_{P \to \infty} \frac{C(P)}{\log_2(P)}. \tag{8}$$

III. MAIN RESULTS

As a preliminary, let us first introduce the optimal DoF of the centralized $K$-user BC setting where the single estimate of accuracy $\alpha$ is perfectly shared by all TXs as $\text{DoF}^{\text{CCSI}}(\alpha)$. It was recently shown in \cite{2} that

$$\text{DoF}^{\text{CCSI}}(\alpha) = 1 + (K - 1)\alpha. \tag{9}$$

We can now present our main results.
A. Upper-bound

**Theorem 1.** The optimal sum DoF of the $K$-user MISO BC with Distributed CSIT satisfies

$$\text{DoF}^{\text{DCSI}}(\alpha) \leq \text{DoF}^{\text{CCSI}}(\alpha^{(1)}), \quad (10)$$

**Proof:** The proof relies on the following important lemma whose technical proof is relegated to Appendix II for clarity.

**Lemma 1.** Let $\hat{\mathcal{H}}^{(j)} \triangleq \mathcal{H} + \bar{P}^{-\alpha^{(j)}} \Delta^{(j)}$, where $\mathcal{H}$, $\Delta^{(j)}$, $\forall j \in \mathcal{K}$, are independent continuous random variables satisfying the Bounded Density assumption. Then, the conditional probability density function $f_{\mathcal{H}|\hat{\mathcal{H}}^{(1)},...,\hat{\mathcal{H}}^{(K)}}$ satisfies that

$$\max_{\mathcal{H}} f_{\mathcal{H}|\hat{\mathcal{H}}^{(1)},...,\hat{\mathcal{H}}^{(K)}} = O \left( \bar{P}^{\max_{j \in \mathcal{K}} \alpha^{(j)}} \right). \quad (11)$$

Let us now assume a genie-aided scenario where all channel estimates are exchanged between all the TXs. Such setting corresponds to a (logically) centralized scenario with a shared CSI composed by $\{\hat{\mathcal{H}}^{(1)},...,\hat{\mathcal{H}}^{(K)}\}$. Interestingly, Lemma 1 indicates that the peak of the probability density function of this genie-aided scenario with multiple estimates has the same scaling as the centralized setting with only $\hat{\mathcal{H}}^{(1)}$, since it is shown in [2] that

$$\max_{\mathcal{H}} f_{\mathcal{H}|\hat{\mathcal{H}}^{(1)}} = O \left( \bar{P}^{\alpha^{(1)}} \right). \quad (12)$$

It then directly follows from the proof in [2, Section V.8] that the DoF of the genie-aided scenario, denoted by $\text{DoF}_{\text{genie}}^{\text{CCSI}}(\alpha)$, is given by

$$\text{DoF}_{\text{genie}}^{\text{CCSI}}(\alpha) = \text{DoF}^{\text{CCSI}}(\alpha^{(1)}). \quad (13)$$

From this equivalence, and the fact that providing with more information does not hurt, the proof is concluded. ☐

**Remark 2.** Lemma 1 is expected to hold in a more general group of distributions, i.e., including cases where the different noise variables are partially correlated. Indeed, for the Gaussian case where the noise variables $\{\Delta^{(j)}_{i,k}\}_{\forall j \in \mathcal{K}}$ are drawn from partially correlated jointly Gaussian distributions, it is easy to show analytically that (11) is also satisfied.

B.1) Achievability: Weak-CSIT Configuration

**Theorem 2.** Let us assume that the $m$ first TXs have the same accuracy, i.e., $\alpha^{(1)} = \cdots = \alpha^{(m)}$, $m < K$. Then, the sum DoF of the $K$-users MISO BC with Distributed CSIT satisfies

$$\text{DoF}^{\text{DCSI}}(\alpha) \geq \text{DoF}^{\text{CCSI}}(\alpha^{(1)}) \quad (14)$$

if $\alpha^{(1)} \leq \alpha^{\text{Weak}_m}$ with

$$\alpha^{\text{Weak}_m} \triangleq \frac{1}{1 + K(K - m - 1)}, \quad (15)$$

which is called the “$m$-TX Weak-CSIT” regime.
**Proof:** The result follows directly from the analysis of the \((m, K)\) mode (defined in Theorem 3) in Section V.

Consequently, in this “Weak-CSIT” regime the upper-bound of Theorem 1 is tight. Surprisingly, for \(m = 1\), the most heterogeneous case, the DoF depends only on the CSI quality of TX 1, although with the downside of reducing the range of the regime. For \(m = K - 1\) it holds that \(\alpha_{K-1}^{\text{Weak}} = 1\), what is consistent with the conventional use of Active-Passive Zero-Forcing (APZF) in [17], and recovers the centralized performance for any value of \(\alpha\).

**Remark 3.** The fact that it is possible to achieve the DoF of the centralized upper-bound with uniformed or badly informed TXs is a surprising result which is not expected to extend to many settings. Indeed, it can be intuitively seen from linear algebra that it is necessary to exploit at least \(K-1\) TXs to cancel \(K-1\) ZF constraints.

\[\square\]

\textbf{B.2) Achievability: Arbitrary CSIT Configuration}

In this section, we propose a transmission scheme extending the robust transmission scheme used in Theorem 2 to any CSIT configuration. The main challenge in this case comes from the large number of CSIT scaling parameters, leading to an even larger number of possible configurations depending on their relative values. Interestingly, it will become clear that there are two critical parameters to optimize, both the number of TXs participating in the transmission and the number of TXs using its instantaneous CSIT, hereinafter called Active TXs. This is a direct consequence of the distributed nature of the CSIT. Indeed, in contrast to the centralized setting with homogeneous CSIT where adding antennas cannot reduce the performance [32], [36], using additional antennas can decrease the achievable DoF in the distributed setting by creating additional interference. Consequently, we will in the following optimize both variables.

**Theorem 3.** The sum DoF of the \(K\)-user D-CSIT BC with CSIT scaling coefficients \(\alpha\) is lower-bounded by \(\text{DoF}^{\text{APZF}}(\alpha)\), obtained by solving the next linear program:

\[
\text{DoF}^{\text{APZF}}(\alpha) = \maximize_{\gamma_{n,k}} \sum_{k=2}^{K-1} \sum_{n=1}^{k-1} \gamma_{n,k} \left(1 + (k-1)\alpha^{(n)}\right)
\]

subject to

\[
\sum_{k=2}^{K-1} \sum_{n=1}^{k-1} \gamma_{n,k} = 1, \quad \gamma_{n,k} \geq 0,
\]

\[
\sum_{k=2}^{K-1} \sum_{n=1}^{k-1} d_{n,k} \gamma_{n,k} \geq 0,
\]

where \(\gamma_{n,k}\) is a time-sharing variable representing the percentage of time allocated to the transmission mode \((n, k)\) in which \(k\) TXs transmit information and \(n < k\) TXs among them are “Active TXs”, and \(d_{n,k} \triangleq 1 - \alpha^{(n)} - k(k - n - 1)\alpha^{(n)}\).

**Proof:** The transmission scheme for a particular mode is described in Section V and, building on this result, the proof of the theorem is given in Section VI.

\[\square\]

The transmission scheme and the achieved DoF are obtained by solving a simple linear programming with low complexity. Furthermore, it can also be shown that there always exists one solution having either a single or two non-
IV. A SIMPLE EXAMPLE

We start by presenting a simple transmission scheme in a toy-example to exemplify the key features of our approach and convey the main intuition in a clear manner. The full scheme achieving the DoF of Section III will then be given in Section V.

We consider then a 3-user setting with $\alpha^{(1)} = 0.1$, $\alpha^{(2)} = 0$, and $\alpha^{(3)} = 0$. The conventional regularized Zero-Forcing would achieve a DoF of 1, that it is the same as for the no CSIT scenario. We will show how it is possible
Fig. 3: Sum-DoF of the $K = 4$-user MISO BC with distributed CSIT as function of $\alpha^{(2)}$, with $\alpha^{(1)} = 1$, and $\alpha^{(3)} = \alpha^{(4)} = 0$.

