Optimal Streaming Erasure Codes over the Three-Node Relay Network

Silas L. Fong, Ashish Khisti, Baochun Li, Wai-Tian Tan, Xiaoqing Zhu, and John Apostolopoulos

Abstract

This paper investigates low-latency streaming codes for a three-node relay network. The source transmits a sequence of messages (a streaming source) to the destination through the relay between them, where the first-hop channel from the source to the relay and the second-hop channel from the relay to the destination are subject to packet erasures. Every source message must be recovered perfectly at the destination subject to a fixed decoding delay. We assume the following packet loss model for each of the two channels: A fixed number of erasures exist on the discrete timeline. Under this channel loss assumption, we fully characterize the maximum achievable rate. The lower bound is proved by using a symbol-wise decode-forward strategy where the source symbols within the same message are decoded by the relay with different delays. The upper bound is proved by analyzing the maximum achievable rate for each channel when the erasures in the other channel are consecutive (bursty). In addition, we show that message-wise decode-forward strategies, which require the source symbols within the same message to be decoded by the relay with the same delay, are sub-optimal in general.

Forward error correction, maximum achievable rate, message-wise decode-forward, packet erasures, streaming, symbol-wise decode-forward, three-node relay network.

1 INTRODUCTION

Real-time video streaming is an essential component for many ultra-reliable and low-latency applications over the Internet including high-definition video conferencing, augmented/virtual reality, and online gaming. Service providers for real-time video streaming are typically hosted in a public cloud, with multiple server instances running within geographically distributed data centers. Providers of public cloud service include Google Cloud, Amazon CloudFront and Microsoft Azure, who have their own cloud content delivery networks (CDN) to support high-throughput and low-latency communications. It was recently forecasted by Cisco [1] that 77 percent of all Internet video traffic will cross CDNs by 2021, up from 67 percent in 2016.

The data centers within the same cloud are distributed across the continents, and there may not exist a direct link between two data centers which are far away from each other. For example, there is no direct link between Europe and Australia due to the absence of a direct optical fiber connection. Consider a simple relaying scenario within a cloud where a data center transmits streaming messages to another data center through an
intermediate data center or other network node [2]. The simple relaying scenario can be modeled as a source transmitting streaming messages to a destination over a three-node relay network with no direct link between the source node and the destination node. In this paper, we focus on the three-node relay network model and investigate the performance of streaming codes over the three-node network.

There are two main approaches for implementing error control over the Internet at the physical layer and the network layer: Automatic repeat request (ARQ) and forward error correction (FEC). Both ARQ and FEC can alleviate the damages of packet losses that may be caused by unreliable wireless links or congestion at network bottlenecks. However, ARQ schemes are not suitable for real-time streaming applications that involve arbitrary global users because each retransmission may incur an extra round-trip delay which may be intolerable. Specifically, correcting an erasure using ARQ results in a 3-way delay (forward + backward + forward), and this aggregate (3-way) delay including transmission, propagation and processing delays is required to be lower than 150 ms for interactive applications such as voice and video according to the International Telecommunication Union [3], [4]. This aggregate delay makes ARQ impractical for communication between two distant global users with aggregate delay larger than 150 ms (even if the signals travel at the speed of light, the minimum possible aggregate delay between two diametrically opposite points on the earth’s circumference is at least 200 ms [5]).

On the contrary, FEC schemes are amenable to low-latency communications among global users because no retransmission is required. Instead of using retransmissions to achieve high reliability, FEC schemes increase the correlation among the transmitted symbols by adding redundant information. Then, any erased packet may be reconstructed by the redundant information in the subsequent surviving packets. Therefore, we investigate only FEC schemes for the three-node relay network in quest of the highest coding rate.

1.1 Related Work
Low-density parity-check (LDPC) and digital fountain codes are two traditional FEC schemes [6], [7] that are recommended in the Internet Engineering Task Force’s real-time transport protocol profiles for non-interactive streaming applications. These codes operate over long block lengths, typically a few thousand symbols, and are thus suitable for applications in which the delay constraints are not stringent. However, LDPC and fountain codes are not suitable for interactive streaming applications where short block lengths (e.g., a few hundred symbols) are required due to the stringent delay constraints.

On the other hand, low-latency FEC schemes which operate over short block lengths are used in existing consumer video chat applications (e.g., Skype), which typically transmit an extra parity-check packet per every two to five packets [8]. Indeed, the use of low-latency FEC schemes for protecting voice streams against packet erasures largely attributed to the success of Skype [9]. Recently, several systematic studies have been carried out to investigate the fundamental limits of low-latency FEC schemes for a point-to-point packet erasure channel [10], [11], [12], [13], [14], [15], [16]. Motivated by the simple relaying scenario described at the beginning of this paper, we perform the first systematic study which analyzes the fundamental limits of low-latency FEC schemes for the three-node relay network.
1.2 System Model

We consider the network model as illustrated in Figure 1. A formal description will appear later in Section 2. The three-node relay network consists of a source, a destination and a relay between them, which are denoted by $s$, $d$ and $r$ respectively. The channel between node $s$ and node $r$ is denoted by $(s, r)$, and the channel between node $r$ and node $d$ is denoted by $(r, d)$. In each time slot, node $s$ chooses a collection of $k$ symbols destined for node $d$ and encodes the $k$ symbols into a collection of $n$ symbols followed by transmitting the $n$ symbols through $(s, r)$. The collection of $n$ symbols transmitted in a time slot are either received perfectly by node $r$ or erased (lost). In the same time slot, node $r$ transmits a collection of $m$ symbols through $(r, d)$. The collection of $m$ symbols transmitted in a time slot are either received perfectly by node $d$ or erased. The fraction $\frac{k}{\max\{n, m\}}$ specifies the overall coding rate, which can be interpreted as the reciprocal of the amount of time needed to simultaneously transfer one unit of information over $(s, r)$ and $(r, d)$. We call the $k$ symbols chosen by node $s$, the $n$ symbols transmitted by node $s$, the $n$ symbols received by node $r$, the $m$ symbols transmitted by node $r$ and the $m$ symbols received by node $d$ the message, the source packet, the relay received packet, the relay transmitted packet and the destination packet respectively. We assume causal encoding at node $s$ and node $r$, meaning that each source packet may depend on the current and previous messages and each relay transmitted packet may depend on the currently and previously received packets. Since every low-latency application is subject to a tight delay constraint, we assume that every message generated in a time slot must be decoded by node $d$ with delay $T$, i.e., within the future $T$ time slots.

We consider the following channel loss model: On the discrete timeline, the channels $(s, r)$ and $(r, d)$ introduce $N_1$ and $N_2$ erasures respectively. Under the erasure channel model described above, we are interested in characterizing the maximum achievable rate — the maximum coding rate $\frac{k}{\max\{n, m\}}$ for sending information over the relay network such that every message can be perfectly recovered by node $d$ with delay $T$. If $N_2 = 0$, then the three-node relay network with erasures reduces to a point-to-point packet erasure channel. It was previously known that [11, Sec. IV] the maximum achievable rate of the point-to-point packet erasure channel with $N_1 = N$ and $N_2 = 0$ is

$$C_{T,N} = \begin{cases} \frac{T-N+1}{T+1} & \text{if } T \geq N, \\ 0 & \text{otherwise.} \end{cases} \quad (1)$$

1.3 Time-Division Decode-Forward: Message-Wise vs. Symbol-Wise

A naive relaying scheme for the three-node relay network is time-division decode-forward where the relay decodes every message with delay $T_1$ before forwarding it to the destination with an additional delay $T_2$. We call the
relaying scheme described above message-wise DF where DF stands for decode-forward. For message-wise DF, all the symbols in the same source message are decoded by the relay subject to the same delay constraint $T_1$, and similarly all the symbols re-encoded by the relay are decoded by the destination subject to the same delay constraint $T_2$. A more flexible relaying scheme is to let the relay decode the symbols in the same source message subject to possibly different delay constraints, and similarly let the destination decode the symbols re-encoded by the relay subject to possibly different delay constraints. We call this flexible scheme the symbol-wise DF. By definition, every message-wise DF can be viewed as a symbol-wise DF. The following example illustrates that symbol-wise DF can outperform message-wise DF.

