Abstract. Reactive systems that operate in environments with complex data, such as mobile apps or embedded controllers with many sensors, are difficult to synthesize. Synthesis tools usually fail for such systems because the state space resulting from the discretization of the data is too large. We introduce TSL, a new temporal logic that separates control and data. We provide a CEGAR-based synthesis approach for the construction of implementations that are guaranteed to satisfy a TSL specification for all possible instantiations of the data processing functions. TSL provides an attractive trade-off for synthesis. On the one hand, synthesis from TSL, unlike synthesis from standard temporal logics, is undecidable in general. On the other hand, however, synthesis from TSL is scalable, because it is independent of the complexity of the handled data. Among other benchmarks, we have successfully synthesized a music player Android app and a controller for an autonomous vehicle in the Open Race Car Simulator (TORCS).

1 Introduction

In reactive synthesis, we automatically translate a formal specification, typically given in a temporal logic, into a controller that is guaranteed to satisfy the specification. Over the past two decades there has been much progress on reactive synthesis, both in terms of algorithms, notably with techniques like GR(1)-synthesis [6] and bounded synthesis [19], and in terms of tools, as showcased, for example, in the annual SYNTCOMP competition [24].

In practice however, reactive synthesis has seen limited success. One of the largest published success stories [5] is the synthesis of the AMBA bus protocol. To push synthesis even further, automatically synthesizing a controller for an autonomous system has been recognized to be of critical importance [53]. Despite many years of experience with synthesis tools, our own attempts to synthesize such controllers with existing tools have been unsuccessful. The reason is that the tools are unable to handle the data complexity of the controllers. The controller only needs to switch between a small number of behaviors, like steering during

a bend, or shifting gears on high rpm. The number of control states in a typical controller (cf. [18]) is thus not much different from the arbiter in the AMBA case study. However, in order to correctly initiate transitions between control states, the driving controller must continuously process data from more than 20 sensors.

If this data is included (even as a rough discretization) in the state space of the controller, then the synthesis problem is much too large to be handled by any available tools. It seems clear then, that a scalable synthesis approach must separate control and data. If we assume that the data processing is handled by some other approach (such as deductive synthesis [38] or manual programming), is it then possible to solve the remaining reactive synthesis problem?

In this paper, we show scalable reactive synthesis is indeed possible. Separating data and control has allowed us to synthesize reactive systems, including an autonomous driving controller and a music player app, that had been impossible to synthesize with previously available tools. However, the separation of data and control implies some fundamental changes to reactive synthesis, which we describe in the rest of the paper. The changes also imply that the reactive synthesis problem is no longer, in general, decidable. We thus trade theoretical decidability for practical scalability, which is, at least with regard to the goal of synthesizing realistic systems, definitely an attractive trade-off.

We introduce Temporal Stream Logic (TSL), a new temporal logic that includes *updates*, such as $\llbracket y \leftarrow f x \rrbracket$, and predicates over arbitrary function terms. The update $\llbracket y \leftarrow f x \rrbracket$ indicates that the result of applying function f to variable x is assigned to y . The implementation of predicates and functions is not part of the synthesis problem. Instead, we look for a system that satisfies the TSL specification *for all possible interpretations of the functions and predicates*.

This implicit quantification over all possible interpretations provides a useful abstraction: it allows us to *independently* implement the data processing part. On the other hand, this quantification is also the reason for the undecidability of the synthesis problem. If a predicate is applied to the same term *twice*, it must (independently of the interpretation) return the *same* truth value. The synthesis must then implicitly maintain a (potentially infinite) set of terms to which the predicate has previously been applied. As we show later, this set of terms can be used to encode PCP [45] for a proof of undecidability.

We present a practical synthesis approach for TSL specifications, which is based on bounded synthesis [19] and counterexample-guided abstraction refinement (CEGAR) [9]. We use bounded synthesis to search for an implementation up to a (iteratively growing) bound on the number of states. This approach underapproximates the actual TSL synthesis problem by leaving the interpretation of the predicates to the environment. The underapproximation allows for inconsistent behaviors: the environment might assign different truth values to the same predicate when evaluated at different points in time, even if the predicate is applied to the same term. However, if we find an implementation in this underapproximation, then the CEGAR loop terminates and we have a correct implementation for the original TSL specification. If we do not find an implementation in the underapproximation, we compute a counter strategy for

Fig. 1: The TSL synthesis procedure uses a modular design. Each step takes input from the previous step as well as interchangeable modules (dashed boxes).

the environment. Because bounded synthesis reduces the synthesis problem to a safety game, the counter strategy is a reachability strategy that can be represented as a finite tree. We check whether the counter strategy is spurious by searching for a pair of positions in the strategy where some predicate results in different truth values when applied to the same term. If the counter strategy is not spurious, then no implementation exists for the considered bound, and we increase the bound. If the counter strategy is spurious, then we introduce a constraint into the specification that eliminates the incorrect interpretation of the predicate, and continue with the refined specification.

A general overview of this procedure is shown in Fig. 1. The top half of the figure depicts the bounded search for an implementation that realizes a TSL specification using the CEGAR loop to refine the specification. If the specification is realizable, we proceed in the bottom half of the process, where a synthesized implementation is converted to a control flow model (CFM) determining the control of the system. We then specialize the CFM to Functional Reactive Programming (FRP), which is a popular and expressive programming paradigm for building reactive programs using functional programming languages [14]. Our framework supports any FRP library using the *Arrow* or *Applicative* design patterns, which covers most of the existing FRP libraries (e.g. [1,2,10,41]). Finally, the synthesized control flow is embedded into a project context, where it is equipped with function and predicate implementations and then compiled to an executable program.

<pre> Sys.leaveApp() if (MP.musicPlaying()) Ctrl.pause(); Sys.resumeApp() { pos = MP.trackPos(); Ctrl.play(Tr, pos); } </pre>	$\left \begin{array}{l} \text{ALWAYS} \left(\text{leaveApp Sys} \wedge \text{musicPlaying MP} \right. \\ \quad \left. \rightarrow \llbracket \text{Ctrl} \leftarrow \text{pause}() \rrbracket \right) \\ \\ \text{ALWAYS} \left(\text{resumeApp Sys} \right. \\ \quad \left. \rightarrow \llbracket \text{Ctrl} \leftarrow \text{play Tr (trackPos MP)} \rrbracket \right) \end{array} \right.$
---	--

Fig. 2: Sample code and specification for the music player app.

Our experience with synthesizing systems based on TSL specifications has been extremely positive. The synthesis works for a broad range of benchmarks, ranging from classic reactive synthesis problems (like escalator control), through programming exercises from functional reactive programming, to novel case studies like our music player app and the autonomous driving controller for a vehicle in the Open Race Car Simulator (TORCS).

2 Motivating Example

To demonstrate the utility of our method, we synthesized a music player Android app³ from a TSL specification. A major challenge in developing Android apps is the temporal behavior of an app through the *Android lifecycle* [47]. The Android lifecycle describes how an app should handle being paused, when moved to the background, coming back into focus, or being terminated. In particular, *resume and restart errors* are commonplace and difficult to detect and correct [47]. Our music player app demonstrates a situation in which a resume and restart error could be unwittingly introduced when programming by hand, but is avoided by providing a specification. We only highlight the key parts of this example here to give an intuition of TSL, leaving a more in-depth exposition to Appendix A.1.

Our music player app utilizes the Android music player library (MP), as well as its control interface (Ctrl). It pauses any playing music when moved to the background (for instance if a call is received), and continues playing the currently selected track (Tr) at the last track position when the app is resumed. In the Android system (Sys), the `leaveApp` method is called whenever the app moves to the background, while the `resumeApp` method is called when the app is brought back to the foreground. To avoid confusion between pausing music and pausing the app, we use `leaveApp` and `resumeApp` in place of the Android methods `onPause` and `onResume`. A programmer might manually write code for this as shown on the left in Fig. 2.

The behavior of this can be directly described in TSL as shown on the right in Fig. 2. Even eliding a formal introduction of the notation for now, the specification closely matches the textual specification. First, when the user leaves the app and the music is playing, the music pauses. Likewise for the second part, when the user resumes the app, the music starts playing again.

³ <https://play.google.com/store/apps/details?id=com.mark.myapplication>.

<pre> bool wasPlaying = false; Sys.leaveApp() if (MP.musicPlaying()) { wasPlaying = true; Ctrl.pause(); } else wasPlaying = false; Sys.resumeApp() if (wasPlaying) { pos = MP.trackPos(); Ctrl.play(Tr, pos); } </pre>	$ \begin{aligned} & \text{ALWAYS} \left(\left(\text{leaveApp Sys} \wedge \text{musicPlaying MP} \right. \right. \\ & \quad \left. \left. \rightarrow \llbracket \text{Ctrl} \leftarrow \text{pause}() \rrbracket \right. \right. \\ & \quad \left. \wedge \left(\llbracket \text{Ctrl} \leftarrow \text{play Tr (trackPos MP)} \rrbracket \right. \right. \\ & \quad \left. \left. \text{AS_SOON_AS resumeApp Sys} \right) \right) \end{aligned} $
--	---

Fig. 3: The effect of a minor change in functionality on code versus a specification.

However, assume we want to change the behavior so that the music only plays on resume when the music had been playing before leaving the app in the first place. In the manually written program, this new functionality requires an additional variable `wasPlaying` to keep track of the music state. Managing the state requires multiple changes in the code as shown on the left in Fig. 3. The required code changes include: a conditional in the `resumeApp` method, setting `wasPlaying` appropriately in two places in `leaveApp`, and providing an initial value. Although a small example, it demonstrates how a minor change in functionality may require wide-reaching code changes. In addition, this change introduces a globally scoped variable, which then might accidentally be set or read elsewhere. In contrast, it is a simple matter to change the TSL specification to reflect this new functionality. Here, we only update one part of the specification to say that if the user leaves the app and the music is playing, the music has to play again as soon as the app resumes.