A. Encoding

The transmission scheme consists in a single channel use during which 3 private data symbols of rate $\alpha^{(1)} \log_2(P)$ bits are sent to each user —thus leading to 9 data symbols being sent in one channel use— while an additional common data symbol of rate $(1 - \alpha^{(1)}) \log_2(P)$ bits is broadcast from TX 1 to all users using superposition coding [35]. Note that the information contained in this common data symbol is not only composed of “fresh” information bits destined to one user, but is also composed of side information necessary for the decoding of the private data symbols, as will be detailed below. The transmitted signal $x \in \mathbb{C}^3$ is then equal to

$$x = s_1 + s_2 + s_3 + \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix} s_0$$

where

- $s_i \in \mathbb{C}^3$ is a vector containing private data symbols destined to user $i$, with power $P \alpha^{(i)}/3$ and rate $\alpha^{(1)} \log_2(P)$ bits.
Fig. 4: Illustration of the received signals at every RX. Each user receives its desired private data symbols and interference scaling in $\bar{P}^{(1)}$. Through superposition coding, it also receives the common data symbol $s_0$ containing a mix of fresh desired data symbols (illustrated in white), and side information to remove interference (illustrated with the color of the relevant RX).

- $s_0$ is the common data symbol transmitted only from TX 1 and destined to be decoded at all users, with power $P - P^{(1)}$ and rate $(1 - \alpha^{(1)}) \log_2(P)$ bits.

The signal received at RX $i$, illustrated in Fig. 4, is equal to

$$y_i = H_i,1 s_0 + h_{i,1}^H s_1 + h_{i,1}^H s_2 + h_{i,1}^H s_3$$

where the power scaling is written under the bracket, and where the noise term has been neglected for clarity.

### B. Interference Estimation and Quantization at TX 1

The key element of the scheme is that the common data symbol $s_0$ is used to convey side information, enabling each user to decode his desired private data symbols. More specifically, TX 1 uses its local CSIT $\hat{H}^{(1)}$ to estimate the interference terms $(\hat{h}_i^{(1)})^H s_k$, $\forall i, k$ with $k \neq i$ which will be generated by the first layer of transmission, quantize them, and then transmit them using the common data symbol $s_0$. Each interference term has a variance scaling in $\bar{P}^{(1)}$ and is quantized using $\alpha^{(1)} \log_2(P)$ bits, such that the quantization noise can be made to remain at the noise floor using an appropriate uniform or a Lloyd quantizer [35]. In total, the transmission of all the quantized estimated interference requires to transmit $6\alpha^{(1)} \log_2(P)$ bits.

These $6\alpha^{(1)} \log_2(P)$ bits can be transmitted via the data symbol $s_0$ if $6\alpha^{(1)} \log_2(P) \leq (1 - \alpha^{(1)}) \log_2(P)$, which is the case for the example considered here since $6 \times 0.1 < 1 - 0.1$. If the inequality is strict (as it is in this case), $s_0$ transmits some additional $(1 - 7\alpha^{(1)}) \log_2(P)$ fresh information bits —$0.3 \log_2(P)$ bits here— to any particular user.
C. Decoding and DoF Analysis

It remains to verify that this transmission scheme achieves the claimed DoF. Let us consider w.l.o.g. the decoding at RX 1 as the decoding at the other users is the same up to a circular permutation of the RX’s indices. Note that signals at the noise floor are systematically omitted.

Using successive decoding \[35\], the common data symbol \(s_0\) is decoded first, followed by the private data symbols \(s_1\). The data symbol \(s_0\) of rate of \((1 - \alpha^{(1)}) \log_2(P)\) bits can be decoded with a vanishing probability of error as its effective SNR can be seen in \(20\) to scale in \(P^{1-\alpha^{(1)}}\). Upon decoding \(s_0\), the quantized estimated interferences \((\hat{h}_1^{(1)})^H s_2\) are obtained up to the quantization noise. As the quantization is at the noise floor, it is neglected in the following. RX 1 has then decoded:

\[
\begin{align*}
(\hat{h}_1^{(1)})^H s_2 &= h_1^H s_2 + \tilde{\alpha}^{(1)}(1) (\delta_1^{(1)})^H s_2.
\end{align*}
\]

This means that the interference terms \(h_1^H s_2\) can be suppressed up to the noise floor at RX 1. Proceeding in the same way with \((\hat{h}_2^{(1)})^H s_3\), the remaining signal at RX 1 is

\[
y_1 = h_1^H s_1.
\]

Using this signal in combination with the interference terms \((\hat{h}_2^{(1)})^H s_1\) and \((\hat{h}_3^{(1)})^H s_1\) obtained through \(s_0\), RX 1 forms a virtual received vector \(y_v^1 \in \mathbb{C}^3\) defined as

\[
y_v^1 \doteq \begin{bmatrix} h_1^H \\ (\hat{h}_2^{(1)})^H \\ (\hat{h}_3^{(1)})^H \end{bmatrix} s_1.
\]

Each component of \(y_v^1\) has an effective SNR scaling in \(P^{\alpha^{(1)}}\) such that user 1 can decode with a vanishing error probability its 3 data symbols of rate \( \alpha^{(1)} \log_2(P) \) bits.

Considering the 3 users, \(9\alpha^{(1)} \log_2(P)\) bits have been transmitted through the private data symbols and \((1 - 7\alpha^{(1)}) \log_2(P)\) bits through the common data symbol \(s_0\), which yields a sum DoF of \(1 + 2\alpha^{(1)}\). For \(\alpha^{(1)} \leq 1/7\), this scheme achieves the optimal sum DoF. By introducing some more advanced ZF precoding leads to a lower amount of retransmitted interference, and hence a larger domain in which the scheme is DoF optimal.

Remark 4. Interestingly, the above scheme is based on interference estimation, quantization and retransmission, in a similar fashion as done in the different context of precoding with delayed CSIT (see e.g. \[4\]–\[6\]). Yet, we exploit in this work the distributed nature of the CSIT instead of the delayed knowledge of the CSIT such that in our scheme the interference are estimated and quantized before even being generated.

V. TRANSMISSION MODE WITH n ACTIVES TXS

We study in this section the transmission mode \((n, K)\) according to the definition in Theorem \[3\] i.e., with \(K\) TXs transmitting and \(n\) TXs actively zero-forcing the interference. The analysis of the \((n, k)\) mode with \(k < K\) is exactly the same, simply replacing \(K\) by \(k\).
We denote the \( K - n \) TXs that do not use their instantaneous CSIT as Passive TXs. Let us remark that \( K \) corresponds to the number of users that are served during the mode, whereas \( n \) gives the number of users whose received interference can be reduced using AP-ZF precoding. Furthermore, this interference reduction is proportional to the worse CSI scaling coefficient among the Active TXs (\( \alpha(n) \)). We first describe the main structure of the transmission in Subsection V-A before describing in detail the precoding scheme in Subsection V-B. The received signal is then studied in Subsection V-C before computing the achieved DoF in Subsections V-D and V-E.

A. Encoding

The transmitted signal \( x \in \mathbb{C}^K \) of the mode \((n, K)\) is

\[
x = \begin{bmatrix}
1 \\
0_{K-1 \times 1}
\end{bmatrix} s_0 + \sum_{i=1}^K T_i^{APZF} s_i
\]

where

- \( s_i \in \mathbb{C}^{K-n} \) contains \( K-n \) data symbols destined to RX \( i \) and that we hence denote as private, each one of rate \( \alpha(n) \log_2(P) \) bits and power \( P^{\alpha(n)}/(K(K-n)) \), distributed in an i.i.d. manner. They are precoded with the AP-ZF precoder \( T_i^{APZF} \in \mathbb{C}^{K \times (K-n)} \) with \( n \) active TXs as described in detail in Subsection V-B.
- \( s_0 \in \mathbb{C} \) is a data symbol destined to be decoded at all users and that we hence denoted as common, of rate \( (1 - \alpha(n)) \log_2(P) \) bits and power \( P - P^{\alpha(n)} \).