**Example 1.** Consider a simple relay network where $N_1 = N_2 = 1$ and $T = 3$.

The forward strategy illustrated in Table 1 where the delay information of each symbol received by $r$ is exploited to improve the forwarding strategy. Suppose $s$ transmits two bits $a_i$ and $b_i$ at each discrete time $i \geq 0$ to $d$ with delay 3. For each time $i$, node $s$ transmits the three-symbol packet $[a_i \ b_i \ a_{i-2} + b_{i-1}]$ according to Table 1(a) where $a_j = b_j = 0$ for any $j < 0$ by convention, and the symbols highlighted in the same color are generated by the same block code. Since channel $(s, r)$ introduces at most $N_1 = 1$ erasure, each $a_i$ and each $b_i$ can be perfectly recovered by $r$ by time $i + 2$ and time $i + 1$ respectively. Therefore at each time $i$, node $r$ should have recovered $a_{i-2}$ and $b_{i-1}$ perfectly with delay 2 and 1 respectively, and it will re-encode them into another three-symbol packet $[b_{i-1} \ a_{i-2} \ b_{i-3} + a_{i-3}]$ according to Table 1(b), where the symbols highlighted in the same color are generated by the same block code.
code. Since \( b_{i-3}, a_{i-3} \) and \( b_{i-3} + a_{i-3} \) are transmitted by node \( r \) at time \( i - 2, i - 1 \) and \( i \) respectively, it follows from the fact \( N_2 = 1 \) that node \( r \) can recover \( a_{i-3} \) and \( b_{i-3} \) by time \( i \) for each \( i \geq 3 \). Consequently, this symbol-wise DF strategy achieves a rate of 2/3, which outperforms all message-wise DF strategies.

### 1.4 Delay Profile

Fix a symbol-wise DF strategy. Let \( s_i[0], s_i[1], \ldots, s_i[k-1] \) be the \( k \) source symbols transmitted by node \( s \) at each discrete time \( i \geq 0 \) where \( s_j[\ell] = 0 \) for any \( j < 0 \) and any \( \ell \) by convention. The delay profile of the symbol-wise DF strategy is defined as the tuple \( ((t_0, \tau_0), (t_1, \tau_1), \ldots, (t_{k-1}, \tau_{k-1})) \) which does not depend on \( i \), where \( t_\ell \) and \( \tau_\ell \) denote the delays by which node \( r \) and node \( d \) must respectively produce estimates of the symbols in \( \{s_i[\ell] | i \in \{0,1,\ldots\} \} \) for each \( \ell \in \{0,1,\ldots,k-1\} \). In other words, for the symbol-wise DF strategy subject to the delay profile \( ((t_0, \tau_0), (t_1, \tau_1), \ldots, (t_{k-1}, \tau_{k-1})) \), the symbol \( s_i[\ell] \) must be estimated by node \( r \) and node \( d \) by time \( i + t_\ell \) and time \( i + \tau_\ell \) respectively for each \( \ell \in \{0,1,\ldots,k-1\} \) and each \( i \in \{0,1,\ldots\} \), and we let \( \hat{s}_i^{(r)}[\ell] \) and \( \hat{s}_i^{(d)}[\ell] \) denote respectively the estimates of \( s_i[\ell] \) by node \( r \) and node \( d \).

Given a delay profile \( ((t_0, \tau_0), (t_1, \tau_1), \ldots, (t_{k-1}, \tau_{k-1})) \), we define the first-hop delay profile and the second-hop delay profile to be \((t_0, t_1, \ldots, t_{k-1})\) and \((\tau_0 - t_0, \tau_1 - t_1, \ldots, \tau_{k-1} - t_{k-1})\) respectively. The first-hop and second-hop delay profiles can be interpreted as the decoding delay constraints imposed on the \( k \) source symbols for the channels \((s, r)\) and \((r, d)\) respectively.

**Example 2.** Consider a symbol-wise DF strategy with delay profile \( ((2,3), (1,3)) \) which is illustrated in Table 2.

The first-hop delay profile is \((2,1)\), which agrees with the facts that the duration between the arrival of \( s_i[0] \) and the construction of \( \hat{s}_i^{(r)}[0] \) equals 2 and that the duration between the construction of \( \hat{s}_i^{(r)}[0] \) and the construction of \( \hat{s}_i^{(d)}[0] \) equals 1 for each \( i \). In other words, for each \( i \), the decoding delay constraints imposed on channels \((s, r)\) and \((r, d)\) for \( s_i[0] \) are 2 and 1 respectively. Similarly, the second-hop delay profile is \((1,2)\), which agrees with the facts that the duration between the arrival of \( s_i[1] \) and the construction of \( \hat{s}_i^{(r)}[1] \) equals 1 and that the duration between the construction of \( \hat{s}_i^{(r)}[1] \) and the construction of \( \hat{s}_i^{(d)}[1] \) equals 2 for each \( i \). In other words, for each \( i \), the decoding delay constraints imposed on channels \((s, r)\) and \((r, d)\) for \( s_i[1] \) are 1 and 2 respectively.

A symbol-wise DF strategy with delay profile \( ((t_0, \tau_0), (t_1, \tau_1), \ldots, (t_{k-1}, \tau_{k-1})) \) is also called a message-wise DF strategy if \( t_0 = t_1 = \ldots = t_{k-1} \) and \( \tau_0 = \tau_1 = \ldots = \tau_{k-1} \), where the delay constraints imposed on channels \((s, r)\) and \((r, d)\) for \( s_i[\ell] \) are \( t_0 \) and \( \tau_0 - t_0 \) respectively for each \( i \in \{0,1,\ldots\} \) and each \( \ell \in \{0,1,\ldots,k-1\} \).

**Example 3.** Consider a message-wise DF strategy with delay profile \( ((1,3), (1,3)) \) which is illustrated in Table 3.

The symbols highlighted in the same color are generated by the same block code. The first-hop and second-hop delay profiles are equal to \((1,2)\), which agree with the facts that the duration between the arrival of \( s_i[\ell] \) and the construction of \( \hat{s}_i^{(r)}[\ell] \) equals 1 and that the duration between the construction of \( \hat{s}_i^{(r)}[\ell] \) and the construction of \( \hat{s}_i^{(d)}[\ell] \) equals 2 for each \( \ell \in \{0,1\} \) and each \( i \in \{0,1,\ldots\} \). In other words, for each \( i \) and each \( \ell \in \{0,1\} \), the decoding delay constraints imposed on channels \((s, r)\) and \((r, d)\) for \( s_i[\ell] \) are 1 and 2 respectively.

**TABLE 3:** A message-wise DF strategy with delay profile ((1, 3), (1, 3))
Motivated by the definition of the delay profile for a symbol-wise DF strategy defined for the three-node relay network, we define the delay spectrum of a point-to-point packet erasure code as follows. Fix a point-to-point packet erasure code. Let $s_i[0], s_i[1], \ldots, s_i[k-1]$ be the $k$ source symbols transmitted by the source at each discrete time $i \geq 0$. The delay spectrum of the point-to-point code is defined as the tuple $(\Delta_0, \Delta_1, \ldots, \Delta_{k-1})$ which does not depend on $i$, where $\Delta_\ell$ denotes the delay by which estimates of the symbols in $\{s_i[\ell] | i \in \{0,1,\ldots\}\}$ must be constructed by the destination for each $\ell \in \{0,1,\ldots,k-1\}$. In other words, for the point-to-point code subject to the delay spectrum $(\Delta_0, \Delta_1, \ldots, \Delta_{k-1})$, the symbol $s_i[\ell]$ must be estimated by the destination by time $i + \Delta_\ell$ for each $\ell \in \{0,1,\ldots,k-1\}$ and each $i \in \{0,1,\ldots\}$, and we let $\hat{s}_i[\ell]$ denote the estimate of $s_i[\ell]$.

**Example 4.** Consider a point-to-point code with delay spectrum $(2,1)$ which is illustrated in Table 4. The symbols highlighted in the same color are generated by the same block code. For the point-to-point code, every symbol $s_i[0]$ must be estimated by the destination by time $i + 2$, and every symbol $s_i[1]$ must be estimated by the destination by time $i + 1$. In other words, the decoding delay constraints imposed for $s_i[0]$ and $s_i[1]$ are 2 and 1 respectively.