Synthesis allows us to specify a temporal behavior without worrying about the implementation details. In this example, writing the specification in TSL has eliminated the need of an additional state variable, similarly to a higher order `map` eliminating the need for an iteration variable. However, in more complex examples the benefits compound, as TSL provides a modular interface to specify behaviors, offloading the management of multiple interconnected temporal behaviors from the user to the synthesis engine.

3 Preliminaries

We assume time to be discrete and denote it by the set \mathbb{N} of positive integers. A value is an arbitrary object of arbitrary type. \mathcal{V} denotes the set of all values. The Boolean values are denoted by $\mathcal{B} \subseteq \mathcal{V}$. A stream $s: \mathbb{N} \rightarrow \mathcal{V}$ is a function fixing values at each point in time. An n -ary function $f: \mathcal{V}^n \rightarrow \mathcal{V}$ determines new values from n given values, where the set of all functions (of arbitrary arity)

is given by \mathcal{F} . Constants are functions of arity 0. Every constant is a value, i.e., is an element of $\mathcal{F} \cap \mathcal{V}$. An n -ary predicate $p: \mathcal{V}^n \rightarrow \mathcal{B}$ checks a property over n values. The set of all predicates (of arbitrary arity) is given by \mathcal{P} , where $\mathcal{P} \subseteq \mathcal{F}$. We use $B^{[A]}$ to denote the set of all total functions with domain A and image B .

In the classical synthesis setting, inputs and outputs are vectors of Booleans, where the standard abstraction treats inputs and outputs as atomic propositions $\mathcal{I} \cup \mathcal{O}$, while their Boolean combinations form an alphabet $\Sigma = 2^{\mathcal{I} \cup \mathcal{O}}$. Behavior then is described through infinite sequences $\alpha = \alpha(0)\alpha(1)\alpha(2)\dots \in \Sigma^\omega$. A *specification* describes a relation between input sequences $\alpha \in (2^{\mathcal{I}})^\omega$ and output sequences $\beta \in (2^{\mathcal{O}})^\omega$. Usually, this relation is not given by explicit sequences, but by a formula in a temporal logic. The most popular such logic is Linear Temporal Logic (LTL) [43], which uses Boolean connectives to specify behavior at specific points in time, and temporal connectives, to relate sub-specifications over time. The realizability and synthesis problems for LTL are 2EXPTIME-complete [44].

An implementation describes a realizing strategy, formalized via infinite trees. A Φ -labeled and \mathcal{Y} -branching tree is a function $\sigma: \mathcal{Y}^* \rightarrow \Phi$, where \mathcal{Y} denotes the set of branching directions along a tree. Every node of the tree is given by a finite prefix $v \in \mathcal{Y}^*$, which fixes the path to reach a node from the root. Every node is labeled by an element of Φ . For infinite paths $\nu \in \mathcal{Y}^\omega$, the branch $\sigma\nu$ denotes the sequence of labels that appear on ν , i.e., $\forall t \in \mathbb{N}. (\sigma\nu)(t) = \sigma(\nu(0)\dots\nu(t-1))$.

4 Temporal Stream Logic

We present a new logic: Temporal Stream Logic (TSL), which is especially designed for synthesis and allows for the manipulation of infinite streams of arbitrary (even non-enumerative, or higher order) type. It provides a straightforward notation to specify how outputs are computed from inputs, while using an intuitive interface to access time. The main focus of TSL is to describe temporal control flow, while abstracting away concrete implementation details. This not only keeps the logic intuitive and simple, but also allows a user to identify problems in the control flow even without a concrete implementation at hand. In this way, the use of TSL scales up to any required abstraction, such as API calls or complex algorithmic transformations.

Architecture A TSL formula φ specifies a reactive system that in every time step processes a finite number of inputs \mathbb{I} and produces a finite number of outputs \mathbb{O} . Furthermore, it uses cells \mathbb{C} to store a value computed at time t , which can then be reused in the next time step $t + 1$. An overview of the architecture of such a system is given in Fig. 4a. In terms of behavior, the environment produces infinite streams of input data, while the system uses pure (side-effect free) functions to transform the values of these input streams in every time step. After their transformation, the data values are either passed to an output stream or are passed to a cell, which pipes the output value from one time step back to the corresponding input value of the next. The behaviour of the system is captured by its infinite execution over time.

Fig. 4: General architecture of reactive systems that are specified in TSL on the left, and the structure of function, predicate and updates on the right.

Function Terms, Predicate Terms, and Updates In TSL we differentiate between two elements: we use purely functional transformations, reflected by functions $f \in \mathcal{F}$ and their compositions, and predicates $p \in \mathcal{P}$, used to control how data flows inside the system. To argue about both elements we use a term based notation, where we distinguish between function terms τ_F and predicate terms τ_P , respectively. Function terms are either constructed from inputs or cells ($\mathbf{s}_i \in \mathbb{I} \cup \mathbb{C}$), or from functions, recursively applied to a set of function terms. Predicate terms are constructed similarly, by applying a predicate to a set of function terms. Finally, an update takes the result of a function computation and passes it either to an output or a cell ($\mathbf{s}_o \in \mathbb{O} \cup \mathbb{C}$). An overview of the syntax of the different term notations is given in Fig. 4b. Note that we use curried argument notation similar to functional programming languages.

We denote sets of function and predicate terms, and updates by \mathcal{T}_F , \mathcal{T}_P and \mathcal{T}_U , respectively, where $\mathcal{T}_P \subseteq \mathcal{T}_F$. We use \mathbb{F} to denote the set of function literals and $\mathbb{P} \subseteq \mathbb{F}$ to denote the set of predicate literals, where the literals \mathbf{s}_i , \mathbf{s}_o , \mathbf{f} and \mathbf{p} are symbolic representations of inputs and cells, outputs and cells, and functions and predicates, respectively. Literals are used to construct terms as shown in Fig. 4b. Since we use a symbolic representation, functions and predicates are not tied to a specific implementation. However, we still classify them according to their arity, i.e., the number of function terms they are applied to, as well as by their type: input, output, cell, function or predicate. Furthermore, terms can be compared syntactically using the equivalence relation \equiv . To assign a semantic interpretation to functions, we use an assignment function $\langle \cdot \rangle: \mathbb{F} \rightarrow \mathcal{F}$.

Inputs, Outputs, and Computations We consider momentary inputs $i \in \mathcal{V}^{[\mathbb{I}]}$, which are assignments of inputs $\mathbf{i} \in \mathbb{I}$ to values $v \in \mathcal{V}$. For the sake of readability let $\mathcal{I} = \mathcal{V}^{[\mathbb{I}]}$. Input streams are infinite sequences $\iota \in \mathcal{I}^\omega$ consisting of infinitely many momentary inputs.

Similarly, a momentary output $o \in \mathcal{V}^{[\mathbb{O}]}$ is an assignment of outputs $\mathbf{o} \in \mathbb{O}$ to values $v \in \mathcal{V}$, where we also use $\mathcal{O} = \mathcal{V}^{[\mathbb{O}]}$. Output streams are infinite sequences $\varrho \in \mathcal{O}^\omega$. To capture the behavior of a cell, we introduce the notion of a computation ς . A computation fixes the function terms that are used to

compute outputs and cell updates, without fixing semantics of function literals. Intuitively, a computation only determines which function terms are used to compute an output, but abstracts from actually computing it.

The basic element of a computation is a computation step $c \in \mathcal{T}_F^{[\mathbb{O} \cup \mathbb{C}]}$, which is an assignment of outputs and cells $\mathbf{s}_o \in \mathbb{O} \cup \mathbb{C}$ to function terms $\tau_F \in \mathcal{T}_F$. For the sake of readability let $\mathcal{C} = \mathcal{T}_F^{[\mathbb{O} \cup \mathbb{C}]}$. A computation step fixes the control flow behaviour at a single point in time. A computation $\varsigma \in \mathcal{C}^\omega$ is an infinite sequence of computation steps.

As soon as input streams, and function and predicate implementations are known, computations can be turned into output streams. To this end, let $\langle \cdot \rangle: \mathbb{F} \rightarrow \mathcal{F}$ be some function assignment. Furthermore, assume that there are predefined constants $init_c \in \mathcal{F} \cap \mathcal{V}$ for every cell $c \in \mathbb{C}$, which provide an initial value for each stream at the initial point in time. To receive an output stream from a computation $\varsigma \in \mathcal{C}^\omega$ under the input stream ι , we use an evaluation function $\eta_{\langle \cdot \rangle}: \mathcal{C}^\omega \times \mathcal{I}^\omega \times \mathbb{N} \times \mathcal{T}_F \rightarrow \mathcal{V}$:

$$\eta_{\langle \cdot \rangle}(\varsigma, \iota, t, \mathbf{s}_i) = \begin{cases} \iota(t)(\mathbf{s}_i) & \text{if } \mathbf{s}_i \in \mathbb{I} \\ init_{\mathbf{s}_i} & \text{if } \mathbf{s}_i \in \mathbb{C} \wedge t = 0 \\ \eta_{\langle \cdot \rangle}(\varsigma, \iota, t-1, \varsigma(t-1)(\mathbf{s}_i)) & \text{if } \mathbf{s}_i \in \mathbb{C} \wedge t > 0 \end{cases}$$

$$\eta_{\langle \cdot \rangle}(\varsigma, \iota, t, \mathbf{f} \tau_0 \cdots \tau_{m-1}) = \langle \mathbf{f} \rangle \eta_{\langle \cdot \rangle}(\varsigma, \iota, t, \tau_0) \cdots \eta_{\langle \cdot \rangle}(\varsigma, \iota, t, \tau_{m-1})$$

Then $\varrho_{\langle \cdot \rangle, \varsigma, \iota} \in \mathcal{O}^\omega$ is defined via $\varrho_{\langle \cdot \rangle, \varsigma, \iota}(t)(\mathbf{o}) = \eta_{\langle \cdot \rangle}(\varsigma, \iota, t, \mathbf{o})$ for all $t \in \mathbb{N}$, $\mathbf{o} \in \mathbb{O}$.