Thus, a total of \( K(K-n)\alpha(n) \log_2(P) \) bits are sent in one channel use through the private data symbols. Furthermore, an additional data symbol of data rate \( (1 - \alpha(n)) \log_2(P) \) bits is broadcast from TX 1. Importantly, we will show that this common data symbol \( s_0 \) will not only contain new information bit, but also side information which will be used to enable the successful decoding of the private data symbols.

B. Precoding: AP-ZF with \( n \) Active TXs

We describe now the AP-ZF precoder serving RX \( i \) with \( n \) Active TXs. This precoder transmits \( K - n \) streams to RX \( i \) while reducing the interference at the \( n \) following RXs, i.e., at RXs \((i + t) \mod [K] + 1, \forall t \in \{1, \ldots, n\}\). For ease of notation, we omit in the following the modulo operation as it is clear what an index bigger than \( K \) refers to. The precoder is obtained from distributed precoding at all TXs such that

\[
T_i^{APZF} = \begin{bmatrix}
e_1^T T_i^{APZF(1)} \\
e_2^T T_i^{APZF(2)} \\
\vdots \\
e_K^T T_i^{APZF(K)}
\end{bmatrix}
\]

where \( e_k \) refers to the \( k \)-th row of the identity matrix \( I_{K \times K} \) and \( T_i^{APZF(j)} \) denotes the AP-ZF precoder computed at TX \( j \). We will therefore consider the design of \( T_i^{APZF(j)} \) at TX \( j \).

Remark 5. Note that although TX \( j \) computes the full precoder \( T_i^{APZF(j)} \), only some coefficients will be effectively used for the transmission due to the distributed precoding configuration, as made clear in (25). \( \square \)
As a preliminary, let us define the active channel $H_A \in \mathbb{C}^{n \times n}$ as the channel coefficients from the Active TXs (TX 1 to TX $n$) to the RXs whose received interference is reduced (RX $i + 1$ to RX $i + n$), i.e.,

$$H_A \triangleq H_{i+1:i+n,1:n}. \quad (26)$$

Similarly, the passive channel $H_P \in \mathbb{C}^{n \times (K-n)}$ contains the channel coefficients from the Passive TXs (TX $n+1$ to TX $K$) to the RXs with reduced interference (RX $i + 1$ to RX $i + n$), i.e.,

$$H_P \triangleq H_{i+1:i+n+1:n}. \quad (27)$$

The Passive TXs do not exploit their instantaneous CSIT. Hence, the passive precoder used is an arbitrarily chosen deterministic full rank matrix denoted by $\lambda_{i \text{APZF}}^P T_{i}^{P} \in \mathbb{C}^{(K-n) \times (K-n)}$, where $\lambda_{i \text{APZF}}^P$ is used to satisfy an average sum power constraint and is detailed afterwards.

On the other hand, every Active TX $j$, $\forall j \in \{1, \ldots, n\}$, computes $T_{i}^{\text{APZF}(j)} \in \mathbb{C}^{K \times K-n}$ on the basis of its own available CSIT $\hat{H}(j)$, such that

$$T_{i}^{\text{APZF}(j)} = \lambda_{i \text{APZF}}^A \begin{bmatrix} T_{i}^{A(j)} \\ T_{i}^{P} \end{bmatrix}. \quad (28)$$

The active precoder $T_{i}^{A(j)}$ is then computed as

$$T_{i}^{A(j)} = - \left( \hat{H}(j) H_{A}^{H} \hat{H}(j) + \frac{1}{P_n} I_n \right)^{-1} \hat{H}(j) H_{P}^{H} T_{i}^{P}. \quad (29)$$

Remark 6. The design of the active precoder in (29) is an extension of the AP-ZF precoder introduced in [17]. Intuitively, the $n$ Active TXs invert the channel to the $n$ chosen RXs so as to cancel the interference generated by
the Passive TXs. Interestingly, the number of Passive TXs limits the rank of the transmitted signal, whereas the number of Active TXs limits the number of users where the interference is attenuated.

Thus, the effective AP-ZF precoder $T_{i}^{\text{APZF}} \in \mathbb{C}^{K \times K-n}$, given in (25), can be expressed as

$$
T_{i}^{\text{APZF}} \triangleq \lambda_{i}^{\text{APZF}} \begin{bmatrix}
    e_{1}^{H}T_{i}^{A(1)} \\
    \vdots \\
    e_{n}^{H}T_{i}^{A(n)} \\
    T_{i}^{P}
\end{bmatrix}
$$

where the normalization coefficient $\lambda_{i}^{\text{APZF}}$ is chosen as

$$
\lambda_{i}^{\text{APZF}} \triangleq \frac{1}{\sqrt{\mathbb{E} \left[ \left\| -\frac{1}{P}H_{A}H_{A}^{-1}H_{P}^{T}P_{i}^{T} \right\|_{F}^{2} \right]}}.
$$

This normalization constant $\lambda_{i}^{\text{APZF}}$ requires only statistical CSI and can hence be applied at every TX. It ensures that an average sum-power normalization constraint is satisfied, i.e., that

$$
\mathbb{E} \left[ \left\| T_{i}^{\text{APZF}} \right\|_{F}^{2} \right] = 1.
$$

The fundamental property of AP-ZF is that it effectively achieves interference reduction at the $n$ RXs up to the worst accuracy across the Active TXs, as stated in the following lemma.

**Lemma 2.** The AP-ZF precoder with $n$ Active TXs satisfies

$$
\left\| h_{\ell}^{H}T_{i}^{\text{APZF}} \right\|_{F}^{2} \leq P^{-\alpha(n)}, \forall \ell \in \{i+1, \ldots, i+n\}.
$$

**Proof:** The proof of Lemma 2 is relegated to Appendix I for clarity, along with the derivation of other important properties of AP-ZF precoding.

**C. Received Signals**

The signal received at RX $i$ is given by

$$
y_{i} = H_{i}^{H}1_{0} + h_{i}^{H}T_{i}^{\text{APZF}}s_{i} + h_{i}^{H} \sum_{\ell \in \mathcal{I}_{i}^{\text{APZF}}} T_{\ell}^{\text{APZF}}s_{\ell} + h_{i}^{H} \sum_{\ell \in \mathcal{K} \backslash \mathcal{I}_{i}^{\text{APZF}}} T_{\ell}^{\text{APZF}}s_{\ell}
$$

where the noise term has been neglected for clarity and with $\mathcal{I}_{i}^{\text{APZF}}$ being defined (omitting the modulo operation) as

$$
\mathcal{I}_{i}^{\text{APZF}} \triangleq \{i+1, \ldots, i+K-n-1\}.
$$

Intuitively, the set $\mathcal{I}_{i}^{\text{APZF}}$ contains the interfering signals that have not been attenuated towards RX $i$. The last term in (34) scales as $P^0$ following the attenuation by $P^{-\alpha(n)}$ due to AP-ZF precoding, as shown in Lemma 2. In Fig. 6 we illustrate the received signal at every RX in the simple $K=3$ user setting. We can see the improvement
Fig. 6: Illustration of the received signals for the Weak CSIT regime in the case of $K = 3$ RXs. Via AP-ZF, the interference generated is reduced and thus extra new information can be sent through $s_0$ (white).

with respect to Fig. 4 since the number of significant interference terms is reduced by half thanks to the AP-ZF precoding.

D. Decoding

TX 1 uses its local CSIT $\hat{H}^{(1)}$ to estimate the interference terms $h_i^H T_{\ell}^{\text{APZF}} s_\ell$, $\forall \ell \in \mathcal{I}_i^{\text{APZF}}$. Each interference term scales in $P_{\alpha}^{(n)}$ such that using $\alpha^{(n)} \log_2(P)$ bits, each term can be quantized with a quantization noise at the noise floor [35]. Considering all users, this means that $K(K - n - 1)\alpha^{(n)} \log_2(P)$ interference bits have to be transmitted. In order to do so, we will use the broadcast data symbol $s_0$. If the quantity of information to be retransmitted exceeds the data rate of $s_0$, additional broadcast resources will need to be find to enable the successful decoding of the private data symbol. This is the essence of the linear optimization in Theorem 3 and will be discussed further in Section VI. We assume now that all the interference terms could be transmitted using the common data symbol $s_0$ and we will verify that it is indeed possible for a given RX $i$ to decode its $(K - n)\alpha^{(n)} \log_2(P)$ intended bits.