### 1.5 Main Contribution

This paper investigates the three-node relay network subject to arbitrary erasures and characterizes the maximum achievable rate denoted by $C_{T,N_1,N_2}$ as

$$C_{T,N_1,N_2} = \min\{C_{T-N_2,N_1}, C_{T-N_1,N_2}\} = \begin{cases} \frac{T - N_1 - N_2 + 1}{T - \min\{N_1, N_2\} + 1} & \text{if } T \geq N_1 + N_2, \\ 0 & \text{otherwise,} \end{cases}$$

(2)

where $C_{T,N}$ is the point-to-point channel capacity defined in (1). The achievability is proved by using a symbol-wise DF scheme (as illustrated in Example 2) and the converse is proved by analyzing the maximum achievable rate for each point-to-point channel when the erasures in the other channel are consecutive (bursty).
In addition, we show that message-wise DF schemes (as illustrated in Example 3) which achieve
\[ R_{T,N_1,N_2}^{\text{message}} = \max_{(T_1,T_2):T_1+T_2 \leq T} \min \{ C_{T_1,N_1}, C_{T_2,N_2} \} \]  
are sub-optimal if and only if \( T > N_1 + N_2 \).

1.6 Paper Outline

This paper is organized as follows. The notation in this paper is explained in the next subsection. Section 2 presents the formulation of streaming codes for the three-node relay network and states the main result. Section 3 presents the converse proof of the main result. Section 4 presents the preliminary results that are useful for the achievability proof of the main result, which include the definitions of the delay profile of a symbol-wise DF scheme and the delay spectrum of a point-to-point code. Section 5 contains the achievability proof of the main result, i.e., the existence of an optimal symbol-wise DF scheme for the three-node relay network for all parameters \((T,N_1,N_2)\). Section 6 investigates message-wise DF and shows that it is suboptimal in general. Section 7 presents numerical results that demonstrate the advantage of using symbol-wise DF over message-wise DF when the channels are subject to independent and identically distributed (i.i.d.) erasures. Section 8 concludes this paper.

1.7 Notation

The set of non-negative integer is denoted by \( \mathbb{Z}_+ \). All the elements of any matrix considered in this paper are taken from a common finite field \( F \), where 0 and 1 denote the additive identity and the multiplicative identity respectively. The set of \( k \)-dimensional row vectors over \( F \) is denoted by \( F^k \), and the set of \( k \times n \) matrices over \( F \) is denoted by \( F^{k \times n} \). For any matrix \( G \), we let \( G^t \) and \( \text{rank}(G) \) denote respectively the transpose and the rank of \( G \). A row vector in \( F^k \) is denoted by \( a \triangleq [a_0 \ a_1 \ldots a_{k-1}] \) where \( a_i \) denotes the \((\ell+1)\)th element of \( a \). The \( k \)-dimensional identity matrix is denoted by \( I_k \) and the \( L_1 \times L_2 \) all-zero matrix is denoted by \( 0^{L_1 \times L_2} \). An \( L \times B \) parity matrix of a systematic maximum-distance separable (MDS) \((L + B, L)\)-code is denoted by \( V^{L \times B} \), which possesses the property that any \( L \) columns of \([I_L \ V^{L \times B}] \in F^{L \times (L+B)} \) are independent. It is well known that a systematic maximum-distance separable (MDS) \((L + B, L)\)-code always exists as long as \(|F| \geq L + B\) [18]. We will take all logarithms to base 2 throughout this paper.

2 Streaming Codes for the Three-Node Relay Network with Arbitrary Erasures

2.1 Problem Formulation

Node \( s \) wants to send a sequence of messages \( \{s_i\}_{i=0}^\infty \) to node \( d \) with the help of the middle node \( r \). Each \( s_i \) is an element in \( F^k \) where \( F \) is some finite field. In each time slot \( i \in \mathbb{Z}_+ \), the source message \( s_i \) is encoded into a length-\( n \) packet \( x_i \in F^n \) to be transmitted to the relay through the erasure channel \((s,r)\), and the relay receives \( y_i^{(r)} \in F^n \cup \{\ast\} \) where \( y_i^{(r)} \) equals either \( x_i \) or the erasure symbol ‘\( \ast \)’. In the same time slot, the relay transmits \( x_i^{(r)} \in F^m \) to the destination through the erasure channel \((r,d)\), and the destination receives \( y_i \in F^n \cup \{\ast\} \) where \( y_i \) equals either \( x_i^{(r)} \) or the erasure symbol ‘\( \ast \)’. The fraction \( \frac{k}{\max\{n,m\}} \) specifies the rate of
the code. Every code is subject to a delay constraint of $T$ time slots, meaning that the destination must produce an estimate of $s_i$, denoted by $\hat{s}_i$, upon receiving $y_{i+T}$. We assume that on the discrete timeline, channels $(s, r)$ and $(r, d)$ introduce $N_1$ and $N_2$ arbitrary erasures respectively. The symbols generated in the three-node relay network at time $i$ is illustrated in Figure 1.

### 2.2 Standard Definitions and Main Result

**Definition 1.** An $(n, m, k, T)_F$-streaming code consists of the following:

1. A sequence of source messages $\{s_i\}_{i=0}^{\infty}$ where $s_i \in F^k$.
2. An encoding function $f_i : \prod_{j=0}^{i} F^k \rightarrow F^n$ for each $i \in \mathbb{Z}_+$, where $f_i$ is used by node $s$ at time $i$ to encode $s_i$ according to
   \[x_i = f_i(s_0, s_1, \ldots, s_i)\] (4)
3. A relaying function $f^{(r)}_i : \prod_{j=0}^{i} F^n \rightarrow F^m$ for each $i \in \mathbb{Z}_+$, where $f^{(r)}_i$ is used by node $r$ at time $i$ to construct
   \[x^{(r)}_i = f^{(r)}_i(y^{(r)}_0, y^{(r)}_1, \ldots, y^{(r)}_i)\] (5)
4. A decoding function $\varphi_{i+T} : \prod_{j=0}^{i+T} F^m \rightarrow F^k$ for each $i \in \mathbb{Z}_+$, where $\varphi_{i+T}$ is used by node $d$ at time $i + T$ to estimate $s_i$ according to
   \[\hat{s}_i = \varphi_{i+T}(y_0, y_1, \ldots, y_{i+T})\] (6)

**Definition 2.** An erasure sequence is a binary sequence denoted by $e^\infty \triangleq \{e_i\}_{i=0}^{\infty}$ where

\[e_i = 1\{\text{erasure occurs at time } i\}\] (7)

An $N$-erasure sequence is an erasure sequence $e^\infty$ that satisfies $\sum_{\ell=0}^{\infty} e_\ell = N$. In other words, an $N$-erasure sequence introduces $N$ arbitrary erasures on the discrete timeline. The set of $N$-erasure sequences is denoted by $\Omega_N$.

**Definition 3.** Let $e \in \{0, 1\}$. The input-output relation of the erasure channel $g_n : F^n \times \{0, 1\} \rightarrow F^n \cup \{*\}$ subject to $e \in \{0, 1\}$ is defined as

\[g_n(x, e) = \begin{cases} x & \text{if } e = 0, \\ * & \text{if } e = 1. \end{cases}\] (8)

For any erasure sequence $e^\infty$ and any $(n, m, k, T)_F$-streaming code, the following input-output relation holds for the erasure channel $(s, r)$ for each $i \in \mathbb{Z}_+$:

\[y^{(r)}_i = g_n(x_i, e_i)\] (9)
Similarly, the following input-output relation holds for the erasure channel \((r, d)\) for each \(i \in \mathbb{Z}_+\):

\[ y_i = g_m(x_i^{(r)}, e_i). \]  

(10)

**Definition 4.** An \((n, m, k, T)\)-streaming code is said to be \((N_1, N_2)\)-achievable if the following holds for any \(N_1\)-erasure sequence \(e^\infty \in \Omega_{N_1}\) and any \(N_2\)-erasure sequence \(\epsilon^\infty \in \Omega_{N_2}\): For all \(i \in \mathbb{Z}_+\) and all \(s_i \in \mathbb{F}^k\), we have

\[ \hat{s}_i = s_i \]  

(11)

where

\[ \hat{s}_i = \varphi_{i+T} \left( g_m(x_0^{(r)}, e_0), \ldots, g_m(x_{i+T}^{(r)}, e_{i+T}) \right) \]  

(12)

due to (6) and (10) and

\[ y_i^{(r)} = f_i^{(r)} \left( g_n(x_0, e_0), \ldots, g_n(x_i, e_i) \right) \]  

(13)

due to (5) and (9).