Syntax Every TSL formula φ is built according to the following grammar:

$$\varphi := \tau \in \mathcal{T}_P \cup \mathcal{T}_U \mid \neg\varphi \mid \varphi \wedge \varphi \mid \bigcirc\varphi \mid \varphi \mathcal{U} \varphi$$

An atomic proposition τ consists either of a predicate term, serving as a Boolean interface to the inputs, or of an update, enforcing a respective flow at the current point in time. Next, we have the Boolean operations via negation and conjunction, that allow us to express arbitrary Boolean combinations of predicate evaluations and updates. Finally, we have the temporal operator next: $\bigcirc\psi$, to specify the behavior at the next point in time and the temporal operator until: $\vartheta \mathcal{U} \psi$, which enforces a property ϑ to hold until the property ψ holds, where ψ must hold at some point in the future eventually.

Semantics Formally, this leads to the following semantics. Let $\langle \cdot \rangle: \mathbb{F} \rightarrow \mathcal{F}$, $\iota \in \mathcal{I}^\omega$, and $\varsigma \in \mathcal{C}^\omega$ be given, then the validity of a TSL formula φ with respect to ς and ι is defined inductively over $t \in \mathbb{N}$ via:

$$\begin{aligned} \varsigma, \iota, t \models_{\langle \cdot \rangle} \mathbf{p} \tau_0 \cdots \tau_{m-1} &: \Leftrightarrow \eta_{\langle \cdot \rangle}(\varsigma, \iota, t, \mathbf{p} \tau_0 \cdots \tau_{m-1}) \\ \varsigma, \iota, t \models_{\langle \cdot \rangle} \llbracket \mathbf{s} \leftarrow \tau \rrbracket &: \Leftrightarrow \varsigma(t)(\mathbf{s}) \equiv \tau \\ \varsigma, \iota, t \models_{\langle \cdot \rangle} \neg\psi &: \Leftrightarrow \varsigma, \iota, t \not\models_{\langle \cdot \rangle} \psi \\ \varsigma, \iota, t \models_{\langle \cdot \rangle} \vartheta \wedge \psi &: \Leftrightarrow \varsigma, \iota, t \models_{\langle \cdot \rangle} \vartheta \wedge \varsigma, \iota, t \models_{\langle \cdot \rangle} \psi \\ \varsigma, \iota, t \models_{\langle \cdot \rangle} \bigcirc\psi &: \Leftrightarrow \varsigma, \iota, t+1 \models_{\langle \cdot \rangle} \psi \\ \varsigma, \iota, t \models_{\langle \cdot \rangle} \vartheta \mathcal{U} \psi &: \Leftrightarrow \exists t'' \geq t. \forall t \leq t' < t''. \varsigma, \iota, t' \models_{\langle \cdot \rangle} \vartheta \wedge \varsigma, \iota, t'' \models_{\langle \cdot \rangle} \psi \end{aligned}$$

Consider that the satisfaction of a predicate depends on the current computation step and the steps of the past, while for updates it only depend on the current computation step. Furthermore, updates are only checked syntactically, while the satisfaction of predicates depends on the given assignment $\langle \cdot \rangle$ and the input stream ι . We say that ς and ι satisfy φ , denoted by $\varsigma, \iota \models_{\langle \cdot \rangle} \varphi$, if $\varsigma, \iota, 0 \models_{\langle \cdot \rangle} \varphi$.

Beside the basic operators we have the standard derived Boolean operators, as well as the derived temporal operators: *release* $\varphi \mathcal{R} \psi \equiv \neg((\neg\psi)\mathcal{U}(\neg\varphi))$, *finally* $\diamond\varphi \equiv \text{true}\mathcal{U}\varphi$, *always* $\Box\varphi \equiv \text{false}\mathcal{R}\varphi$, the *weak* version of *until* $\varphi \mathcal{W} \psi \equiv (\varphi\mathcal{U}\psi) \vee (\Box\varphi)$, and *as soon as* $\varphi \mathcal{A} \psi \equiv \neg\psi \mathcal{W}(\psi \wedge \varphi)$.

Realizability We are interested in the following realizability problem: given a TSL formula φ , is there a strategy $\sigma \in \mathcal{C}^{\mathbb{Z}^+}$ such that for every input $\iota \in \mathcal{I}^\omega$ and function implementation $\langle \cdot \rangle: \mathbb{F} \rightarrow \mathcal{F}$, the branch $\sigma\iota$ satisfies φ , i.e.,

$$\exists \sigma \in \mathcal{C}^{\mathbb{Z}^+}. \forall \iota \in \mathcal{I}^\omega. \forall \langle \cdot \rangle: \mathbb{F} \rightarrow \mathcal{F}. \sigma\iota, \iota \models_{\langle \cdot \rangle} \varphi$$

If such a strategy σ exists, we say σ realizes φ . If we additionally ask for a concrete instantiation of σ , we consider the synthesis problem of TSL.

5 TSL Properties

In order to synthesize programs from TSL specifications, we give an overview of the first part of our synthesis process, as shown in Fig. 1. First we show how to approximate the semantics of TSL through a reduction to LTL. However, due to the approximation, finding a realizable strategy immediately may fail. Our solution is a CEGAR loop that improves the approximation. This CEGAR loop is necessary, because the realizability problem of TSL is undecidable in general.

Approximating TSL with LTL We approximate TSL formulas with weaker LTL formulas. The approximation reinterprets the syntactic elements, \mathcal{T}_P and \mathcal{T}_U , as atomic propositions for LTL. This strips away the semantic meaning of the function application and assignment in TSL, which we reconstruct by later adding assumptions lazily to the LTL formula.

Formally, let \mathcal{T}_P and \mathcal{T}_U be the finite sets of predicate terms and updates, which appear in φ_{TSL} , respectively. For every assigned signal, we partition \mathcal{T}_U into $\bigsqcup_{s_o \in \mathbb{O} \cup \mathbb{C}} \mathcal{T}_U^{s_o}$. For every $c \in \mathbb{C}$ let $\mathcal{T}_{U/id}^c = \mathcal{T}_U^c \cup \{\llbracket c \leftarrow c \rrbracket\}$, for $o \in \mathbb{O}$ let $\mathcal{T}_{U/id}^o = \mathcal{T}_U^o$, and let $\mathcal{T}_{U/id} = \bigcup_{s_o \in \mathbb{O} \cup \mathbb{C}} \mathcal{T}_{U/id}^{s_o}$. We construct the LTL formula φ_{LTL} over the input propositions \mathcal{T}_P and output propositions $\mathcal{T}_{U/id}$ as follows:

$$\varphi_{LTL} = \Box \left(\bigwedge_{s_o \in \mathbb{O} \cup \mathbb{C}} \bigvee_{\tau \in \mathcal{T}_{U/id}^{s_o}} (\tau \wedge \bigwedge_{\tau' \in \mathcal{T}_{U/id}^{s_o} \setminus \{\tau\}} \neg \tau') \right) \wedge \text{SYNTACTICCONVERSION}(\varphi_{TSL})$$

Intuitively, the first part of the equation partially reconstructs the semantic meaning of updates by ensuring that a signal is not updated with multiple values at a time. The second part extracts the reactive constraints of the TSL formula without the semantic meaning of functions and updates.

Theorem 1. *If φ_{LTL} is realizable, then φ_{TSL} is realizable.*

$$\begin{array}{lll}
\Box (\llbracket y \leftarrow y \rrbracket \vee \llbracket y \leftarrow x \rrbracket) & \Box \neg(y_to_y \wedge x_to_y) & \rightarrow \text{blue circle with self-loop} \\
\wedge \Diamond p\ x \rightarrow \Diamond p\ y & \wedge \Box (y_to_y \vee x_to_y) & \rightarrow p_x \wedge \neg p_y \\
& \wedge \Diamond p_x \rightarrow \Diamond p_y &
\end{array}$$

(a) TSL specification (b) initial approximation (c) spurious counter-strategy

Fig. 5: A TSL specification (a) with input x and cell y that is realizable. A winning strategy is to save x to y as soon as $p(x)$ is satisfied. However, the initial approximation (b), that is passed to an LTL synthesis solver, is unrealizable, as proven through the counter-strategy (c) returned by the LTL solver.

The proof of Thm. 1 is given in Appendix A.2. Note that unrealizability of φ_{LTL} does not imply that φ_{TSL} is unrealizable. It may be that we have not added sufficiently many environment assumptions to the approximation in order for the system to produce a realizing strategy.

Example As an example, we present a simple TSL specification in Fig. 5a. The specification asserts that the environment provides an input x for which the predicate $p\ x$ will be satisfied eventually. The system must guarantee that eventually $p\ y$ holds. According to the semantics of TSL the formula is realizable. The system can take the value of x when $p\ x$ is true and save it to y , thus guaranteeing that $p\ y$ is satisfied eventually. This is in contrast to LTL, which has no semantics for pure functions - taking the evaluation of $p\ y$ as an environmentally controlled value that does not need to obey the consistency of a pure function.