Using successive decoding, the data symbol $s_0$ of rate of $(1 - \alpha^{(n)}) \log_2(P)$ bits can be decoded with a vanishing probability of error as its effective SNR can be seen in (34) to scale as $P_{1 - \alpha^{(n)}}$. Upon decoding $s_0$, we obtain the estimated interferences $(\hat{h}_i^{(1)})^H T_{\ell}^{\text{APZF}(1)} s_\ell$, for $\ell \in \mathcal{I}_i^{\text{APZF}}$ up to the quantization noise at the noise floor. It then holds that

$$
(\hat{h}_i^{(1)})^H T_{\ell}^{\text{APZF}(1)} s_\ell = \left(h_i^H + \tilde{P}^{-\alpha^{(1)}} (\delta_i^{(1)})^H \right) T_{\ell}^{\text{APZF}(1)} s_\ell
$$

(36)

$$
= h_i^H T_{\ell}^{\text{APZF}(1)} s_\ell + \tilde{P}^{-\alpha^{(1)}} (\delta_i^{(1)})^H T_{\ell}^{\text{APZF}(1)} s_\ell
$$

(37)

$$
= h_i^H T_{\ell}^{\text{APZF}} s_\ell + h_i^H \left(T_{\ell}^{\text{APZF}(1)} - T_{\ell}^{\text{APZF}}\right) s_\ell
$$

(38)

where (38) is obtained after omitting the second term of (37), since its power scales as $P^{-\alpha^{(1)}} P_{\alpha^{(1)}} = P_0$, i.e., it lies on the noise floor. It holds that, $\forall \ell \in \mathcal{K}$, $\forall j \in \{1, \ldots, n\}$, the AP-ZF precoding satisfies the following property
(see the proof in Appendix I):

\[ \| T^\text{APZF}(j) - T^\text{APZF}_\ell \|_F^2 \leq P - \alpha^{(j)}. \]  

(39)

It follows from (39) that

\[ h^H_i \left( T^\text{APZF}(1) - T^\text{APZF}_\ell \right) s_\ell = P_0. \]  

(40)

After having subtracted the quantized interference terms, the remaining signal at RX \( i \) up to the noise floor is

\[ y_i = h^H_i T^\text{APZF}_i s_i. \]  

(41)

The key point of the approach consists in the property that RX \( i \) receives also through the broadcast data symbol the interference created by its own intended symbols at the others RXs, i.e., the estimated interference terms \((\hat{h}_i^{(1)})^H T^\text{APZF}_i s_i, \forall \ell \) such that \( i \in I^\text{APZF}_\ell \). Each of those terms is an independent linear combination of the symbols \( s_i \), and thus RX \( i \) can form a virtual received vector \( y^*_i \in \mathbb{C}^{K-n} \) equal to

\[ y^*_i \triangleq \begin{bmatrix} h^H_i \\ (\hat{h}_i^{(1)})^H \\ \vdots \\ (\hat{h}_{i-(K-n-1)})^H \end{bmatrix} T^\text{APZF}_i s_i. \]  

(42)

Each component of \( y^*_i \) has a SINR scaling in \( P_0^{\alpha^{(n)}} \) and the AP-ZF precoder is of rank \( K - n \) (See Lemma 4 in Appendix I) such that RX \( i \) can decode its desired \( K - n \) data symbols, each with the rate of \( \alpha^{(n)} \log_2(P) \) bits.

**Remark 7.** The rank in (42) is ensured by the use of the Passive TXs. Hence, it is interesting to observe how even uninformed TXs prove to be instrumental in improving the achieved DoF.

**E. DoF Analysis**

The transmission to each RX \( i \) creates \( |I^\text{APZF}_i| = K - n - 1 \) interferences terms which gives in total \( K(K - n - 1)\alpha^{(n)} \log_2(P) \) bits that need to be retransmitted. Consequently, we define DoF\(_{\text{Interf}}^{(\cdot)} \) as the DoF consumed in order to transmit these interference terms and which is given by

\[ \text{DoF}_{\text{Interf}}^{(\cdot)} \triangleq K(K - n - 1)\alpha^{(n)}. \]  

(43)

In contrast, the symbol \( s_0 \) carries \((1 - \alpha^{(n)}) \log_2(P) \) bits, i.e., the DoF of the common data symbol DoF\(_n^{\text{BC}} \) is given by

\[ \text{DoF}_n^{\text{BC}} \triangleq 1 - \alpha^{(n)}. \]  

(44)

Finally, considering the \((K-n)\alpha^{(n)} \log_2(P) \) private bits for all \( K \) users leads to the private DoF denoted by DoF\(_n^{\text{Priv}} \) and defined as

\[ \text{DoF}_n^{\text{Priv}} \triangleq K(K - n)\alpha^{(n)}. \]  

(45)
Putting (43), (44), and (45) together, the total DoF is
\[
\text{DoF}_n = \text{DoF}_{n}^{\text{Priv}} + \text{DoF}_{n}^{\text{BC}} - \text{DoF}_{n}^{\text{Interf}(\cdot)}
\]
(46)
at the condition that \(\text{DoF}_{n}^{\text{BC}} - \text{DoF}_{n}^{\text{Interf}(\cdot)} \geq 0\), i.e., that all interference terms could have been retransmitted. If this condition does not hold, the retransmission of the interference is managed through the time-sharing optimization of the different modes as discuss in Section [VI].

VI. PROOF OF THEOREM 3

We start by considering that the number of transmitters participating in the transmission is \(K\). Let us then define \(d_n\) as the difference between the DoF available in the broadcast symbol \(s_0\) and the DoF that has to be retransmitted in this \((n, K)\) mode as studied in Section [V], i.e.,
\[
d_n \triangleq \text{DoF}_{n}^{\text{BC}} - \text{DoF}_{n}^{\text{Interf}(\cdot)}
\]
(47)
\[
= 1 - \alpha(n) - K(K - n - 1)\alpha(n),
\]
(48)
Each mode does not need to retransmit all its interference terms, it is only necessary that the combination of the different modes leads to the complete retransmission of the interference terms. Hence, the interference retransmission constraint can in fact be written as
\[
\sum_{n=1}^{K-1} \gamma_n d_n \geq 0,
\]
(49)
with \(\gamma_n\) being the time sharing variable, i.e., \(\gamma_n \geq 0\) and \(\sum_{n=1}^{K} \gamma_n = 1\). Interestingly, with that constraint, the sum DoF can then be rewritten as
\[
\sum_{n=1}^{K-1} \gamma_n \text{DoF}_n = \text{DoF}_{n}^{\text{Priv}} + \text{DoF}_{n}^{\text{BC}} - \text{DoF}_{n}^{\text{Interf}(\cdot)}
\]
(50)
\[
= \sum_{n=1}^{K-1} \gamma_n \left(1 + (K - 1)\alpha(n)\right).
\]
(51)
Therefore, the optimal time allocated to each transmission mode is clearly obtained by solving the following optimization problem:
\[
\max_{\gamma_n} \sum_{n=1}^{k-1} \gamma_n \left(1 + (K - 1)\alpha(n)\right)
\]
(52)
subject to
\[
\sum_{n=1}^{k-1} \gamma_n = 1, \quad \gamma_n \geq 0,
\]
(53)
\[
\sum_{n=1}^{k-1} d_n \gamma_n \geq 0.
\]
(54)
The optimization problem given in Theorem 3 is easily obtained from the optimization problem state above by optimizing over the number of TXs \(K\) participating in the transmission. Considering then \(k \leq K\) TXs instead of \(K\) in the optimization problem above with \(n < k\) Active TXs concludes the proof.
VII. CONCLUSION

We have described a novel D-CSIT robust transmission scheme improving over the DoF achieved by state-of-the-art precoding approaches when facing distributed CSIT. In order to evaluate the performance of our novel schemes, we have first derived an upper-bound coined as the centralized upper-bound, consisting in a genie-aided setting where all the CSI versions are made available at all TXs. This has allowed us to uncover the surprising result that in a certain so-called “Weak CSIT” regime, it is possible to achieve this upper-bound in the extreme case where the CSIT is handed at a single TX. The robust precoding scheme proposed relies on new methods such as the estimation of the interference and their transmission from a single TX, and a modified ZF precoding with multiple Passive TXs and multiple Active TXs. These new methods have a strong potential for improvement in other wireless configurations with distributed CSIT. Building these new design principles, a generic transmission scheme is proposed for an arbitrary CSIT configuration. Although not provably DoF optimal, it significantly improves the achieved DoF allowing the transmission to be more robust to the CSIT heterogeneity and the CSIT inconsistencies. Converting these new innovative transmission schemes into practical transmissions schemes in realistic environments is an interesting and ongoing research direction which could yield important gains in practice and make advanced precoding schemes more robust and practical. Furthermore, deriving tighter distributed upper-bounds is a very challenging topic to be addressed in future works.