**Definition 5.** The rate of an \((n, m, k, T)\)-streaming code is

\[ k_{\max} \{ n, m \}. \]  

**Remark 1.** For any \((n, m, k, T)\)-streaming code, if the transmission time of a packet is proportional to the packet length, then \(n\) unit time is needed to transmit \(k\) units of information over \((s, r)\) and \(m\) unit time is needed to transmit \(k\) unit of information over \((s, r)\). Therefore, \(\max \{ n, m \}\) can be interpreted as the amount of time needed to simultaneously transmit \(k\) units of information over \((s, r)\) and \((r, d)\). Consequently, the rate \(k_{\max} \{ n, m \}\) in Definition 5 can be interpreted as the reciprocal of the amount of time needed to simultaneously transmit one unit of information over the two channels.

**Definition 6.** The \((T, N_1, N_2)\)-capacity, denoted by \(C_{T, N_1, N_2}\), is the maximum rate achievable by \((n, m, k, T)\)-streaming codes that are \((N_1, N_2)\)-achievable, i.e.,

\[ C_{T, N_1, N_2} = \sup \left\{ \frac{k}{\max \{ n, m \}} \left| \begin{array}{l} \text{There exists an \((N_1, N_2)\)-achievable } \(n, m, k, T)\text{-streaming code for some } n, m, k \text{ and } \mathbb{F} \end{array} \right. \right\}. \]  

(14)

The following theorem is the main result of this paper. The converse and achievability proofs are provided in Sections 3 and 5 respectively.

**Theorem 1.** For any \((T, N_1, N_2)\), we have

\[ C_{T, N_1, N_2} = \min \left\{ C_{T-N_2, N_1}, C_{T-N_1, N_2} \right\}. \]  

(15)

In particular, for any \(\mathbb{F}\) with \(|\mathbb{F}| \geq T + 1\), there exists an \((N_1, N_2)\)-achievable \((n, m, k, T)\)-streaming code where

\[ \frac{k}{\max \{ n, m \}} = C_{T, N_1, N_2}. \]  

(16)
3 Converse Proof of Theorem \[1\]

Fix any \((T, N_1, N_2)\). Suppose we are given an \((N_1, N_2)\)-achievable \((n, m, k, T)\)_F-streaming code for some \(n, m, k\) and \(F\). Our goal is to show that

\[
\frac{k}{\max\{n, m\}} \leq \min\{C_{T-N_2,N_1}, C_{T-N_1,N_2}\}. \tag{17}
\]

To this end, we let \(\{s_i\}_{i \in \mathbb{Z}_+}\) be i.i.d. random variables where \(s_0\) is uniform on \(F\). Since the \((n, m, k, T)\)_F-streaming code is \((N_1, N_2)\)-achievable, we have

\[
H(s_i | y_i, y_{i+1}, \ldots, y_{i+T}; s_0, s_1, \ldots, s_{i-1}) = 0 \tag{18}
\]

for any \(i \in \mathbb{Z}_+\), any \(\epsilon^\infty \in \Omega_{N_1}\) and any \(\epsilon^\infty \in \Omega_{N_2}\). Consider the following two cases.

Case \(T < N_1 + N_2\):  
Let \(\epsilon^\infty \in \Omega_{N_1}\) and \(\epsilon^\infty \in \Omega_{N_2}\) such that

\[
\epsilon_i = \begin{cases} 
1 & \text{if } 0 \leq i \leq N_1 - 1, \\
0 & \text{otherwise},
\end{cases} \tag{19}
\]

and

\[
\epsilon_i = \begin{cases} 
1 & \text{if } N_1 \leq i \leq N_1 + N_2 - 1, \\
0 & \text{otherwise}. \tag{20}
\end{cases}
\]

Due to (19) and (20) and Definition \[1\] we have

\[
I(s_0; y_0, y_1, \ldots, y_{N_1+N_2-1}) = 0. \tag{21}
\]

Combining (18), (21) and the assumption that \(T < N_1 + N_2\), we obtain \(H(s_0) = 0\), which implies that

\[
k = 0. \tag{22}
\]

Case \(T \geq N_1 + N_2\):  
For every \(i \in \mathbb{Z}_+\) and any \(\epsilon^\infty \in \Omega_{N_1}\), message \(s_i\) has to be perfectly recovered by node \(r\) by time \(i + T - N_2\) given that \(s_0, s_1, \ldots, s_{i-1}\) have been correctly decoded by node \(r\), or otherwise a length-\(N_2\) burst erasure from time \(i + T - N_2 + 1\) to \(i + T\) introduced on channel \((r, d)\) would result in a decoding failure for both node \(r\) and node \(d\). It then follows that

\[
H\left(s_i \mid \{x_i, x_{i+1}, \ldots, x_{i+T-N_2}\} \setminus \left\{x_{\theta_1}, x_{\theta_2}, \ldots, x_{\theta_{N_1}}\right\}, s_0, s_1, \ldots, s_{i-1}\right) = 0 \tag{23}
\]

for any \(i \in \mathbb{Z}_+\) and any \(N_1\) non-negative integers denoted by \(\theta_1, \theta_2, \ldots, \theta_{N_1}\). By (23) and the chain rule, we conclude the following for each \(j \in \mathbb{N}\) whose derivation is elaborated in Appendix \[A\]

\[
H\left(s_0, s_1, \ldots, s_{T-N_2+(j-1)(T-N_2+1)} \mid \{x_{i(T-N_2+1)}, x_{1+i(T-N_2+1)}, \ldots, x_{T-N_1-N_2+i(T-N_2+1)}\}_{i=0}^{j}\right) = 0 \tag{24}
\]
where the conditional entropy involves \( j(T-N_2+1) \) source messages and \((j+1)(T-N_1-N_2+1) \) source packets. Therefore, the \((N_1, N_2)\)-achievable \((n, m, k, T)\_p\)-streaming code restricted to channel \((s, r)\) can be viewed as an \(N_1\)-achievable point-to-point \((n, k, T-N_2)\)-code that can correct the periodic erasure sequence \(\hat{e}^\infty\) illustrated in Figure 2 which is formally defined as

\[
\hat{e}_i = \begin{cases} 
0 & \text{if } 0 \leq i \mod (T-N_2+1) \leq T-N_1-N_2, \\
1 & \text{otherwise}
\end{cases}
\]  

(25)

for all \(i \in \mathbb{Z}_+\). By standard arguments which are elaborated in Appendix A we conclude that

\[
\frac{k}{n} \leq \frac{T-N_1-N_2+1}{T-N_2+1} = C_{T-N_2,N_1}.
\]  

(26)

In addition, for every \(i \in \mathbb{Z}_+\) and any \(e^\infty \in \Omega_{N_2}\), message \(s_i\) has to be perfectly recovered from \((y_{i+N_1}, y_{i+N_1+1}, \ldots, y_{i+T})\) by node \(d\) given that \(s_0, s_1, \ldots, s_{i-1}\) have been correctly decoded by node \(d\), or otherwise a length-\(N_1\) burst erasure from time \(i\) to \(i+N_1-1\) introduced on channel \((s, r)\) would result in a decoding failure for node \(d\). It then follows that

\[
H \left( s_i \left| \left\{ x_{i+N_1}^{(r)}, x_{i+N_1+1}^{(r)}, \ldots, x_{i+T}^{(r)} \right\} \right\} \setminus \left\{ x_{\theta_1}^{(r)}, x_{\theta_2}^{(r)}, \ldots, x_{\theta_{N_2}}^{(r)} \right\} , s_0, s_1, \ldots, s_{i-1} \right) = 0
\]  

(27)

for any \(i \in \mathbb{Z}_+\) and any \(N_2\) non-negative integers denoted by \(\theta_1, \theta_2, \ldots, \theta_{N_2}\). By (27) and the chain rule, we conclude the following for each \(j \in \mathbb{N}\) whose derivation is elaborated in Appendix A

\[
H \left( s_0, s_1, \ldots, s_{T-N_1+(j-1)(T-N_1+1)} \left\{ x_{N_1+N_2+i(T-N_1+1)}^{(r)}, x_{N_1+N_2+1+i(T-N_1+1)}^{(r)}, \ldots, x_{T+i(T-N_1+1)}^{(r)} \right\} \right) = 0
\]  

(28)

where \(x_i \triangleq 0^{1 \times m}\) and the conditional entropy involves \(j(T-N_1+1)\) source messages and no more than \((j+2)(T-N_1-N_2+1)\) relay transmitted packets. Therefore, the \((N_1, N_2)\)-achievable \((n, m, k, T)\_p\)-streaming code restricted to channel \((r, d)\) can be viewed as an \(N_2\)-achievable point-to-point \((m, k, T-N_1)\)-code that can correct the periodic erasure sequence \(\hat{e}^\infty\) illustrated in Figure 3 which is formally defined as

\[
\hat{e}_i = \begin{cases} 
0 & \text{if } N_1+N_2 \leq i \mod (T-N_1+1) \leq T, \\
1 & \text{otherwise}
\end{cases}
\]  

(29)

for all \(i \in \mathbb{Z}_+\). By standard arguments which are elaborated in Appendix A we conclude that

\[
\frac{k}{m} \leq \frac{T-N_1-N_2+1}{T-N_1+1} = C_{T-N_1,N_2}.
\]  

(30)
Combining the above two cases and using (22), (26) and (30), we conclude that (17) holds for all \((T, N_1, N_2)\).