Refining the LTL Approximation It is possible that the LTL solver returns a counter-strategy for the environment although the original TSL specification is realizable. We call such a counter-strategy *spurious* as it exploits the additional freedom of LTL to violate the purity of predicates as made possible by the underapproximation. Formally, a counter-strategy is an infinite tree $\pi: \mathcal{C}^* \rightarrow 2^{\mathcal{T}_P}$, which provides predicate evaluations in response to possible update assignments of function terms $\tau_F \in \mathcal{T}_F$ to outputs $o \in \mathbb{O}$. W.l.o.g. we can assume that \mathbb{O} , \mathcal{T}_F and \mathcal{T}_P are finite, as they can always be restricted to the outputs and terms that appear in the formula. A counter-strategy is spurious, iff there is a branch $\pi \upharpoonright \zeta$ for some computation $\zeta \in \mathcal{C}^\omega$, for which the strategy chooses an inconsistent evaluation of two equal predicate terms at different points in time, i.e.,

$$\begin{aligned}
& \exists \zeta \in \mathcal{C}^\omega. \exists t, t' \in \mathbb{N}. \exists \tau_P \in \mathcal{T}_P. \\
& \tau_P \in \pi(\zeta(0)\zeta(1) \dots \zeta(t-1)) \wedge \tau_P \notin \pi(\zeta(0)\zeta(1) \dots \zeta(t'-1)) \wedge \\
& \forall \langle \cdot \rangle: \mathbb{F} \rightarrow \mathcal{F}. \eta_{\langle \cdot \rangle}(\zeta, \pi \upharpoonright \zeta, t, \tau_P) = \eta_{\langle \cdot \rangle}(\zeta, \pi \upharpoonright \zeta, t', \tau_P).
\end{aligned}$$

Note that a non-spurious strategy can be inconsistent along multiple branches. Due to the definition of realizability the environment can choose function and predicate assignments differently against every system strategy accordingly.

By purity of predicates in TSL the environment is forced to always return the same value for predicate evaluations on equal values. However, this semantic property cannot be enforced implicitly in LTL. To resolve this issue we use the returned counter-strategy to identify spurious behavior in order to strengthen

Algorithm 1 Check-Spuriousness

Input: bound b , counter-strategy $\pi: \mathcal{C}^* \rightarrow 2^{\mathcal{T}_P}$ (finitely represented using m states)

- 1: **for all** $v \in \mathcal{C}^{m \cdot b}$, $\tau_P \in \mathcal{T}_P$, $t, t' \in \{0, 1, \dots, m \cdot b - 1\}$ **do**
 - 2: **if** $\eta_{\langle \cdot \rangle_{\text{id}}}(v, \iota_{\text{id}}, t, \tau_P) \equiv \eta_{\langle \cdot \rangle_{\text{id}}}(v, \iota_{\text{id}}, t', \tau_P) \wedge$
 $\tau_P \in \pi(v_0 \dots v_{t-1}) \wedge \tau_P \notin \pi(v_0 \dots v_{t'-1})$ **then**
 - 3: $w \leftarrow \text{reduce}(v, \tau_P, t, t')$
 - 4: **return** $\square(\bigwedge_{i=0}^{t-1} \bigcirc^i w_i \wedge \bigwedge_{i=0}^{t'-1} \bigcirc^i w_i \rightarrow (\bigcirc^t \tau_P \leftrightarrow \bigcirc^{t'} \tau_P))$
 - 5: **return** “non-spurious”
-

the LTL underapproximation with additional environment assumptions. After adding the derived assumptions, we re-execute the LTL synthesizer to check whether the added assumptions are sufficient in order to obtain a winning strategy for the system. If the solver still returns a spurious strategy, we continue the loop in a CEGAR fashion until the set of added assumptions is sufficiently complete. However, if a non-spurious strategy is returned, we have found a proof that the given TSL specification is indeed unrealizable and terminate.

Algorithm 1 shows how a returned counter-strategy π is checked for being spurious. To this end, it is sufficient to check π against system strategies bounded by the given bound b , as we use bounded synthesis [19]. Furthermore, we can assume w.l.o.g. that π is given by a finite state representation, which is always possible due to the finite model guarantees of LTL. Also note that π , as it is returned by the LTL synthesizer, responds to sequences of sets of updates $(2^{\mathcal{T}_{U/\text{id}}})^*$. However, in our case $(2^{\mathcal{T}_{U/\text{id}}})^*$ is an alternative representation of \mathcal{C}^* , due to the additional constraints added during the construction of φ_{LTL} .

The algorithm iterates over all possible responses $v \in \mathcal{C}^{m \cdot b}$ of the system up to depth $m \cdot b$. This is sufficient, since any deeper exploration would result in a state repetition of the cross-product of the finite state representation of π and any system strategy bounded by b . Hence, the same behaviour could also be generated by a smaller sequence. At the same time, the algorithm iterates over predicates $\tau_P \in \mathcal{T}_P$ appearing in φ_{TSL} and times t and t' smaller than $m \cdot b$. For each of these elements, spuriousness is checked by comparing the output of π for the evaluation of τ_P at times t and t' , which should only differ, if the inputs to the predicates are different as well. This can only happen, if the passed input terms have been constructed differently over the past. We check it by using the evaluation function η equipped with the identity assignment $\langle \cdot \rangle_{\text{id}}: \mathbb{F} \rightarrow \mathbb{F}$, with $\langle \mathbf{f} \rangle_{\text{id}} = \mathbf{f}$ for all $\mathbf{f} \in \mathbb{F}$, and the input sequence ι_{id} , with $\iota_{\text{id}}(t)(\mathbf{i}) = (t, \mathbf{i})$ for all $t \in \mathbb{N}$ and $\mathbf{i} \in \mathbb{I}$, that always generates a fresh input. Syntactic inequality of $\eta_{\langle \cdot \rangle_{\text{id}}}(v, \iota_{\text{id}}, t, \tau_P)$ and $\eta_{\langle \cdot \rangle_{\text{id}}}(v, \iota_{\text{id}}, t', \tau_P)$ then is a sufficient condition for the existence of an assignment $\langle \cdot \rangle: \mathcal{T}_F \rightarrow \mathcal{F}$, for which τ_P evaluates differently at times t and t' .

If spurious behaviour of π could be found, then the revealing response $v \in \mathcal{C}^*$ is first simplified using **reduce**, which turns v back to a sequence of sets of updates $w \in (2^{\mathcal{T}_{U/\text{id}}})^*$ and removes updates that do not affect the behavior of τ_P at the times t and t' to accelerate the termination of the CEGAR loop.

Afterwards, the sequence w is turned into a new assumption that prohibits the found spurious behavior and, thus, further refines the LTL underapproximation.

As an example of this process, reconsider the spurious counter-strategy of Fig. 5c. Already after the first system response $\llbracket y \leftarrow x \rrbracket$, the environment produces an inconsistency by evaluating $\mathbf{p} \ x$ and $\mathbf{p} \ y$ differently. This is inconsistent, as the cell y holds the same value at time $t = 1$ as the input x at time $t = 0$. Using Algorithm 1 we generate the new assumption $\square(\llbracket y \leftarrow x \rrbracket \rightarrow (\mathbf{p} \ x \leftrightarrow \bigcirc \mathbf{p} \ y))$. After adding this strengthening the LTL synthesizer returns a realizability result.

Undecidability Although we can approximate the semantics of TSL with LTL, there are TSL formulas that cannot be expressed as LTL formulas of finite size.

Theorem 2. *The realizability problem of TSL is undecidable.*

Proof. We reduce an instance of the Post Correspondence Problem (PCP) [45], consisting of an alphabet Σ and sequences $w_0 w_1 \dots w_n, v_0 v_1 \dots v_n \in \Sigma^*$, to the realizability of a TSL formula φ . To this end, we fix some unary predicate $\mathbf{p} \in \mathbb{P}$, a unary function $\mathbf{f} \in \mathbb{F}$ for every alphabet symbol $f \in \Sigma$, and some 0-ary function $\mathbf{X} \in \mathbb{F}$. The system has no inputs \mathbb{I} , but two outputs $\mathbf{A} \in \mathbb{O}$ and $\mathbf{B} \in \mathbb{O}$.

Initially, we assign the signals \mathbf{A} and \mathbf{B} the constant value \mathbf{X} . From then on, we non-deterministically pick pairs (w_j, v_j) in every time step, as provided by the PCP instance, where every w_j and v_j is represented as a stacked composition of the corresponding alphabet functions. Our choice is stored in the signals \mathbf{A} and \mathbf{B} for w_j and v_j , respectively. Finally, we check that the sequences of function applications, constructed over time, are equal at some point, using the eventually operator \diamond and the universally quantified predicate \mathbf{p} to check for equality. \square

A more detailed version of the proof can be found in Appendix A.3. Also note that no inputs are used by the proof, which additionally shows that the “satisfiability” problem of TSL is undecidable as well.

6 TSL Synthesis

Our synthesis framework provides a modular refinement process to synthesize executables from TSL specifications, as depicted in Fig. 1. The user initially provides a TSL specification over predicate and function terms. At the end of the procedure, the user receives an executable to control a reactive system.

The first step of our method answers the synthesis question of TSL: if the specification is realizable, then a control flow model is returned. To this end, an intermediate translation to LTL is used, utilizing an LTL synthesis solver that produces circuits in the AIGER format. If the specification is realizable, the resulting control flow model is turned into Haskell code, which is implemented as an independent Haskell module. The user has the choice between two different targets: a module built on Arrows, which is compatible with any Arrowized FRP library, or a module built on Applicative, which supports Applicative FRP libraries. Our procedure generates a single Haskell module per TSL specification.

Fig. 6: Example CFM of the music player generated from a TSL specification.

This makes naturally decomposing a project according to individual tasks possible. Each module provides a single component, which is parameterized by their initial state and the pure function and predicate transformations. As soon as these are provided as part of the surrounding project context, a final executable can be generated by compiling the Haskell code.

An important feature of our synthesis approach is that implementations for the terms used in the specification are only required after synthesis. This allows the user to explore several possible specifications before deciding on any term implementations.