APPENDIX I

In this appendix, we start by showing some simple but important properties of the AP-ZF precoder. We consider in the following properties the precoder towards RX \(i\) and we omit hereinafter for clarity the RX’s sub-index \(i\).

Lemma 3. Let \(H \in \mathbb{C}^{n \times K}\) denote the channel matrix towards the \(n\) RXs whose received interference is canceled. With perfect channel knowledge at all (active) TXs, the AP-ZF precoder with \(n\) Active TXs and \(K-n\) Passive TXs satisfies

\[
HT^{\text{APZF}*} \xrightarrow{p \to \infty} 0_{n \times (K-n)}
\]

where \(T^{\text{APZF}*}\) denotes the AP-ZF precoder based on perfect CSIT according to the Description in Section V-B and is given as

\[
T^{\text{APZF}*} \triangleq \lambda^{\text{APZF}} \begin{bmatrix} T^A* \\ T^P \end{bmatrix}.
\]

Proof: Using the well known Resolvent identity \([37]\) Lemma 6.1, we can write that

\[
\left( H_A^H H_A + \frac{1}{P} I_n \right)^{-1} - \left( H_A^H H_A \right)^{-1} = - \left( H_A^H H_A \right)^{-1} \frac{1}{P} I_n \left( H_A^H H_A + \frac{1}{P} I_n \right)^{-1}.
\]

We can then compute the leaked interference as

\[
HT^{\text{APZF}*} = \lambda^{\text{APZF}} H_A T^{A*} + \lambda^{\text{APZF}} H_p T^P
\]

\[
= \lambda^{\text{APZF}} H_A \left( H_A^H H_A \right)^{-1} \frac{1}{P} I_n \left( H_A^H H_A + \frac{1}{P} I_n \right)^{-1} H_A^H H_p T^P
\]
where equality \((a)\) follows from inserting (57) inside the AP-ZF precoder and simplifying. Letting the available power \(P_t\) tend to infinity, the leaked interference tends to zero.

**Lemma 4.** The AP-ZF precoder with \(n\) Active TXs and \(K - n\) Passive TXs is of rank \(K - n\).

**Proof:** The passive precoder was chosen such that \(T^p\) is full rank, i.e., of rank \(K - n\). The precoder \(T^{A(j)}\) is a linear combination of \(T^p\) for each \(j\), such that the effective AP-ZF precoder \(T^{APZF}\) resulting from distributed precoding is exactly of rank \(K - n\).

**A. Proof of Lemma 2**

Following a similar approach as in [17], we can use once more the resolvent identity [37, Lemma 6.1] to approximate the matrix inverse and show that

\[
\|T^{APZF(j)} - T^{APZF*}\|_F^2 \leq P^{-\alpha(j)}. \tag{60}
\]

It then follows that

\[
\|HT^{APZF}\|_F^2 \leq \|H(T^{APZF} - T^{APZF*})\|_F^2 \tag{61}
\]

\[
\leq \|H\|_F^2 \|T^{APZF} - T^{APZF*}\|_F^2 \tag{62}
\]

\[
\leq \|H\|_F^2 \sum_{j=1}^{n} \|T^{APZF(j)} - T^{APZF*}\|_F^2 \tag{63}
\]

\[
\leq P^{-\min_{j\in[n]} \alpha(j)} \tag{64}
\]

where (61) comes from Lemma 3 and (64) follows from (60).

**Remark 8.** The interference attenuation of AP-ZF precoding is only limited by the worst CSIT accuracy at the Active TXs, and does not depend on the CSI accuracy at the Passive TXs.

**APPENDIX II**

**Proof of Lemma 1**

In this section, we prove Lemma 1—and so Theorem 1—for a broad general case, where the estimation noise random variables are mutually independent and they are drawn from continuous distributions with density. We first enunciate some definitions and hypothesis that are taken on the random variables and their probability density functions (pdf). Later we prove the lemma for the \(K = 2\) users case and, to conclude, we prove the general \(K > 2\) users case by induction. From the independence between different channel coefficients, we can restrict ourselves to an arbitrary link such that we omit the previously used sub-indexes \(i, k\).

1) Preliminaries:

We recall that the probability density function of a random variable \(\mathcal{X}\) is denoted as \(f_{\mathcal{X}}(x)\).
**Definition 2.** For \( \varepsilon > 0 \), the \( \varepsilon \)-support of a random variable \( X \) is defined as

\[
S^\varepsilon_X = \{ x \ | \ f_X(x) > \varepsilon \}. \tag{65}
\]

The following assumptions are adopted:

H1) Bounded Support: A random variable \( X \) has bounded support if \( \exists M_X < \infty \) such that \( x \leq |M_X| \ \forall x \in S^\varepsilon_X, \forall \varepsilon. \)

H2) Bounded probability density function: A random variable \( X \) has bounded probability density function if \( \exists f_X^{\max} < \infty \) such that \( f_X(x) \leq f_X^{\max} \ \forall x. \)

H3) \( \mathcal{H}, \Delta_i^{(j)}, \forall j \in \mathcal{K}, \) are continuous random variables with density that satisfy the hypothesis H1)-H2).

H4) \( \hat{\mathcal{H}}(j) \triangleq \mathcal{H} + \bar{P}^{-\alpha(j)} \Delta(j) \)

H5) \( P > 1 \) and \( 1 \geq \alpha(1) \geq \cdots \geq \alpha(K) \geq 0. \)

H6) \( \mathcal{H}, \Delta_i^{(j)} \), are independent of \( P, \alpha^{(j)}. \)

H7) \( \mathcal{H}_{i,k} \) is independent of \( \mathcal{H}_{i',k'}, \forall (i, k) \neq (i', k'). \)

H8) \( \Delta_{i,k}^{(j)} \) is independent of \( \Delta_{i',k'}^{(j')}, \forall (i, k, j) \neq (i', k', j'). \)

We further denote the samples drawn from the aforementioned variables as \( h \sim \mathcal{H}, \quad \delta^{(j)} \sim \Delta^{(j)}, \quad \hat{h}^{(j)} \sim \hat{\mathcal{H}}^{(j)}, \)

and consequently \( \hat{\mathcal{H}}^{(j)} \triangleq h + \bar{P}^{-\alpha(j)} \delta^{(j)}. \) As a refresher, and because we will make extensive use of it, we recall the well-known formula for the pdf of a random variable multiplied by a positive constant.

**Proposition 1.** If \( X \) is a continuous random variable with probability density function \( f_X(x) \), then, for \( c > 0 \), so is \( c \cdot X \) a continuous random variable with probability density function

\[
f_{cX}(x) = \frac{1}{c} f_X \left( \frac{x}{c} \right). \tag{66}
\]

Furthermore, we present a useful lemma on the convergence of the estimate variables \( \hat{\mathcal{H}}^{(j)} \) that we apply during the proof.