4 Symbol-Wise Decode-Forward Strategy

This section provides the preliminary results for the achievability proof of Theorem 1. The symbol-wise DF and its delay profile are formally described in Section 4.1, while the point-to-point code and its delay spectrum are formally described in Section 4.2.

4.1 Symbol-Wise DF and Its Delay Profile

Definition 7. A delay profile is defined as \(((t_0, \tau_0), (t_1, \tau_1), \ldots, (t_{k-1}, \tau_{k-1}))\) for some \(k \in \mathbb{Z}_+\) where \((t_\ell, \tau_\ell) \in \mathbb{Z}^2_+\) satisfies \(t_\ell \leq \tau_\ell\).

Remark 2. Examples of delay profiles are \(((2,3), (1,3))\) in Example 2 and \(((1,1), (3,3))\) in Example 3.

Definition 8. Let \(k\) be a non-negative integer and fix a delay profile \(d \triangleq ((t_0, \tau_0), (t_1, \tau_1), \ldots, (t_{k-1}, \tau_{k-1}))\). Define \(T \triangleq \max_{0 \leq \ell \leq k-1} \tau_\ell\). A symbol-wise DF \((n, m, k, d)_{\text{DE}}\)-code is an \((n, m, k, T)_{\text{DE}}\)-streaming code (cf. Definition 1) which produces estimates of the source symbols at nodes \(r\) and \(d\) as follows. Let \(s_i[\ell] \in \mathbb{F}\) be the \((\ell + 1)^{\text{th}}\) source symbol generated at time \(i\) for each \(\ell \in \{0, 1, \ldots, k - 1\}\) and each \(i \in \mathbb{Z}_+\), and recall that \(x_i \in \mathbb{F}^n\) and \(y_i^{(r)} \in \mathbb{F}^n\) denote the source packet and the relay received packet respectively at time \(i\). For each \(\ell \in \{0, 1, \ldots, k - 1\}\) and each \(i \in \mathbb{Z}_+\), an estimate of \(s_i[\ell]\) denoted by \(\hat{s}_i^{(r)}[\ell]\) is produced by node \(r\) at time \(i + t_\ell\) based on \((y_0^{(r)}, y_1^{(r)}, \ldots, y_{i+t_\ell}^{(r)})\). Next, letting

\[
\hat{S}_i^{(r)} \triangleq \left\{ \hat{s}_j^{(r)}[\ell] \middle| \begin{array}{l}
\ell \in \mathbb{Z}_+, \ell \in \{0, 1, \ldots, k - 1\}, \\
n_j \in \mathbb{F}^n, j \in \{0, 1, \ldots, i\} \end{array} \right\} \quad (31)
\]

be the collection of estimates that have been made by node \(r\) by time \(i\), node \(r\) constructs and transmits \(x_i^{(r)} \in \mathbb{F}^m\) at time \(i\) for each \(i \in \mathbb{Z}_+\) where \(x_i^{(r)}\) is a function of \(\hat{S}_i^{(r)}\). Finally, recalling that \(y_i \in \mathbb{F}^m\) denotes the destination packet received at time \(i\), node \(d\) constructs an estimate of \(s_i[\ell]\) denoted by \(\hat{s}_i^{(d)}[\ell]\) by time \(i + \tau_\ell\) based on \((y_0, y_1, \ldots, y_{i+\tau_\ell})\) for each \(\ell \in \{0, 1, \ldots, k - 1\}\) and each \(i \in \mathbb{Z}_+\).

The following corollary is a direct consequence of Definition 3 and Definition 4.

Corollary 1. A symbol-wise DF \((n, m, k, d)_{\text{DE}}\)-code is \((N_1, N_2)\)-achievable if the following holds for any \(\epsilon^\infty \in \Omega_{N_1}\) and any \(\epsilon^\infty \in \Omega_{N_2}\): For all \(i \in \mathbb{Z}_+\) and all \(s_i = [s_i[0] s_i[1] \ldots s_i[k-1]] \in \mathbb{F}^k\), we have

\[
\hat{s}_i^{(d)}[\ell] = \hat{s}_i^{(r)}[\ell] = s_i[\ell] \quad (32)
\]

for each \(\ell \in \{0, 1, \ldots, k - 1\}\).
4.2 Delay Spectrum for Point-to-Point Streaming Code

The following three definitions are standard (cf. [12]).

Definition 9. Let \((u, v) \in \{(s, r), (r, d)\}\) be a point-to-point channel in the relay network. A point-to-point \((n, k, T)F\)-streaming code over \((u, v)\) consists of the following:

1) A sequence of messages \(\{u_i\}_{i=0}^{\infty}\) where \(u_i \in \mathbb{F}^k\).

2) An encoding function \(f_i^{(u)}: \mathbb{F}^k \times \cdots \times \mathbb{F}^k \to \mathbb{F}^n\) for each \(i \in \mathbb{Z}_+\), where \(f_i^{(u)}\) is used by node \(u\) at time \(i\) to encode \(u_i\) according to

\[
x_i^{(u)} = f_i(u_0, u_1, \ldots, u_i).
\]  

3) A decoding function \(\varphi_i^{(v)}: \mathbb{F}^n \cup \{\ast\} \times \cdots \times \mathbb{F}^n \cup \{\ast\} \to \mathbb{F}^k\) for each \(i \in \mathbb{Z}_+\), where \(\varphi_i^{(v)}\) is used by node \(v\) at time \(i + T\) to estimate \(u_i\) according to

\[
\hat{u}_i = \varphi_i^{(v)}(y_0^{(v)}, y_1^{(v)}, \ldots, y_{i+T}^{(v)}).
\]

Definition 10. A point-to-point \((n, k, T)F\)-streaming code over \((u, v)\) is said to be \(N\)-achievable if the following holds for any \(N\)-erasure sequence \(e_i^\infty \in \Omega_N\): For all \(i \in \mathbb{Z}_+\) and all \(u_i \in \mathbb{F}^k\), we have

\[
\hat{u}_i = u_i
\]  

where

\[
\hat{u}_i = \varphi_i^{(v)}(g_n(x_0^{(u)}, e_0), \ldots, g_n(x_{i+T}^{(u)}, e_{i+T}))
\]  

due to (34), (9) and (10).

Definition 11. The \((T, N)\)-capacity, denoted by \(C_{T,N}\), is the maximum rate achievable by point-to-point \((n, k, T)F\)-streaming codes that are \(N\)-achievable, i.e.,

\[
C_{T,N} \triangleq \sup \left\{ \frac{k}{n} \right\} \text{ There exists an } N\text{-achievable point-to-point } (n, k, T)F\text{-streaming code for some } n, k \text{ and } \mathbb{F} \right\}.
\]  

Theorem 2 ([11] Sec. IV). For any \(T\) and any \(N\), we have

\[
C_{T,N} = \begin{cases} 
\frac{T-N+1}{T+1} & \text{if } T \geq N, \\
0 & \text{otherwise.}
\end{cases}
\]

Definition 12. A delay spectrum is defined as \((\Delta_0, \Delta_1, \ldots, \Delta_{k-1})\) for some \(k \in \mathbb{Z}_+\) where \(\Delta_\ell \in \mathbb{Z}_+\).