Control Flow Model The first step of our approach is the synthesis of a *Control Flow Model* \mathcal{M} (CFM) from the given TSL specification φ , which provides us with a uniform representation of the control flow structure of our final program. Formally, a CFM \mathcal{M} is a tuple $\mathcal{M} = (\mathbb{I}, \mathbb{O}, \mathbb{C}, V, \ell, \delta)$, where \mathbb{I} is a finite set of inputs, \mathbb{O} is a finite set of outputs, \mathbb{C} is a finite set of cells, V is a finite set of vertices, $\ell: V \rightarrow \mathbb{F}$ assigns a vertex a function $f \in \mathbb{F}$ or a predicate $p \in \mathbb{P}$, and

$$\delta: (\mathbb{O} \cup \mathbb{C} \cup V) \times \mathbb{N} \rightarrow (\mathbb{I} \cup \mathbb{C} \cup V \cup \{\perp\})$$

is a dependency relation that relates every output, cell, and vertex of the CFM with $n \in \mathbb{N}$ arguments, which are either inputs, cells, or vertices. Outputs and cells $s \in \mathbb{O} \cup \mathbb{C}$ always have only a single argument, i.e., $\delta(s, 0) \neq \perp$ and $\forall m > 0. \delta(s, m) \equiv \perp$, while for vertices $x \in V$ the number of arguments $n \in \mathbb{N}$ align with the arity of the assigned function or predicate $\ell(x)$, i.e., $\forall m \in \mathbb{N}. \delta(s, m) \equiv \perp \leftrightarrow m > n$. A CFM is valid if it does not contain circular dependencies, i.e., on every cycle induced by δ there must lie at least a single cell. We only consider valid CFMs.

An example CFM for our music player of Sec. 2 is depicted in Fig. 6. Inputs \mathbb{I} come from the left and outputs \mathbb{O} leave on the right. The example contains a single cell $c \in \mathbb{C}$, which holds the stateful memory `Cell`, introduced during synthesis for the module. The green, arrow shaped boxes depict vertices V , which are labeled with functions and predicates names, according to ℓ . For the Boolean decisions that define δ , we use circuit symbols for conjunction, disjunction, and negation. Boolean decisions are piped to a multiplexer gate that selects the respective update streams. This allows each update stream to be passed to an output stream if and only if the respective Boolean trigger evaluates positively, while our construction ensures mutual exclusion on the Boolean triggers. For code generation, the logic gates are implemented using the corresponding dedicated Boolean functions. After building a control structure, we assign semantics to functions and predicates by providing implementations. To this end, we use Functional Reactive Programming (FRP). Prior work has established Causal Commutative Arrows (CCA) as an FRP language pattern equivalent of a CFM [33,34,55]. CCAs are an abstraction subsumed by other functional reactive programming abstractions, such as Monads, Applicative and Arrows [33,32]. There are many FRP libraries using Monads [12,14,42], Applicative [1,2,22,49], or Arrows [10,39,41,52], and since every Monad is also an Applicative and Applicative/Arrows both are universal design patterns, we can give uniform translations to all of these libraries using translations to just Applicative and Arrows. Both translations are possible due to the flexible notion of a CFM.

In the last step, the synthesized FRP program is compiled into an executable, using the provided function and predicate implementations. This step is not fixed to a single compiler implementation, but in fact can use any FRP compiler (or library) that supports a language abstraction at least as expressive as CCA. For example, instead of creating an Android music player app, we could target an FRP web interface [49] to create an online music player, or an embedded FRP library [22] that allows us to directly instantiate the player on a computationally more restricted device. By using the strong core of CCA, we even can go down the whole chain and directly implement the player in hardware, which is for example possible with the CλaSH compiler [2]. Note that we still need to give separate implementations for the functions and predicates for each target. However, our specification and the synthesized CFM always stay the same.

7 Experimental Results

To evaluate our synthesis procedure we implemented a tool that follows the structure of Fig. 1. Our tool first encodes the given TSL specification in LTL and then refines it until an LTL solver either produces a realizability result or returns a counter-strategy that is non-spurious. For LTL synthesis we use the bounded synthesis tool BoSy [16]. As soon as we get a realizing strategy, given as a circuit, it is translated to a corresponding CFM. Then, we generate the FRP program structure. Finally, after providing function and predicate implementations the resulting program is compiled into an executable.

To demonstrate the effectiveness of synthesizing TSL, we applied our tool to a collection of benchmarks from different application domains, listed in Table 1. Every benchmark class consists of multiple specifications, addressing different features of TSL. We created all specifications from scratch, where we took care that they either relate to existing textual specifications, or real world scenarios. A short description of each benchmark class is given in Appendix A.4.

For every benchmark, we report the synthesis time and the size of the synthesized CFM, split into the number of cells ($|\mathcal{C}_{\mathcal{M}}|$) and vertices ($|\mathcal{V}_{\mathcal{M}}|$) used. The synthesized CFM may use more cells than the original TSL specification if synthesis requires more memory in order to realize a correct control flow. The synthesis was executed on a quad-core Intel Xeon processor (E3-1271 v3, 3.6GHz, 32 GB RAM, PC1600, ECC), running Ubuntu 64bit LTS 16.04.

The experiments of Table 1 show that TSL successfully lifts the applicability of synthesis from the Boolean data domain to arbitrary data domains, which allows for new applications that can utilize every level of required abstraction. For the benchmarks, we could always find a realizable system within a reasonable amount of time, where the solutions found often required synthesized cells to realize the underlying control flow behavior.

We also considered a preliminary set of benchmarks that require multiple refinement steps to be synthesizable. An overview of the results is given in Table 2. The benchmarks are inspired by examples of the Reactive Banana FRP library [1]. Here, purity of function and predicate applications must be utilized by the system to ensure that the value of one or two counters never goes out of range. Thereby, the system not only needs purity to verify this condition, but also to take the correct decisions in the resulting implementation to be synthesized.

8 Related Work

Synthesizing reactive programs has been explored in domains such as imperative programs over finite domains [35] and parallel execution strategies for sequential programs [4]. There have also been many alternatives to LTL for specifying properties of reactive systems, such as μ -calculus [31], Signal Temporal Logic [46], Ground Temporal Logic [11], and coalgebraic logics [7]. An example of a synthesis approach that integrates control and data is recent work on strategy synthesis for linear arithmetic games [15]. While reactive synthesis has focused on the complex control aspects of reactive systems, deductive and inductive synthesis has been concerned with the data transformation aspects in non-reactive and sequential programs [50,30,40,48,17,51]. Abstraction-based approaches to reactive synthesis [3,13,23,37] can be seen as a link between deductive and reactive synthesis. In terms of FRP, a Curry-Howard correspondence between LTL and FRP in a dependently typed language was discovered [27,28] and used to prove properties of FRP programs [8,29].

9 Conclusions

We have introduced Temporal Stream Logic, which allows the user to specify the control flow of a reactive program. The logic cleanly separates control from complex data, forming the foundation for our procedure to synthesize FRP programs. By utilizing the purity of function transformations our logic scales independently of the complexity of the data to be handled. While we have shown that scalability comes at the cost of undecidability, we addressed this issue by using a CEGAR loop, which lazily refines the underapproximation until either a realizing system implementation or an unrealizability proof is found.

TSL also provides the foundations for further extensions. For example, a user may want to fix the semantics for a partial set of functions and predicates to be utilized by the synthesis tool. Such additional refinements can be implemented as part of a much richer *TSL Modulo Theory* framework.

Our experiments indicate that TSL synthesis works well in practice and on a wide range of programming applications. In general, we hope the applications of this new logic and approach to reactive synthesis will stimulate further research into the scalable, real-world use of temporal logics for synthesis.

A Appendix

A.1 Specifying a Music Player in TSL

To demonstrate the simplicity of TSL, we illustrate the creation of a TSL specification for the music player Android app of Sec. 2. For the concrete implementation, we use the `MediaPlayer` class (MP) from the Android API, which provides functions to pause and play, as well as a predicate to check if music is currently playing or not. Specific to the Android OS, we receive signals when a user leaves or resumes the app. Specific to our particular app, we also use two buttons in the UI that deliver signals when a user presses play or pause.

In contrast to the FRP model, the Android system uses callback structures and functions have side effects, such as playing the music. Although the Android code is not using an FRP model, the theoretical foundations provided by FRP make embedding the synthesized control code a straightforward task.

Nevertheless, we need to consider that libraries used by the app and the surrounding android system carry their own state, which needs to be reflected within the model. To do so, we introduce a separate stream for each interface, which we assume to carry all the necessary state. We use the input stream `Sys` to receive system events and button presses, while the input stream `MP` provides us the interface to the `MediaPlayer` class. Updates to the `MediaPlayer` class are provided via its control interface `Ctrl`. This allows us to embed the synthesized program into any larger context to manipulate the music player. We cannot use the same name for input and output here, as we would miss state changes that could be made by a component plugged after this, which is a specific result of the clear modularization utilized within CCA. This is also why we do not need a separate system output here, as we only receive signals from the system. Finally, we also utilize the input stream `Tr`, which provides us with the currently selected music track.

We partition the individual properties of the specification into two categories: assumptions A and guarantees G . The final specification then results from their implication: $\bigwedge_{\vartheta \in A} \vartheta \rightarrow \bigwedge_{\psi \in B} \psi$. Our specification uses the following signals, function terms and predicates:

$$\begin{aligned} \mathbb{I} &= \{ \text{MP}, \text{Sys}, \text{Tr} \} \\ \mathbb{O} &= \{ \text{Ctrl} \} \\ \mathbb{C} &= \{ \text{Ctrl} \} \\ \mathcal{T}_P &= \{ \text{musicPlaying}, \text{pauseButton}, \text{playButton}, \text{leaveApp}, \text{resumeApp} \} \\ \mathcal{T}_F &= \mathcal{T}_P \cup \{ \text{pause}, \text{play}, \text{trackPos} \} \end{aligned}$$

The function `pause m` pauses a played track on the passed music player stream m . The function `play t p` plays the selected track t at the given track position p . The track position is carried by the music player stream, and can be extracted using the function `trackPos`. In our model, `play` resets any state that is passed by MP, while `pause` does not. The predicate `musicPlaying` checks whether music

is playing on a music player stream, while the remaining predicates check the respective conditions from the surrounding android system.