**Lemma 5.** Let \( \hat{\mathcal{H}}^{(j)}, \forall j \in \mathcal{K}, \) be defined from assumptions H1)-H8), such that \( \alpha^{(i)} > 0. \) Then, \( f_{\hat{\mathcal{H}}^{(i)}} \) converges almost surely to \( f_\mathcal{H}, \) i.e.,

\[
\lim_{P \to \infty} f_{\hat{\mathcal{H}}^{(i)}}(x) = f_\mathcal{H}(x). \tag{67}
\]

**Corollary 1.** Let \( \alpha^{(1)} > 0. \) Then,

\[
\lim_{P \to \infty} f_{\Delta^{(1)}|\hat{\mathcal{H}}^{(1)}, \ldots, \hat{\mathcal{H}}^{(K)}}(y|\hat{h}^{(1)}, \ldots, \hat{h}^{(K)}) = f_{\Delta^{(1)}}(y). \tag{68}
\]

**Proof:** The proof of both lemma and corollary is relegated to the Appendix [II-A].

Finally, we recall here the Lebesgue’s Dominated Convergence Theorem [38].

**Theorem 4 (Theorem 16.4).** Let \( \{ f_n \} \) be a sequence of functions on the measure space \( (\Omega, \Sigma, \mu) \), where \( \Omega \) is a non-empty sample space, \( \Sigma \) is a \( \sigma \)-algebra on the space \( \Omega \), and \( \mu \) a measure on \( (\Omega, \Sigma) \). Suppose that

\[
\lim_{n \to \infty} f_n(x) = f(x) \tag{69}
\]
almost surely. Further suppose that exists an integrable non-negative function $G$ such that $|f_n(x)| \leq G(x)$, $\forall n$, almost surely. Then $\{f_n\}$ and $f$ are integrable and

$$\lim_{n \to \infty} \int f_n(x) d\mu(x) = \int f(x) d\mu(x).$$

(70)

2) Proof for the $K=2$ estimates Case:

We can write

$$f_{\mathcal{H}\mathcal{H}(1),\mathcal{H}(2)}(h|\hat{h}(1),\hat{h}(2)) = \frac{f_{\mathcal{H},\mathcal{H}(1),\mathcal{H}(2)}(h,\hat{h}(1),\hat{h}(2))}{f_{\mathcal{H}(1),\mathcal{H}(2)}(\hat{h}(1),\hat{h}(2))}$$

(71)

$$= \frac{(a)f_{\mathcal{H},\mathcal{H}(1)}(h,\hat{h}(1))f_{P^{-\alpha}}(\Delta(2) \hat{h}(2) - h)}{f_{\mathcal{H}(1)}(h(1))f_{\mathcal{H}(2)|\mathcal{H}(1)}(\hat{h}(2) | \hat{h}(1))}$$

(72)

$$= f_{\mathcal{H}|\mathcal{H}(1)}(h|\hat{h}(1))f_{P^{-\alpha}}(\Delta(2) \hat{h}(2) - h)$$

(73)

where $(a)$ comes from the independence between $\mathcal{H}$, $\Delta(1)$, $\Delta(2)$. Furthermore, using Bayes’ formula we obtain that

$$f_{\mathcal{H}|\mathcal{H}(1)}(h|\hat{h}(1)) = \frac{f_{P^{-\alpha}}(\Delta(1) \delta(1))f_{\mathcal{H}(h)}}{f_{\hat{h}(1)}(h(1))}$$

(74)

$$= P^{\alpha}(\Delta(1) \delta(1))f_{\mathcal{H}(h)}$$

(75)

where (75) comes from Proposition 1. Let us consider separately the cases where $\alpha(1) = 0$ and where $\alpha(1) > 0$.

a) $\alpha(1) = 0$: In this case, (75) does not depend on $P$, since $P^0 = 1$, $\forall P > 0$. From H3), $f_{\mathcal{H}}$ and $f_{\Delta(1)}$ are bounded away from $\infty$. Moreover, if $\hat{h}(1) \in S^\varepsilon_{\mathcal{H}(1)}$, then $f_{\hat{h}(1)}$ is also lower-bounded by $\varepsilon$. Thus,

$$\max f_{\mathcal{H}|\mathcal{H}(1)}(h|\hat{h}(1)) = O(P^0).$$

(76)

b) $\alpha(1) > 0$: From Lemma 5 we have that $f_{\hat{h}(1)}$ converges almost surely (a.s.) to $f_{\mathcal{H}}$, and from H3) that $\max f_{\Delta(1)} < \infty$. Thus, from (75) it holds that

$$\max f_{\mathcal{H}|\mathcal{H}(1)}(h|\hat{h}(1)) = O(P^{\alpha(1)}).$$

(77)

Hence, in order to prove Lemma 1, i.e., that

$$\max f_{\mathcal{H}|\mathcal{H}(1),\mathcal{H}(2)} = O(P^{\alpha(1)}),$$

(78)

for any $\alpha(1) \geq 0$ we need to demonstrate that the limit

$$\lim_{P \to \infty} \frac{f_{\mathcal{H}|\mathcal{H}(1),\mathcal{H}(2)}(h|\hat{h}(1),\hat{h}(2))}{f_{\mathcal{H}|\mathcal{H}(1)}(h|\hat{h}(1))}$$

(79)

exists and is bounded away from 0 and $\infty$. First, note that from (75) we have that

$$\frac{f_{\mathcal{H}|\mathcal{H}(1),\mathcal{H}(2)}(h|\hat{h}(1),\hat{h}(2))}{f_{\mathcal{H}|\mathcal{H}(1)}(h|\hat{h}(1))} = \frac{f_{P^{-\alpha}}(\Delta(2) \hat{h}(2) - h)}{f_{\mathcal{H}(2)|\mathcal{H}(1)}(\hat{h}(2) | \hat{h}(1))}.$$
Let us focus first on the denominator of the right-hand side of (80). Using again that \( \Delta^{(j)} \) is independent of \( H \), and that \( \hat{H}(2) = \hat{H}(1) - \bar{P} - \alpha^{(1)} \Delta^{(1)} + \bar{P} - \alpha^{(2)} \Delta^{(2)} \) we obtain that

\[
\begin{align*}
\int_{\hat{H}(2)|\hat{H}(1)} \left( \hat{h}^{(2)} | \hat{h}^{(1)} \right) &= \int_{\hat{H}(1) - \bar{P} - \alpha^{(1)} \Delta^{(1)} + \bar{P} - \alpha^{(2)} \Delta^{(2)} | \hat{H}(1)} \left( \hat{h}^{(1)} + \hat{h}^{(2)} - \hat{h}^{(1)} | \hat{h}^{(1)} \right) \\
&= \int_{\bar{P} - \alpha^{(2)} \Delta^{(2)} - \bar{P} - \alpha^{(1)} \Delta^{(1)} | \hat{H}(1)} \left( \hat{h}^{(2)} - \hat{h}^{(1)} | \hat{h}^{(1)} \right).
\end{align*}
\tag{81}
\]

Note that \( \hat{h}^{(2)} - \hat{h}^{(1)} = \bar{P} - \alpha^{(2)} \delta^{(2)} - \bar{P} - \alpha^{(1)} \delta^{(1)} \). From the independence of \( \Delta^{(1)} \) and \( \Delta^{(2)} \), (82) can be expressed using the convolution as

\[
\begin{align*}
\int_{\hat{H}(2)|\hat{H}(1)} \left( \hat{h}^{(2)} | \hat{h}^{(1)} \right) &= \int_{\bar{P} - \alpha^{(2)} \Delta^{(2)} - \bar{P} - \alpha^{(1)} \Delta^{(1)} | \hat{H}(1)} \left( \hat{h}^{(2)} - \hat{h}^{(1)} | \hat{h}^{(1)} \right) \\
&= \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \left( \hat{h}^{(2)} - \hat{h}^{(1)} - x \right) f_{\bar{P} - \alpha^{(2)} \Delta^{(2)} - \bar{P} - \alpha^{(1)} \Delta^{(1)} | \hat{H}(1)} \left( x | \hat{h}^{(1)} \right) f_{\bar{P} - \alpha^{(2)} \Delta^{(2)} - \bar{P} - \alpha^{(1)} \Delta^{(1)} | \hat{H}(1)} \left( \hat{h}^{(2)} - \hat{h}^{(1)} | \hat{h}^{(1)} \right) dx. \\
\end{align*}
\tag{82}
\]