Remark 3. An example of delay spectrum is \((2,1)\) in Example 4.
Definition 13. Let \( k \) be a non-negative integer and fix a delay spectrum \( \Delta \triangleq (\Delta_0, \Delta_1, \ldots, \Delta_{k-1}) \). Define \( T \triangleq \max_{0 \leq \ell \leq k-1} \Delta_\ell \). A point-to-point \((n, k, \Delta)\)-code over \((u, v)\) is a point-to-point \((n, k, T)\)-streaming code (cf. Definition 9) which produces estimates of the source symbols at node \( d \) as follows. Let \( u_i[\ell] \in \mathbb{F} \) be the \((\ell + 1)^{\text{th}}\) source symbol generated by node \( u \) at time \( i \) for each \( \ell \in \{0, 1, \ldots, k-1\} \) and each \( i \in \mathbb{Z}_+ \), and recall that \( y_i^{(v)} \in \mathbb{F}^n \) denotes the destination packet received by node \( v \) at time \( i \). For each time \( i \in \mathbb{Z}_+ \) and each \( \ell \in \{0, 1, \ldots, k-1\} \), node \( d \) constructs an estimate of \( u_i[\ell] \) denoted by \( \hat{u}_i^{(v)}[\ell] \) by time \( i + \Delta_\ell \) based on \((y_0^{(v)}, y_1^{(v)}, \ldots, y_i^{(v)})(\ell+1)\).

The following corollary is a direct consequence of Definition 13 and Definition 10.

Corollary 2. A point-to-point \((n, k, \Delta)\)-code over \((u, v)\) is \(N\)-achievable if the following holds for any \( e^\infty \in \Omega_N \): For all \( i \in \mathbb{Z}_+ \) and all \( u_i = [u_i[0] u_i[1] \ldots u_i[k-1]] \in \mathbb{F}^k \), we have

\[
\hat{u}_i^{(v)}[\ell] = u_i[\ell]
\]

for all \( \ell \in \{0, 1, \ldots, k-1\} \).

4.3 Construction of a Point-to-Point Streaming Code Based on a Block Code

We would like to construct a point-to-point streaming code described in Definition 13 based on a point-to-point block code described below such that they have the same delay spectrum and error-correcting capability. The following two definitions concerning systematic point-to-point block codes are standard (cf. [12]).

Definition 14. A (systematic) point-to-point \((n, k, T)\)-block code over \((u, v)\) consists of the following:

1) A sequence of \( k \) symbols \( \{u[\ell]\}_{\ell=0}^{k-1} \) where \( u[\ell] \in \mathbb{F} \).
2) A generator matrix \( G = [I_k \; P] \in \mathbb{F}^{k \times n} \) for some parity matrix \( P \in \mathbb{F}^{k \times (n-k)} \). The source codeword is generated according to

\[
[x[0] \; x[1] \; \ldots \; x[n-1]] = [u[0] \; u[1] \; \ldots \; u[k-1]] G.
\]

3) A decoding function \( \varphi_{\ell+T} : \mathbb{F} \cup \{x\} \times \ldots \times \mathbb{F} \cup \{x\} \rightarrow \mathbb{F} \) for each \( \ell \in \{0, 1, \ldots, k-1\} \), where \( \varphi_{\ell+T} \) is used by node \( v \) at time \( \min\{\ell + T, n - 1\} \) to estimate \( u[\ell] \) according to

\[
\hat{u}[\ell] = \begin{cases} 
\varphi_{\ell+T}(y[0], y[1], \ldots, y[\ell+T]) & \text{if } \ell + T \leq n - 1, \\
\varphi_{\ell+T}(y[0], y[1], \ldots, y[n-1]) & \text{if } \ell + T > n - 1.
\end{cases}
\]

Definition 15. A point-to-point \((n, k, T)\)-block code is said to be \(N\)-achievable if the following holds for any \( N \)-erasure sequence \( e^\infty \in \Omega_N \): For the \((n, k, T)\)-block code, we have

\[
\hat{u}[\ell] = u[\ell]
\]
for all $\ell \in \{0, 1, \ldots, k-1\}$ and all $u[\ell] \in \mathbb{F}$, where

\[
\hat{u}[\ell] = \begin{cases} 
\phi_{\ell+T}(g_1(x[0], e_0), \ldots, g_1(x[\ell+T], e_{\ell+T})) & \text{if } \ell + T \leq n - 1, \\
\phi_{\ell+T}(g_1(x[0], e_0), \ldots, g_1(x[n-1], e_{n-1})) & \text{if } \ell + T > n - 1 
\end{cases}
\]  

(43)

with $g_1$ being the symbol-wise erasure function that was defined in (8).

The symbols generated by the point-to-point block code described in Definition 14 is illustrated in Figure 4, where $[x[0] \ x[1] \ldots \ x[n-1]]$ denotes the symbols generated by a systematic block code according to (40).

The delay spectrum of a point-to-point block code can be defined in a similar way to that of a point-to-point streaming code (cf. Definition 13).

**Definition 16.** Let $k$ be a non-negative integer and fix a delay spectrum $\Delta \triangleq (\Delta_0, \Delta_1, \ldots, \Delta_{k-1})$. Define $T \triangleq \max_{0 \leq \ell \leq k-1} \Delta_\ell$. A point-to-point $(n, k, \Delta)$-$\mathbb{F}$-block code over $(u, v)$ is a point-to-point $(n, k, T)$-$\mathbb{F}$-block code (cf. Definition 14) which produces estimates of the source symbols at node $v$ as follows. Let $u[\ell] \in \mathbb{F}$ be the source symbol generated by node $u$ at time $\ell$ for each $\ell \in \{0, 1, \ldots, k-1\}$. For each time $\ell \in \{0, 1, \ldots, k-1\}$, node $d$ constructs an estimate of $u[\ell]$ denoted by $\hat{u}[\ell]$ by time $\min\{\ell + \Delta_\ell, n-1\}$ based on $(y[0], y[1], \ldots, y[\min\{\ell + \Delta_\ell, n-1\}])$.

The following lemma states the delay spectrum of an $N$-achievable point-to-point block code that achieves the rate $C_{T,N}$ as defined in (38).

**Lemma 3.** Suppose $T \geq N$, and let $k \triangleq T - N + 1$ and $n \triangleq k + N$. For any $\mathbb{F}$ such that $|\mathbb{F}| \geq n$, there exists an $N$-achievable point-to-point $(n, k, \Delta)$-$\mathbb{F}$-block code over $(u, v)$ with delay spectrum

$\Delta = (T, T - 1, \ldots, N)$.  

(44)

**Proof:** Fix any $\mathbb{F}$ such that $|\mathbb{F}| \geq n$ and let $V^{k \times N}$ be the parity matrix of an MDS code, whose existence is guaranteed due to the explanation given in Section 1.7. Construct the $(n, k, n-1)$-block code with generator matrix $G \triangleq [I_k \ V^{k \times N}]$ where the decoding delay is at most the number of columns of $G$ minus one, i.e., $n-1$. Since the block code is MDS, it is $N$-achievable. In addition, all the symbols have to be estimated by the end of the block code, which implies that the $(n, k, n-1)$-block code can be viewed as an $(n, k, \Delta)$-block code where

$\Delta \triangleq (n-1, n-2, \ldots, n-k)$

\[
= (T, T - N, \ldots, N).
\]  

(45)
The following lemma states that we can construct a point-to-point streaming code from a point-to-point block code such that they have the same delay profile and error-correcting capability. The proof is based on periodic interleaving (c.f. [19] and [10] Sec. IV-A)) and is analogous to the proof in [12] Lemma 1, and therefore is deferred to Appendix B.

**Lemma 4.** Given a point-to-point \((n, k, \Delta)\)-block code which is \(N\)-achievable, we can construct a point-to-point \((n, k, \Delta)\)-streaming code which is also \(N\)-achievable.

**Example 5.** Suppose we are given a 2-achievable \((5, 3, (4, 3, 2))\)-block code with generator matrix

\[
G = \begin{bmatrix}
1 & 0 & 0 & 1 & 1 \\
0 & 1 & 0 & 1 & 2 \\
0 & 0 & 1 & 1 & 4
\end{bmatrix},
\]

and let \(\{u_i\}_{i \in \mathbb{Z}_+}\) be the streaming messages where \(u_i = [u_i[0] u_i[1] u_i[2]] \in \mathbb{F}^3\). From time \(i - 2\) to \(i + 5\), the symbols yielded by the \((5, 3, (4, 3, 2))\)-streaming code constructed by interleaving the length-5 block code according Lemma 4 are shown in Table 5. The symbols in Table 5 which are highlighted in the same color diagonally (in direction \(\uparrow\)) are encoded using the same block code. Given the fact that each \((5, 3, (4, 3, 2))\)-block code is 2-achievable, we can see from Table 5 that \(u_i = [u_i[0] u_i[1] u_i[2]]\) can be perfectly recovered by time \(i + 5\) as long as the erasure sequence is taken from \(\Omega_2\).