Assumptions. We start with straightforward assumptions about the user interface. In our model, we assume that the pause and play buttons cannot be pressed at the same time. Also, from the Android OS behavior, we know the app cannot leave and resume at the same time.

$$\Box \neg(\text{playButton Sys} \wedge \text{pauseButton Sys}) \quad (\text{A1})$$

$$\Box \neg(\text{leaveApp Sys} \wedge \text{resumeApp Sys}) \quad (\text{A2})$$

Again from the Android OS, once a user has left the app it is not possible to press the play or pause buttons until the user resumes the app.

$$\Box \left(\text{leaveApp Sys} \rightarrow \left((\neg \text{playButton Sys} \wedge \neg \text{pauseButton Sys}) \mathcal{W} \text{resumeApp Sys} \right) \right) \quad (\text{A3})$$

We use the `musicPlaying` predicate to monitor changes according to the play and pause actions. Technically, `musicPlaying` is not necessary to specify correct behavior - we could remember the music playing state on a separate looping stream. However, the method is provided by the `MediaPlayer` interface and it helps to improve readability, which is why we also use it for our the specification. To obtain a correct behavior, we do not need to mimic the full behavior of the method's implementation. It suffices to specify the behavior with respect to the pause and play actions.

$$\Box \left(U_{\text{play}} \rightarrow \bigcirc (\text{musicPlaying MP} \mathcal{W} U_{\text{pause}}) \right) \quad (\text{A4})$$

$$\Box \left(U_{\text{pause}} \rightarrow \bigcirc (\neg \text{musicPlaying MP} \mathcal{W} U_{\text{play}}) \right) \quad (\text{A5})$$

We use U_{play} as a shortcut for $\llbracket \text{Ctrl} \leftarrow \text{play Tr} (\text{trackPos MP}) \rrbracket$ and U_{pause} as a shortcut for $\llbracket \text{Ctrl} \leftarrow \text{pause MP} \rrbracket$.

Guarantees. To specify the desired behavior of our app under the given assumptions, we define the following TSL guarantees. First, whenever the user presses one of the buttons in the app, the output signal has to take the corresponding action. This desired behavior is what necessitates the assumption that both buttons cannot be pressed at the same time. Removing the assumption that both buttons cannot be pressed at the same time would require to relax these guarantees.

$$\Box (\text{playButton Sys} \rightarrow U_{\text{play}}) \quad (\text{G1})$$

$$\Box (\text{pauseButton Sys} \rightarrow U_{\text{pause}}) \quad (\text{G2})$$

The only way that the music can be paused is either by the user leaving the app or pressing pause. In the latter case, the music should not start playing again until either the user resumes the app or presses play.

$$\Box (U_{\text{pause}} \rightarrow (\text{leaveApp Sys} \vee \text{pauseButton Sys})) \quad (\text{G3})$$

$$\Box (\text{leaveApp Sys} \rightarrow (\neg U_{\text{play}} \mathcal{W} \text{resumeApp Sys})) \quad (\text{G4})$$

$$\Box (\text{pauseButton Sys} \rightarrow (\neg U_{\text{play}} \mathcal{W} \text{playButton Sys})) \quad (\text{G5})$$

The last two parts of the specification were already introduced in the motivating example. If the music is playing, the music should pause when leaving the app and start playing again when returning to the app.

$$\square (\text{musicPlaying MP} \wedge \text{leaveApp Sys} \rightarrow U_{\text{pause}}) \quad (\text{G6})$$

$$\square (\text{musicPlaying MP} \wedge \text{leaveApp Sys} \rightarrow ((\text{pauseButton Sys} \vee U_{\text{play}}) \mathcal{A} \text{resumeApp Sys})) \quad (\text{G7})$$

Note that in contrast to Sec. 2 we also test for the `event(pauseButton)` in guarantee Eq. (G7). This is necessary, since the specification would be unrealizable otherwise, as revealed by our synthesis tool. Indeed, the user may be smart enough to immediately pause the music when resuming the app, in which case it should not be played again.

A.2 Proof of Thm. 1

Proof. Assume φ_{LTL} is realizable. Then there exists a winning strategy $\sigma: (2^{\mathcal{T}_P})^+ \rightarrow 2^{\mathcal{T}_{U/id}}$ for the system player in the underlying LTL realizability game. Assume for the sake of contradiction that φ_{TSL} is not realizable. Then there exists in input $\iota \in \mathcal{I}^\omega$ and a function assignment $\langle \cdot \rangle: \mathcal{T}_F \rightarrow \mathcal{F}$ such that for all $\kappa: \mathcal{I}^+ \rightarrow \mathcal{C}$ we have that $\kappa \lambda \iota, \iota, \not\models_{\langle \cdot \rangle} \varphi_{TSL}$. We inductively construct the input sequence $\nu \in (2^{\mathcal{T}_P})^\omega$ and the computation $\varsigma \in \mathcal{C}^\omega$ over $t \in \mathbb{N}$ as follows:

$$\begin{aligned} \nu(t) &= \{\tau_P \in \mathcal{T}_P \mid \eta_{\langle \cdot \rangle}(\varsigma, \iota, t, \tau_P)\} \\ \varsigma(t)(\mathbf{s}) &= \tau_F, \quad \text{where } \tau_F \text{ is the unique element} \\ &\quad \text{such that } \llbracket \mathbf{s} \leftarrow \tau_F \rrbracket \in \sigma(\nu(0)\nu(1)\dots\nu(t)) \end{aligned}$$

Note that τ_F must be unique, due to the additional constraint

$$\square \left(\bigwedge_{\mathbf{s} \in \mathcal{O}} \bigvee_{\tau \in \mathcal{T}_{U/id}^{\mathbf{s}}} (\tau \wedge \bigwedge_{\tau' \in \mathcal{T}_{U/id}^{\mathbf{s}} \setminus \{\tau\}} \neg \tau') \right)$$

introduced in the underapproximation. Furthermore, also note that ν and ς are well-defined, since $\eta_{\langle \cdot \rangle}(\varsigma, \iota, t, \tau_P)$ only considers values of ς at previous times $t' < t$. Since φ_{LTL} is realizable, we have that $\sigma \lambda \nu, \nu \models \varphi_{LTL}$ ⁴, but at the same time $\varsigma, \iota \not\models_{\langle \cdot \rangle} \varphi_{TSL}$ by the unrealizability of φ_{TSL} . We show that this is contradictory via a structural induction over the structure of φ_{TSL} for all $t \in \mathbb{N}$:

– Case $\varphi_{TSL} = \tau_P$:

$$\begin{aligned} &\varsigma, \iota, t \models_{\langle \cdot \rangle} \tau_P \\ \Leftrightarrow &\eta_{\langle \cdot \rangle}(\varsigma, \iota, t, \tau_P) \\ \Leftrightarrow &\tau_P \in \nu(t) \\ \Leftrightarrow &\sigma \lambda \nu, \nu, t \models \text{SYNTACTICCONVERSION}(\tau_P) \end{aligned}$$

⁴ For a suitable definition for the semantics of \models consider for example [19].

– Case $\varphi_{TSL} = \llbracket \mathbf{s} \leftarrow \tau_F \rrbracket$:

$$\begin{aligned}
& \varsigma, \iota, t \models_{\langle \rangle} \llbracket \mathbf{s} \leftarrow \tau_F \rrbracket \\
& \Leftrightarrow \varsigma(t)(\mathbf{s}) = \tau_F \\
& \Leftrightarrow \llbracket \mathbf{s} \leftarrow \tau_F \rrbracket \in \sigma(\nu(0)\nu(1)\dots\nu(t)) \\
& \Leftrightarrow \sigma\lambda\nu, \nu, t \models \text{SYNTACTICCONVERSION}(\llbracket \mathbf{s} \leftarrow \tau_F \rrbracket)
\end{aligned}$$

– Case $\varphi_{TSL} = \neg\psi$:

$$\begin{aligned}
& \varsigma, \iota, t \models_{\langle \rangle} \neg\psi \\
& \Leftrightarrow \varsigma, \iota, t \not\models_{\langle \rangle} \psi \\
& \stackrel{IH}{\Leftrightarrow} \sigma\lambda\nu, \nu, t \not\models \text{SYNTACTICCONVERSION}(\psi) \\
& \Leftrightarrow \sigma\lambda\nu, \nu, t \models \text{SYNTACTICCONVERSION}(\neg\psi)
\end{aligned}$$

– Case $\varphi_{TSL} = \vartheta \wedge \psi$:

$$\begin{aligned}
& \varsigma, \iota, t \models_{\langle \rangle} \vartheta \wedge \psi \\
& \Leftrightarrow \varsigma, \iota, t \models_{\langle \rangle} \vartheta \wedge \varsigma, \iota, t \models_{\langle \rangle} \psi \\
& \stackrel{IH}{\Leftrightarrow} \sigma\lambda\nu, \nu, t \models \text{SYNTACTICCONVERSION}(\vartheta) \wedge \sigma\lambda\nu, \nu, t \models \text{SYNTACTICCONVERSION}(\psi) \\
& \Leftrightarrow \sigma\lambda\nu, \nu, t \models \text{SYNTACTICCONVERSION}(\vartheta \wedge \psi)
\end{aligned}$$

– Case $\varphi_{TSL} = \circ\psi$:

$$\begin{aligned}
& \varsigma, \iota, t \models_{\langle \rangle} \circ\psi \\
& \Leftrightarrow \varsigma, \iota, t+1 \models_{\langle \rangle} \psi \\
& \stackrel{IH}{\Leftrightarrow} \sigma\lambda\nu, \nu, t+1 \models \text{SYNTACTICCONVERSION}(\psi) \\
& \Leftrightarrow \sigma\lambda\nu, \nu, t \models \text{SYNTACTICCONVERSION}(\circ\psi)
\end{aligned}$$