We start by applying the change of pdf of Proposition 1 from \( f_{\bar{P} - \alpha^{(1)} \Delta^{(1)}} \) to \( f_{\Delta^{(1)}} \) such that

\[
\begin{align*}
\int_{\hat{H}(2)|\hat{H}(1)} \left( \hat{h}^{(2)} | \hat{h}^{(1)} \right) &= \int_{-\infty}^{\infty} \bar{P}^{\alpha^{(2)}} \int_{-\infty}^{\infty} \left( \hat{h}^{(2)} - \hat{h}^{(1)} - x \right) f_{\bar{P} - \alpha^{(2)} \Delta^{(2)} - \bar{P} - \alpha^{(1)} \Delta^{(1)} | \hat{H}(1)} \left( x | \hat{h}^{(1)} \right) f_{\bar{P} - \alpha^{(2)} \Delta^{(2)} - \bar{P} - \alpha^{(1)} \Delta^{(1)} | \hat{H}(1)} \left( \hat{h}^{(2)} - \hat{h}^{(1)} | \hat{h}^{(1)} \right) dx. \\
\end{align*}
\tag{83}
\]

Changing the integration variable to \( y = \bar{P}^{\alpha^{(1)}} x \) (and thus \( dx = \bar{P} - \alpha^{(1)} dy \)) it holds that

\[
\begin{align*}
\int_{\hat{H}(2)|\hat{H}(1)} \left( \hat{h}^{(2)} | \hat{h}^{(1)} \right) &= \bar{P}^{\alpha^{(2)}} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \left( \hat{h}^{(2)} - \hat{h}^{(1)} - \bar{P} - \alpha^{(1)} y \right) f_{\Delta^{(1)} | \hat{H}(1)} \left( y | \hat{h}^{(1)} \right) dy \\
&= \bar{P}^{\alpha^{(2)}} \int_{-\infty}^{\infty} v_{P}(y) dy \\
\end{align*}
\tag{84}
\]

where

\[
\begin{align*}
v_{P}(y) &\triangleq f_{\Delta^{(1)}} \left( \delta^{(2)} - \bar{P} - \alpha^{(2)} - \alpha^{(1)} \delta^{(1)} + y \right) f_{\Delta^{(1)} | \hat{H}(1)} \left( y | \hat{h}^{(1)} \right) \\
\end{align*}
\tag{85}
\]

comes from applying \( \frac{\hat{h}^{(1)}}{} = \hat{h} + \bar{P} - \alpha^{(1)} \delta^{(1)} \). From (87) and applying again the change of pdf of Proposition 1 to the numerator, the term \( f_{\Delta^{(2)} \Delta^{(2)} | \hat{H}(1)} \hat{h}^{(2)} - h \) can be expressed as

\[
\begin{align*}
\frac{f_{\Delta^{(2)} | \hat{H}(1)} \hat{h}^{(2)} - h}{f_{\Delta^{(2)} | \hat{H}(1)} \hat{h}^{(2)}} &= \frac{f_{\Delta^{(2)}}}{f_{\Delta^{(2)}} | \hat{h}^{(1)}} \int_{-\infty}^{\infty} v_{P}(y) dy. \\
\end{align*}
\tag{86}
\]

From continuity of \( f_{\Delta^{(1)}} \) and \( f_{\Delta^{(2)}} \), and Corollary 1, we obtain the limit of \( v_{P}(y) \) in (88) when \( P \to \infty \). This limit has two possible expressions depending on the relation between \( \alpha^{(1)} \) and \( \alpha^{(2)} \). Specifically, it holds that

\[
\lim_{P \to \infty} v_{P}(y) = f_{\Delta^{(2)}} \left( \delta^{(2)} - \delta^{(1)} - y \right) f_{\Delta^{(1)} | \hat{h}^{(1)}} \\
\tag{87}
\]

if \( \alpha^{(1)} = \alpha^{(2)} \), and that

\[
\lim_{P \to \infty} v_{P}(y) = f_{\Delta^{(2)}} \left( \delta^{(2)} \right) f_{\Delta^{(1)} | \hat{h}^{(1)}} \\
\tag{88}
\]

if \( \alpha^{(1)} > \alpha^{(2)} \). Now we prove separately each of the two possible cases.
a) $\alpha^{(1)} = \alpha^{(2)}$: From the Lebesgue’s Dominated Convergence Theorem (Theorem 4), H2), and (90), the limit exists and it holds that

$$\lim_{P \to \infty} \int_{-\infty}^{\infty} v_P(y) \, dy = f_{-\Delta^{(1)}} * f_{\Delta^{(2)}} (\delta^{(2)} - \delta^{(1)}).$$

(92)

From (89) and (92), it holds that

$$\lim_{P \to \infty} \int_{-\infty}^{\infty} \nu_P(y) \, dy = f_{-\Delta^{(1)}} * f_{\Delta^{(2)}} (\delta^{(1)}).$$

(93)

From H2), we have that, $\forall i \in \{1, 2\}, \exists f_{\Delta^{(i)} < \infty} : f_{\Delta^{(i)}}(x) \leq f_{\Delta^{(i)}} \forall x$. Then, it holds that

$$f_{-\Delta^{(1)}} * f_{\Delta^{(2)}} (x) \leq \max(f_{\Delta^{(1)}}, f_{\Delta^{(2)}}).$$

(94)

Conversely, let $\mathbb{I}$ be the indicator function and let then $\tau$ be

$$\tau \triangleq \int_{-\infty}^{\infty} \mathbb{I}_{x < S_{-\Delta^{(1)}}} \times \mathbb{I}_{(\delta^{(2)} - \delta^{(1)}) - x} \in S_{\Delta^{(2)}} \, dx.$$ (95)

Then,

$$f_{-\Delta^{(1)}} * f_{\Delta^{(2)}} (\delta^{(2)} - \delta^{(1)}) > \epsilon^2 \tau$$

(96)

and $\tau > 0$ if $\delta^{(1)} \in S_{-\Delta^{(1)}}$ and $\delta^{(2)} \in S_{\Delta^{(2)}}$. From (94) and (96), (93) satisfies

$$\frac{\epsilon}{\max(f_{\Delta^{(1)}}, f_{\Delta^{(2)}})} < \frac{f_{\Delta^{(2)}} (\delta^{(2)})}{f_{-\Delta^{(1)}} * f_{\Delta^{(2)}} (\delta^{(2)} - \delta^{(1)})} < \frac{f_{\Delta^{(2)}} (\delta^{(2)})}{\epsilon^2 \tau}.$$ This implies (78) and thus the proof is concluded for the $\alpha^{(2)} = \alpha^{(1)}$ case.

b) $\alpha^{(1)} > \alpha^{(2)}$: From the Lebesgue’s Dominated Convergence Theorem and (91), the limit exists and it holds that

$$\lim_{P \to \infty} v_P(y) = \int_{-\infty}^{\infty} f_{\Delta^{(2)}} (\delta^{(2)}) f_{-\Delta^{(1)}} (y) \, dy = f_{\Delta^{(2)}} (\delta^{(2)}).$$

(97)

(98)

and applying (98) in (89) we obtain that

$$\lim_{P \to \infty} \frac{\tilde{P}_{-\Delta^{(2)}} (\tilde{h}^{(2)} - h)}{\lim_{P \to \infty} f_{\Delta^{(2)}} (\tilde{h}^{(2)} - \tilde{h}^{(1)})} = 1.$$ (99)

This concludes the proof of Lemma I for the 2-estimate case.