The achievability proof of Theorem 1 hinges on the next lemma, which investigates the delay profile of a streaming code over the three-node relay network when the streaming code is formed by concatenating two point-to-point codes. More specifically, the resultant first-hop and second-hop delay profiles of the concatenated codes equal the respective delay spectrums of the two point-to-point codes. The proof of Lemma 5 is straightforward and hence deferred to Appendix C.

**Lemma 5.** Fix three natural numbers \(k, n, m\) such that \(k \leq \min\{n, m\}\). In addition, let \(t \triangleq (t_0, t_1, \ldots, t_{k-1})\) and \(\Delta \triangleq (\Delta_0, \Delta_1, \ldots, \Delta_{k-1})\) be two delay spectrums. Suppose an \(N_1\)-achievable point-to-point \((n, k, t)\)-
code and an $N_2$-achievable point-to-point $(m, k, \Delta)$-point-to-point code are given. Then, there exists an $(N_1, N_2)$-achievable $(\max\{n, m\}, k, \mathbf{d})$-code over the three-node relay network whose delay profile is
\begin{equation}
\mathbf{d} \triangleq ((t_0, t_0 + \Delta_0), (t_1, t_1 + \Delta_1), \ldots, (t_{k-1}, t_{k-1} + \Delta_{k-1})).
\end{equation}

5 Achievability Proof of Theorem 1

Fix any $(T, N_1, N_2)$, and fix $\mathbb{F}$ such that $|\mathbb{F}| \geq T + 1$. In view of the converse statement [17] proved in Section 3, it suffices to prove the existence of an $(N_1, N_2)$-achievable $(\max\{n, m\}, k, T)$-code such that
\begin{equation}
\frac{k}{\max\{n, m\}} = \min \{C_{T-N_2, N_1}, C_{T-N_1, N_2}\},
\end{equation}
which together with [17] would imply (15). Since the right hand side of (49) equals zero if $T < N_1 + N_2$, we assume in the rest of the proof that $T \geq N_1 + N_2$.

Define $k \triangleq T - N_1 - N_2 + 1$, $n \triangleq k + N_1$ and $m \triangleq k + N_2$, and we would like to leverage Lemma 5 to prove the existence of an $(N_1, N_2)$-achievable $(\max\{n, m\}, k, T)$-code. To this end, we invoke Lemma 3 to obtain an $N_1$-achievable point-to-point $(n, k, t)$-code and an $N_2$-achievable point-to-point $(n, k, \Delta)$-code where
\begin{equation}
t \triangleq (T - N_2, T - N_2 - 1, \ldots, N_1)
\end{equation}
and
\begin{equation}
\Delta \triangleq (T - N_1, T - N_1 - 1, \ldots, N_2).
\end{equation}
Using Lemma 4 there exist an $N_1$-achievable point-to-point $(n, k, t)$-code and an $N_2$-achievable point-to-point $(n, k, \Delta)$-code respectively. In addition, by relabeling the $k$ symbols transmitted at time $i$ for each $i \in \mathbb{Z}_+$, the $N_2$-achievable point-to-point $(n, k, \Delta)$-code can be viewed as an $N_2$-achievable point-to-point $(n, k, \tilde{\Delta})$-code where
\begin{equation}
\tilde{\Delta} \triangleq (N_2, N_2 + 1, \ldots, T - N_1).
\end{equation}
It then follows from Lemma 5 (50) and (52) that there exists an $(N_1, N_2)$-achievable $(\max\{n, m\}, k, \mathbf{d})$-code over the three-node relay network whose delay profile is
\begin{equation}
\mathbf{d} \triangleq ((T - N_2, T), (T - N_2 - 1, T), \ldots, (N_1, T)).
\end{equation}
In particular, the $(\max\{n, m\}, k, \mathbf{d})$-code is an $(\max\{n, m\}, k, T)$-code that satisfies (49).

6 Message-Wise Decode-Forward and Its Achievable Rate

The following definition of message-wise decode-forward (DF) is consistent with the brief description in Section 1.3.
Definition 17. Let \( d = ((t_0, \tau_0), (t_1, \tau_1), \ldots, (t_{k-1}, \tau_{k-1})) \) be a delay profile. A message-wise DF \((n, m, k, d)_F\)-code is a symbol-wise DF \((n, m, k, d)_F\)-code with the additional delay constraints

\[
t_0 = t_1 = \ldots, t_{k-1} = t
\]

and

\[
\tau_0 = \tau_1 = \ldots, \tau_{k-1} = \tau.
\]

The maximum achievable rate for message-wise DF is characterized in the following definition and theorem.

Definition 18. The maximum achievable rate for message-wise DF is defined as

\[
R_{T,N_1,N_2}^{\text{message}} \triangleq \sup \left\{ \frac{k}{\max\{n, m\}} \left| \begin{array}{l}
\text{There exists an } (N_1, N_2)\text{-achievable message-wise DF} \\
\text{\((n, m, k, d)_F\)-streaming code for some } n, m, k, d \text{ and } F \\
\text{such that } \max_{0 \leq \ell \leq k-1} \tau_\ell \leq T
\end{array} \right. \right\}.
\]

(56)

Theorem 3. For any \((T, B, N)\),

\[
R_{T,N_1,N_2}^{\text{message}} = \max_{(T_1, T_2): T_1 + T_2 \leq T} \min \left\{ C_{T_1,N_1}, C_{T_2,N_2} \right\}.
\]

(57)

In particular, for any \(T\), there exists an \((N_1, N_2)\)-achievable message-wise DF \((n, m, k, d)_F\)-code where

\[
\frac{k}{\max\{n, m\}} = R_{T,N_1,N_2}^{\text{message}}.
\]

(58)

Proof: For the achievability part, we fix any \(F\) with \(|F| \geq T + 1\), and it follows from Lemma 3 that there exists an \(N_1\)-achievable point-to-point \((n, k, t)_F\)-streaming code over \((s, r)\) with delay spectrum

\[
t = (T_1, T_1, \ldots, T_1)
\]

such that

\[
\frac{k}{n} = C_{T_1,N_1},
\]

(60)

and there exists an \(N_2\)-achievable point-to-point \((m, k, \Delta)_F\)-streaming code over \((r, d)\) with delay spectrum

\[
\Delta = (T_2, T_2, \ldots, T_2)
\]

such that

\[
\frac{k}{m} = C_{T_2,N_2}
\]

(62)

for any \((T_1, T_2)\) that satisfies \(T_1 + T_2 \leq T\). Consequently, it follows from Lemma 3 that

\[
R_{T,N_1,N_2}^{\text{message}} \geq \max_{(T_1, T_2): T_1 + T_2 \leq T} \min \left\{ C_{T_1,N_1}, C_{T_2,N_2} \right\}.
\]

(63)

For the converse part, we first fix an \((N_1, N_2)\)-achievable message-wise DF \((n, m, k, d)_F\)-code where \(\max_{0 \leq \ell \leq k-1} \tau_\ell \leq T\). By Definition 17, there exist non-negative integers \(T_1\) and \(T_2\) such that \(T_1 + T_2 \leq T\).
\[ d = ((T_1, T_1 + T_2), (T_1, T_1 + T_2), \ldots, (T_1, T_1 + T_2)). \]

Since the first-hop and second-hop delay profiles are \((T_1, T_1, \ldots, T_1)\) and \((T_2, T_2, \ldots, T_2)\) respectively, the \((N_1, N_2)\)-achievable \((n, m, k, d)_{TF}\)-code restricted to \((s, r)\) and \((r, d)\) can be respectively viewed as an \(N_1\)-achievable point-to-point \((n, k, T_1)\)-streaming code and an \(N_2\)-achievable point-to-point \((m, k, T_2)\)-streaming code (cf. Definition 4 and Definition 8). Therefore, we obtain by Theorem 2 that \(k/n \leq C_{T_1, N_1}\) and \(k/m \leq C_{T_2, N_2}\). It then follows from Definition 18 that

\[ R_{T, N_1, N_2}^{\text{message}} \leq \max_{(T_1, T_2): T_1 + T_2 \leq T} \min \{ C_{T_1, N_1}, C_{T_2, N_2} \}. \]

(65)

Using Theorem 1 and Theorem 3, we conclude that

\[ R_{T, N_1, N_2}^{\text{message}} < C_{T, N_1, N_2} \]

(66)

if and only if \(T > N_1 + N_2\). In other words, message-wise DF is sub-optimal if and only if \(T > N_1 + N_2\). The sub-optimality of message-wise DF can also been seen in Figure 5 which shows that the set of achievable pairs \((N_1, N_2)\) for symbol-wise DF is strictly larger than that for message-wise DF under the two constraints that \(T\) equals 11 and the rate is no smaller than 2/3.