– Case $\varphi_{TSL} = \vartheta \mathcal{U} \psi$:

$$\begin{aligned}
& \varsigma, \iota, t \models_{\langle \rangle} \vartheta \mathcal{U} \psi \\
& \Leftrightarrow \exists t'' \geq t. \forall t \leq t' < t''. \varsigma, \iota, t' \models_{\langle \rangle} \vartheta \wedge \varsigma, \iota, t'' \models_{\langle \rangle} \psi \\
& \stackrel{IH}{\Leftrightarrow} \exists t'' \geq t. \forall t \leq t' < t''. \\
& \quad \sigma\lambda\nu, \nu, t' \models \text{SYNTACTICCONVERSION}(\vartheta) \wedge \\
& \quad \sigma\lambda\nu, \nu, t'' \models \text{SYNTACTICCONVERSION}(\psi) \\
& \Leftrightarrow \sigma\lambda\nu, \nu, t \models \text{SYNTACTICCONVERSION}(\vartheta \mathcal{U} \psi) \quad \square
\end{aligned}$$

A.3 Extended proof of Thm. 2

Proof. We give a reduction from the Post Correspondence Problem (PCP). Given two finite lists $w_0w_1\dots w_n$ and $v_0v_1\dots v_n$ of equal length, each containing n finite words over some finite alphabet Σ , is there some finite sequence

$i_0 i_1 \dots i_k \in \mathbb{N}^*$ such that $w_{i_0} w_{i_1} \dots w_{i_k} = v_{i_0} v_{i_1} \dots v_{i_k}$. The problem is undecidable [45]. We reduce PCP to the realizability question of TSL, where we translate an arbitrary instance of PCP to a TSL formula φ , which is realizable if and only if there is a solution to the PCP instance. To this end, let $n \in \mathbb{N}$, $w_0 w_1 \dots w_n \in \Sigma^*$ and $v_0 v_1 \dots v_n \in \Sigma^*$ be given. We fix $\mathbb{P} = \{\mathbf{p}\}$ for some unary predicate p , $\mathbb{F} = \mathbb{P} \cup \Sigma \cup \{\mathbf{X}\}$, where every $\mathbf{f} \in \Sigma$ corresponds to a unary function and \mathbf{X} corresponds to a 0-nary function, $\mathbb{I} = \emptyset$, $\mathbb{O} = \{\mathbf{A}, \mathbf{B}\}$, and $\mathbb{C} = \mathbb{O}$. We define φ via:

$$\begin{aligned} \varphi = & \left(\llbracket \mathbf{A} \leftarrow \mathbf{X}() \rrbracket \wedge \llbracket \mathbf{B} \leftarrow \mathbf{X}() \rrbracket \right) \wedge \\ & \bigcirc \square \left(\bigvee_{j=0}^n (\llbracket \mathbf{A} \leftarrow \mu(w_j, \mathbf{A}) \rrbracket \wedge \llbracket \mathbf{B} \leftarrow \mu(v_j, \mathbf{B}) \rrbracket) \right) \wedge \\ & \bigcirc \bigcirc \diamond (\mathbf{p} \mathbf{A} \leftrightarrow \mathbf{p} \mathbf{B}) \end{aligned}$$

where $\mu(x_0 x_1 \dots x_m, s) = x_0 (x_1 (\dots (x_m s) \dots))$.

Intuitively, we first assign the signals \mathbf{A} and \mathbf{B} a constant base value. Then, from the next time step on, we have to pick pairs (w_j, v_j) in every time step. Our choice is stored in the signals \mathbf{A} and \mathbf{B} , respectively. Finally, we check that the constructed sequences of function applications are equal at some point in time, where we use the universally quantified predicate \mathbf{p} to check for equality.

The TSL formula φ is realizable if and only if there is an index sequence $i_0 i_1 \dots i_k$ such that $w_{i_0} w_{i_1} \dots w_{i_k} = v_{i_0} v_{i_1} \dots v_{i_k}$:

“ \Rightarrow ”: Assume that φ is realizable, i.e., there is some strategy $\sigma: \mathcal{I}^* \rightarrow \varsigma$ that satisfies φ for $\iota = \emptyset^\omega$ and all possible choices of $\langle \cdot \rangle: \mathbb{F} \rightarrow \mathcal{F}$. We fix $\langle \text{init}_{\mathbf{A}} \rangle = \langle \text{init}_{\mathbf{B}} \rangle = \langle \mathbf{X} \rangle = \varepsilon$ and $\langle x \rangle: \Sigma^* \rightarrow \Sigma^*$ with $\langle x \rangle w = wx$ for all $w \in \Sigma^*$ and $x \in \Sigma$. We do not fix any assignment to \mathbf{p} . Nevertheless, by the realizability of φ , there is a position $m > 1$ at which $\mathbf{p} \mathbf{A} \leftrightarrow \mathbf{p} \mathbf{A}$ is satisfied, independent of the predicate assigned to \mathbf{p} . We obtain that $\eta_{\langle \cdot \rangle}(\sigma \upharpoonright \iota, \iota, m, \mathbf{A}) = \eta_{\langle \cdot \rangle}(\sigma \upharpoonright \iota, \iota, m, \mathbf{B})$, since otherwise there would be a predicate that detects the difference. As there is no other influence on $\sigma \upharpoonright \iota \in \mathcal{C}^\omega$, depending on the choice of \mathbf{p} , we obtain that the semantics of $\varrho_{\langle \cdot \rangle, \varsigma, \iota} \in \mathcal{O}^\omega$

$$\begin{aligned} \varrho_{\langle \cdot \rangle, \varsigma, \iota} = & \{ \varrho_{\langle \cdot \rangle, \varsigma, \iota}(0)(\mathbf{A}) \mapsto a_0, \varrho_{\langle \cdot \rangle, \varsigma, \iota}(0)(\mathbf{B}) \mapsto b_0 \} \\ & \{ \varrho_{\langle \cdot \rangle, \varsigma, \iota}(1)(\mathbf{A}) \mapsto a_1, \varrho_{\langle \cdot \rangle, \varsigma, \iota}(1)(\mathbf{B}) \mapsto b_1 \} \\ & \dots \end{aligned}$$

are well defined (even without fixing \mathbf{p}) and induce the sequences $a_0 a_1 \dots \in \Sigma^\omega$ and $b_0 b_1 \dots \in \Sigma^\omega$. First, we observe that $a_0 = a_1 = b_0 = b_1 = \varepsilon$ by the definition of φ and the choice of the initialization functions and $\langle \cdot \rangle$. From the choice of $\langle \cdot \rangle$, we also obtain that $a_t = a_{t-1} w_{i_t}$ and $b_t = b_{t-1} v_{i_t}$ for every $t > 1$ and some $0 \leq i_t \leq n$. A simple induction shows that every $a_t = w_{i_2} w_{i_3} \dots w_{i_t}$ and $b_t = v_{i_2} v_{i_3} \dots v_{i_t}$ for every $t > 1$. It follows that $w_{i_2} w_{i_3} \dots w_{i_{m-1}} = v_{i_2} v_{i_3} \dots v_{i_m}$ from equality of a_m and b_m at position m . This concludes this part of the proof, since we have that $i_2 i_3 \dots i_m$ is a solution for the PCP instance.

“ \Leftarrow ”: Now, assume that there is a solution $i_0 i_1 \dots i_k$ to the PCP instance. Since $\mathbb{I} = \emptyset$ it suffices to construct the computation $\varsigma = c_0 c_1 \dots$

with $c_0(\mathbf{A}) = c_0(\mathbf{B}) = \mathbf{X}()$ and for all $t > 0$: $c_t(\mathbf{A}) = \mu(w_{(t-1) \bmod (k+1)}, \mathbf{A})$ and $c_t(\mathbf{B}) = \mu(w_{(t-1) \bmod (k+1)}, \mathbf{B})$. It is straightforward to see that ς satisfies $\llbracket \mathbf{A} \leftarrow \mathbf{X} \rrbracket$, $\llbracket \mathbf{B} \leftarrow \mathbf{X} \rrbracket$ and

$$\square \square \left(\bigvee_{j=0}^n (\llbracket \mathbf{A} \leftarrow \mu(w_j, \mathbf{A}) \rrbracket \wedge \llbracket \mathbf{B} \leftarrow \mu(v_j, \mathbf{B}) \rrbracket) \right).$$

Thus, it just remains to argue that ς satisfies $\square \square \diamond (\mathbf{p} \mathbf{A} \leftrightarrow \mathbf{p} \mathbf{B})$. To this end, let $j_0 j_1 \dots = (i_0 i_1 \dots i_k)^\omega$. Then a simple induction shows that

$$\varrho_{\langle \cdot \rangle, \varsigma, \iota}(t)(\mathbf{A}) = \eta_{\langle \cdot \rangle}(\varsigma, \iota, t, \mu(w_{j_0} w_{j_1} \dots w_{j_{t-2}}, \mathbf{X}))$$

and $\varrho_{\langle \cdot \rangle, \varsigma, \iota}(t)(\mathbf{B}) = \eta_{\langle \cdot \rangle}(\varsigma, \iota, t, \mu(v_{j_0} v_{j_1} \dots v_{j_{t-2}}, \mathbf{X}))$ for all $t > 1$, $\iota = \emptyset^\omega$, and all choices of $\langle \cdot \rangle$. Now, consider that especially for $t = k + 2$ we have that

$$\begin{aligned} w_{j_0} w_{j_1} \dots w_{j_{t-2}} &= w_{i_0} w_{i_1} \dots w_{i_k} \\ &= v_{i_0} v_{i_1} \dots v_{i_k} \\ &= v_{j_0} v_{j_1} \dots v_{j_{t-2}} \end{aligned}$$

and, thus, also $\varrho_{\langle \cdot \rangle, \varsigma, \iota}(k + 2)(\mathbf{A}) = \varrho_{\langle \cdot \rangle, \varsigma, \iota}(k + 2)(\mathbf{B})$, independent of the choice of $\langle \cdot \rangle$. As this implies that $p(\varrho_{\langle \cdot \rangle, \varsigma, \iota}(k + 2)(\mathbf{A})) = p(\varrho_{\langle \cdot \rangle, \varsigma, \iota}(k + 2)(\mathbf{B}))$ for any unary predicate $p \in \mathcal{P}$, it proves that ς satisfies $\mathbf{p} \mathbf{A} \leftrightarrow \mathbf{p} \mathbf{B}$ at position $k + 2$. Hence, the computation ς also satisfies $\square \square \diamond (\mathbf{p} \mathbf{A} \leftrightarrow \mathbf{p} \mathbf{B})$, which concludes the proof. \square

Note that we do not use any inputs to encode the PCP instance in the proof above. As a consequence, it immediately follows that the satisfiability problem of TSL is undecidable as well.