3) Proof for $K > 2$ estimates:

In this section we prove by induction that Lemma I also holds for any number $K$ of estimates. We have proved that it is true for the base cases $K = 1$ —trivial— and $K = 2$. In the following, we prove the induction step. We denote the set of estimates as $\mathcal{G}_K \triangleq \{\tilde{h}^{(1)}, \ldots, \tilde{h}^{(K)}\}$ and, consistently, the set of given values as $\bar{g}_K \triangleq \{\hat{h}^{(1)}, \ldots, \hat{h}^{(K)}\}$. 
Let us assume that Lemma 1 is verified for a given $K$. We consider $K + 1$ estimates. Then from the mutual independence of the estimation noise variables $\Delta^{(j)}$ and Bayes’ formula we obtain that

$$f_{\tilde{H} | \tilde{G}_{\infty}, \tilde{G}_{(K+1)}} (\tilde{h} | \tilde{G}_{\infty}) = \frac{f_{\tilde{H} | \tilde{G}_{\infty}, \tilde{h}_{(K+1)}} (\tilde{h}, \tilde{G}_{\infty})}{f_{\tilde{h}_{(K+1)} | \tilde{G}_{\infty}}} f_{\tilde{G}_{\infty}} (\tilde{G}_{\infty}) f_{\tilde{h}_{(K+1)}} (\tilde{h})$$

\hspace{1cm} (100)

From the induction hypothesis, it holds that

$$\max f_{\tilde{H} | \tilde{G}_{\infty}} (h | \tilde{G}_{\infty}) = O \left( \tilde{P}^{a(1)} \right).$$

(101)

Thus, we need to prove that

$$0 < \lim_{\tilde{P} \to \infty} \frac{f_{\tilde{P} - a(K+1)} (\tilde{h}_{(K+1)} - h)}{f_{\tilde{H}_{(K+1)} | \tilde{G}_{\infty}}} < \infty.$$  

(102)

Taking into consideration that

$$\tilde{h}_{(K+1)} - \tilde{h}^{(1)} = \tilde{P}^{-a(K+1)} \tilde{h}^{(1)} + \tilde{P}^{-a(1)} \tilde{h}^{(1)},$$

(103)

the denominator of the expression in (102) satisfies that

$$f_{\tilde{H}_{(K+1)} | \tilde{G}_{\infty}} (\tilde{h}^{(1)} | \tilde{G}_{\infty}) = f_{\tilde{H}^{(1)} + \Delta^{(K+1)}} (\tilde{h}_{(K+1)} - \tilde{h}^{(1)} | \tilde{G}_{\infty})$$

\hspace{1cm} (104)

$$= f_{\Delta^{(K+1)} | \tilde{G}_{\infty}} (\tilde{P}^{-a(K+1)} \delta^{(K+1)} - \tilde{P}^{-a(1)} \delta^{(1)} | \tilde{G}_{\infty})$$

\hspace{1cm} (105)

where $\Delta' = \tilde{P}^{-a(K+1)} \Delta^{(K+1)} - \tilde{P}^{-a(1)} \Delta^{(1)}$. Hence, expressing $f_{\Delta} | \tilde{G}_{\infty}$ as convolution of pdfs we have that

$$f_{\tilde{H}_{(K+1)} | \tilde{G}_{\infty}} (\tilde{h}^{(1)} | \tilde{G}_{\infty}) = f_{\tilde{P}^{-a(K+1)} \Delta^{(K+1)}} \ast f_{\tilde{P}^{-a(1)} \Delta^{(1)}} (\tilde{h}_{(K+1)} - \tilde{h}^{(1)} | \tilde{G}_{\infty})$$

\hspace{1cm} (106)

Applying the same steps as in (84)-(89), we obtain

$$f_{\tilde{P}^{-a(K+1)} \Delta^{(K+1)}} (\tilde{h}_{(K+1)} - h) = \int_{-\infty}^{\infty} f_{\Delta^{(K+1)}} (\delta^{(K+1)}) f_{\delta^{(1)}} (y | \tilde{G}_{\infty}, \tilde{h}_{(K+1)} - \tilde{h}^{(1)}) \, dy$$

\hspace{1cm} (107)

where we have introduced the notation

$$\delta'_y \triangleq \delta^{(K+1)} - \tilde{P}^{-a(K+1)} \delta^{(1)} + y$$

\hspace{1cm} (108)

for ease of reading. We can see that (107) is equivalent to (89) with $\Delta^{(K+1)}$ in place of $\Delta^{(2)}$. Then, following the same derivation as in the 2-estimate case, i.e., using Corollary 1 and Lebesgue’s Dominated Convergence Theorem, we conclude the induction step. From the base case and the induction step, Lemma 1 is proven.
A. Proof of Lemma [3]

Assuming $\alpha^{(i)} > 0$, we have that

$$
\lim_{P \to \infty} f_{\hat{H}^{(i)}}(\hat{h}^{(i)}) = \lim_{P \to \infty} f_{\hat{H}_+ \hat{P}_- \alpha^{(i)} \Delta^{(i)}}(h + \hat{P}_- \alpha^{(i)} \delta^{(i)})
$$

(109)

$$
= \lim_{P \to \infty} \int_{-\infty}^{\infty} f_{\hat{H}}(h + \hat{P}_- \alpha^{(i)} \delta^{(i)} - x) f_{\hat{P}_- \alpha^{(i)} \Delta^{(i)}}(x) \, dx
$$

(110)

$$
= \lim_{P \to \infty} \int_{-\infty}^{\infty} f_{\hat{H}}(h + \hat{P}_- \alpha^{(i)} \delta^{(i)} - \hat{P}_- \alpha^{(i)} y) f_{\Delta^{(i)}}(y) \, dy
$$

(111)

$$
= \int_{-\infty}^{\infty} f_{\hat{H}}(h) f_{\Delta^{(i)}}(y) \, dy
$$

(112)

$$
= f_{\hat{H}}(h),
$$

(113)

where (111) comes from applying the relation between $f_{\hat{P}_- \alpha \Delta}$ and $f_{\Delta}$, —see Proposition [1]—, and from the change of integration variable $y = \hat{P}_- \alpha x$. Finally, (112) follows from applying Lebesgue’s Dominated Convergence Theorem. Therefore, $f_{\hat{H}^{(i)}}$ converges almost surely to $f_{\hat{H}}$ and hence Lemma [5] is proven. Then, in order to prove Corollary [1] i.e., that

$$
\lim_{P \to \infty} f_{\Delta^{(i)}|\hat{H}^{(i)}, \ldots, \hat{H}^{(K)}}(y|\hat{h}^{(1)}, \ldots, \hat{h}^{(K)}) = f_{\Delta^{(i)}(y)}
$$

(114)

we apply Bayes’ formula such that

$$
f_{\Delta^{(i)}|\hat{H}^{(i)}, \ldots, \hat{H}^{(K)}}(y|\hat{h}^{(1)}, \ldots, \hat{h}^{(K)}) = \frac{f_{\hat{H}^{(i)}, \ldots, \hat{H}^{(K)}|\Delta^{(i)}(\hat{h}^{(1)}, \ldots, \hat{h}^{(K)})|y} f_{\Delta^{(i)}(y)}
$$

(115)

$$
= \frac{f_{\hat{H}, \hat{H}^{(2)}, \ldots, \hat{H}^{(K)}}(h, h^{(2)}, \ldots, h^{(K)})}{f_{\hat{H}^{(1)}, \ldots, \hat{H}^{(K)}}(h^{(1)}, \ldots, h^{(K)})} f_{\Delta^{(i)}(y)}
$$

(116)

From (113) and the fact that $\alpha^{(1)} > 0$ we obtain that

$$
\lim_{P \to \infty} \frac{f_{\hat{H}, \hat{H}^{(2)}, \ldots, \hat{H}^{(K)}}(h, h^{(2)}, \ldots, h^{(K)})}{f_{\hat{H}^{(1)}, \ldots, \hat{H}^{(K)}}(h^{(1)}, \ldots, h^{(K)})} = 1.
$$

(117)

Taking the limit on (116) and applying (117), it holds that

$$
\lim_{P \to \infty} f_{\Delta^{(i)}|\hat{H}^{(i)}, \ldots, \hat{H}^{(K)}}(y|h_1, \ldots, h_K) = f_{\Delta^{(i)}(y)}
$$

(118)

what concludes the proof.