A.4 Other Benchmarks

Escalator As an illustrative example of the logic, we build up the specification of an escalator controller. To this end, we first commit to the following physical model. To interact with the environment the escalator is equipped with a motor, which moves its steps either up, down, or is turned off. To observe the environment, it additionally can read from two sensors, at the bottom and at the top, that reliably detect whenever somebody enters or exists. To program the controller, we receive the inputs of the sensors via two input signals: `bottom` and `top`. The steps are controlled via the output signal: `steps`. We start with a simple, non-reactive version that continuously moves up. This behavior is described via:

$$\square \llbracket \mathbf{steps} \leftarrow \text{MOVEUP}() \rrbracket$$

Note that we use `MOVEUP()` as a 0-ary function here, as the command does not depend on any other given signal. However, for a concrete system, we instead would replace it with the matching library call (including possible static parameters), that passes the movement command to the motor's driver. Nevertheless, reflecting these details here would go beyond the scope of this illustration.

Next, let us make our escalator reactive, in the sense that it only moves up, if there is actually somebody on it, using it. A first specification looks as follows:

$$\square \left(\left((\text{enterEvent bottom} \wedge \neg \text{exitEvent top}) \leftrightarrow \llbracket \text{steps} \leftarrow \text{MOVEUP}() \rrbracket \right) \wedge \right. \\ \left. \left((\text{exitEvent top} \wedge \neg \text{enterEvent bottom}) \leftrightarrow \llbracket \text{steps} \leftarrow \text{STOP}() \rrbracket \right) \right)$$

While this specification is realizable, it also turns out to be incomplete. The elevator stops as soon as the first user leaves it at the top, but there still may be other users behind.

A short inspection reveals that we cannot solve this problem via purely reacting to the given inputs. Instead, we need to introduce a counter (used as an internal signal), which keeps track of the users on the escalator. Hence, we change the previous specification into

$$\square \left(\left((\text{enterEvent bottom} \wedge \neg \text{exitEvent top}) \leftrightarrow \llbracket \text{users} \leftarrow (+) \text{ users } 1 \rrbracket \right) \wedge \right. \\ \left. \left((\text{exitEvent top} \wedge \neg \text{enterEvent bottom}) \leftrightarrow \llbracket \text{users} \leftarrow (+) \text{ users } (-1) \rrbracket \right) \right)$$

With this change, it only remains to start and stop the escalator whenever the number of users toggles between zero and non-zero:

$$\square \left(\left(((=) \text{ users } 0 \wedge \bigcirc \neg ((=) \text{ users } 0)) \leftrightarrow \bigcirc \llbracket \text{steps} \leftarrow \text{MOVEUP}() \rrbracket \right) \right. \\ \left. \left((\neg ((=) \text{ users } 0) \wedge \bigcirc ((=) \text{ users } 0)) \leftrightarrow \bigcirc \llbracket \text{steps} \leftarrow \text{STOP}() \rrbracket \right) \right)$$

In conjunction with the previous part, we obtain a complete description of a reactive escalator, which we can use to synthesize a respective FPP program. The result not only satisfies the specification, but also is immediately executable on the controller (after compilation).

Note that we can easily extend our specification, by adding even more properties. This is possible without changing the previous parts at all. For example, consider an alarm, that is activated whenever there are too many users on the escalator. Another variant would be a smart version, which moves up and down, triggered by the entrance point of the next user whenever the system is idle. For the sake of illustration of these statements, we give a possible realization of the second variant in the sequel.

We present the specification of a smart escalator, which is able to move into both directions: up and down. Thereby, the direction is determined by the entrance point of the first user entering the escalator when it is empty. If the escalator already moves into a specific direction, we ignore enter and exit events into the opposite direction until it stopped again. The specification $\varphi = \square \psi \rightarrow \bigwedge_{j=0}^7 \square \vartheta_j$ consists of:

$$\begin{aligned}
\psi &= \neg((==) \text{ steps } \text{MOVEDOWN}()) \wedge (==) \text{ steps } \text{MOVEUP}() \wedge \\
&\quad \neg(\text{enterEvent top} \wedge \text{exitEvent top}) \wedge \\
&\quad \neg(\text{enterEvent bottom} \wedge \text{exitEvent bottom}) \\
\vartheta_0 &= ((\text{enterEvent bottom} \wedge \neg \text{exitEvent top} \wedge \neg((==) \text{ steps } \text{MOVEDOWN}())) \vee \\
&\quad (\text{enterEvent top} \wedge \neg \text{exitEvent bottom} \wedge \neg((==) \text{ steps } \text{MOVEUP}()))) \\
&\quad \leftrightarrow \llbracket \text{users} \leftarrow (+) \text{ users } 1 \rrbracket \\
\vartheta_1 &= ((\text{exitEvent top} \wedge \neg \text{enterEvent bottom} \wedge \neg((==) \text{ steps } \text{MOVEDOWN}())) \vee \\
&\quad (\text{exitEvent bottom} \wedge \neg \text{enterEvent top} \wedge \neg((==) \text{ steps } \text{MOVEUP}()))) \\
&\quad \leftrightarrow \llbracket \text{users} \leftarrow (+) \text{ users } (-1) \rrbracket \\
\vartheta_2 &= \llbracket \text{steps} \leftarrow \text{MOVEUP}() \rrbracket \\
&\quad \rightarrow (==) \text{ users } 0 \wedge \text{enterEvent bottom} \\
\vartheta_3 &= \llbracket \text{steps} \leftarrow \text{MOVEDOWN}() \rrbracket \\
&\quad \rightarrow (==) \text{ users } 0 \wedge \text{enterEvent top} \\
\vartheta_4 &= (==) \text{ users } 0 \wedge \text{enterEvent bottom} \wedge \neg \text{enterEvent top} \\
&\quad \rightarrow \llbracket \text{steps} \leftarrow \text{MOVEUP}() \rrbracket \\
\vartheta_5 &= (==) \text{ users } 0 \wedge \text{enterEvent top} \wedge \\
&\quad \neg \text{enterEvent bottom} \rightarrow \llbracket \text{steps} \leftarrow \text{MOVEDOWN}() \rrbracket \\
\vartheta_6 &= (==) \text{ users } 0 \wedge \text{enterEvent top} \wedge \text{enterEvent bottom} \\
&\quad \rightarrow (\llbracket \text{steps} \leftarrow \text{MOVEUP}() \rrbracket \vee \llbracket \text{steps} \leftarrow \text{MOVEDOWN}() \rrbracket) \\
\vartheta_7 &= \neg((==) \text{ users } 0) \wedge \text{O}((==) \text{ users } 0 \wedge \neg \text{enterEvent top} \wedge \neg \text{enterEvent bottom}) \\
&\quad \leftrightarrow \llbracket \text{steps} \leftarrow \text{STOP} \rrbracket
\end{aligned}$$

FRPZoo A special role is played by the FRPZoo benchmark set, which refers to a standard online benchmark suite, designed to compare FRP library language designs [20]. The specification separates between three different behaviors, given as scenarios 0, 5, and 10. In every scenario, two buttons can be clicked: a “click count” button, which counts the number of clicks, and a “toggle” button, which toggles the enable/disable state of the “click count” button. The value of the counter is displayed via some output interface. The three scenarios differ with respect to the exact conditions of when the counter is updated, reset or displayed.

Haskell-TORCS The Haskell-TORCS benchmarks synthesize controllers for an autonomous vehicle. Our specifications build upon the example of the Haskell-TORCS bindings for building FRP controllers [18] in The Open Race Car Simulator (TORCS) [54]. The bindings are also used to run the synthesized implementations within the simulator. Autonomous vehicles use limited sensor data

about the environment (*e.g.* the distance to nearest obstacle) to control actuators in the car (*e.g.* the steering wheel). The Haskell-TORCS set of benchmarks synthesize a controller from TSL specifications where the sensors and actuators are the input and output signals respectively. The functions used in the TSL specifications for the Haskell-TORCS benchmarks, for example “slowDown” or “turnLeft”, are implemented after the controller synthesis process. In this way, we obtain a guarantee on the larger behavior of the system, while still allowing numerically sensitive, data level manipulations, to be optimized as required by the application.

The first “simple” Haskell-TORCS controller combines simple functions without states. The “advanced” controllers included more detailed planning behavior when approaching a turn. The specifications are also modular, in the sense that control of the steering wheel and control of the gears are given separate specifications, and combined into a single FRP program after synthesis.

Counters The benchmarks of Table 2 consider a user interface that allows to increment either one or two counters while at the same time ensuring that each counter stays in range, as restricted by predicate. The benchmarks are inspired by examples of the Reactive Banana FRP library [1], which can be found under <https://wiki.haskell.org/Reactive-banana/Examples>. The benchmarks work on a small interface, over which the user can increment or decrement one or two counters. In the two counter case, he or she can switch between the counters using an additional toggling input.

In the simple variant, the system only must ensure that each counter stays in range, where it is allowed to ignore an increment or decrement request from the user, if this could produce a counter value out of range. In the more advanced variant, we also assume the existence of a graphical interface, where the inputs are realized via pressing different buttons. Here, the synthesizer can only avoid an increment of the user by disabling a button before pressing it could lead to an out of range update. For all benchmarks, the synthesizer must utilize purity of the increment / decrement operation to test early enough whether the environment could produce an out of range value to prevent this either by ignoring the input or by disabling the corresponding buttons.