### 7 Numerical Results

Consider a statistical three-node relay network where i.i.d. erasures are independently introduced to both channels, and let \(\alpha = P\{e_0 = 1\}\) and \(\beta = P\{e_0 = 1\}\) be the respective probabilities of experiencing an erasure in each time slot for channels \((s, r)\) and \((r, d)\). We will compare the symbol-wise DF and message-wise DF schemes constructed by concatenating point-to-point streaming codes as prescribed by Lemma 3 (constructing block codes), Lemma 4 (constructing point-to-point streaming codes from block codes) and Lemma 5 (constructing DF schemes by concatenating two point-to-point streaming codes). More precisely, we will consider symbol-wise DF and message-wise DF schemes constructed by concatenating an \((n, k, T_1)_{TF}\)-code and an \((m, k, T_2)_{TF}\)-code.
where $F$ is chosen to satisfy $|F| \geq T + 1$. We will also consider an instantaneous forwarding (IF) strategy which uses a point-to-point streaming code (as prescribed by Lemma 3 and Lemma 4) over the three-node relay network as if the network is a point-to-point channel. More specifically, the source transmits symbols generated by the streaming code and the relay under the IF strategy forwards every symbol received from $(s, r)$ to $(r, d)$ in each time slot. The overall point-to-point channel induced by the IF strategy experiences an erasure if either one of the channels experiences an erasure. It follows from (1) that the IF strategy achieves the theoretical rate $C_{T,N_1+N_2}$.

In order to demonstrate the advantage of using symbol-wise DF over message-wise DF and IF, we investigate their loss probabilities where each loss probability is generated by simulating the schemes over $10^8$ channel uses. Suppose $T = 11$. Choose an arbitrary finite field $F$ such that $|F| \geq T + 1 = 12$. Consider every symbol-wise DF, message-wise DF and IF scheme with finite field $F$ and delay $T = 11$ such that the coding rate is greater than or equal to $2/3$. Our simulation results reveal the following:

1) The symbol-wise DF scheme which concatenates two 3-achievable point-to-point $(9, 6, 8)$-codes achieves the lowest loss probabilities among all symbol-wise DF schemes with rate no less than $2/3$.

2) The message-wise DF scheme which concatenates two 2-achievable point-to-point $(6, 4, 5)$-codes achieves the lowest loss probabilities among all message-wise DF schemes with rate no less than $2/3$. Although the message-wise DF that concatenates a 2-achievable point-to-point $(6, 4, 5)$-code and a 2-achievable point-to-point $(7, 5, 6)$-code achieves the same rate $2/3$, it is not the best message-wise DF strategy because a point-to-point $(6, 4, 5)$-code can correct more erasure patterns than a point-to-point $(7, 5, 6)$-code. For example, the periodic erasure pattern shown in Figure 6 can be perfectly recovered by a point-to-point $(6, 4, 5)$-code but not a point-to-point $(7, 5, 6)$-code.

3) The IF scheme which uses a 4-achievable point-to-point $(12, 8, 11)$-code achieves the lowest loss probabilities among all IF schemes with rate no less than $2/3$.

We plot in Figure 7 the loss probabilities of the aforementioned symbol-wise DF, message-wise DF and IF schemes with lowest loss probabilities. As shown in Figure 7, symbol-wise DF uniformly outperforms both message-wise DF and IF for $0.01 \leq \alpha = \beta \leq 0.1$ where each scheme is operated at rate $2/3$ with decoding delay $T = 11$.

8 Concluding Remarks

The maximum coding rate of streaming codes with decoding delay $T$ that correct $N_1$ and $N_2$ erasures introduced by the respective channels $(s, r)$ and $(s, r)$ is proved to be $C_{T,N_1,N_2}$ as state in Theorem 1. The maximum coding rate can be achieved by symbol-wise DF. Symbol-wise DF outperforms message-wise DF if and only if $T > N_1 + N_2$ as shown in Section 6. All the results presented in this paper can be easily generalized to the
Fig. 7: Loss probabilities for symbol-wise DF, message-wise DF and IF with rate $2/3$ and erasure probabilities $\alpha = \beta$ when $T = 11$

following sliding window model: The erasures introduced by channels $(s, r)$ and $(s, r)$ are at most $N_1$ and $N_2$ respectively for any sliding window consisting of $T + 1$ consecutive time slots. Numerical results in Section 7 demonstrate that symbol-wise DF outperforms both message-wise DF and instantaneous forwarding (IF) for some three-node relay network where the channels are subject to i.i.d. erasures.

Future work may explore streaming codes over the three-node relay network that correct both burst and arbitrary erasures and investigate the corresponding maximum coding rate, similar to the studies carried out for the point-to-point channel in [12], [16]. Another direction may generalize the existing streaming models for point-to-point channels [13], [14], [15] and investigate the corresponding streaming codes over the three-node relay network. As explained in the Introduction, the motivation behind studying streaming codes over the three-node relay network is to explore streaming codes that are suitable for low-latency applications in a practical cloud CDN that spans across continents. Therefore, future studies may implement the symbol-wise DF, message-wise DF and IF relaying strategies over the data centers in a practical cloud CDN.

**APPENDIX A**

**DERIVATIONS IN THE CONVERSE PROOF OF THEOREM 1**

Derivation of (24): For all $\ell \in \mathbb{Z}_+$,

$$\left| \left\{ \ell, \ell + 1, \ldots, \ell + T - N_2 \right\} \cap \{i(T - N_2 + 1), 1 + i(T - N_2 + 1), \ldots, T - N_1 - N_2 + i(T - N_2 + 1)\} \right| = T - N_1 - N_2 + 1. \quad (67)$$
Using the chain rule, we have

\[
H \left( s_0, s_1, \ldots, s_{T-N_2+j-1}(T-N_2+1) \right) \left\{ X_i(T-N_2+1), X_1+i(T-N_2+1), \ldots, X_{T-N_1-N_2+i(T-N_2+1)} \right\}_{i=0}^j
\]

\[
= \sum_{\ell=0}^{T-N_1+1} (j-1)(T-N_2+1) H \left( s_\ell \left| \{X_i(T-N_2+1), X_1+i(T-N_2+1), \ldots, X_{T-N_1-N_2+i(T-N_2+1)}\}_{i=0}^j, s_0, s_1, \ldots, s_{\ell-1} \right. \right)
\]

\[
= 0
\]

where the last equality is due to (67) and (23).

**Derivation of** (28): Since the \((N_1, N_2)\)-achievable \((n, m, k, T)\) streaming code restricted to channel \((s, r)\) can be viewed as an \(N_1\)-achievable point-to-point \((n, k, T - N_2)\)-code that can correct the periodic erasure sequence \(\hat{e}^\infty\) illustrated in Figure 3, it follows from the arguments in [16, IV-A] that (26) holds. For the sake of completeness, we present a rigorous proof below.

Since \(j(T - N_1 + 1)\) source messages can take \(|\mathbb{P}|^{k \times j(T - N_1 + 1)}\) values and \((j + 2)(T - N_1 - N_2 + 1)\) relay transmitted packets can take at most \(|\mathbb{P}|^{m \times (j+2)(T - N_1 - N_2 + 1)}\) values for each \(j\), it follows from (28) that

\[
|\mathbb{P}|^{k \times j(T - N_1 + 1)} \leq |\mathbb{P}|^{m \times (j+2)(T - N_1 - N_2 + 1)}.
\]

Taking logarithm on both sides of (70) followed by dividing both sides by \(j\), we have

\[
k(T - N_1 + 1) \leq m(1 + 2/j)(T - N_1 - N_2 + 1).
\]

Since (71) holds for all \(j \in \mathbb{N}\), it follows that (26) holds.

**Derivation of** (28): For all \(\ell \in \mathbb{Z}_+\),

\[
\left| \{\ell + N_1, \ell + N_1 + 1, \ldots, \ell + T\} \cap \{N_1 + N_2 + i(T - N_1 + 1), N_1 + N_2 + 1 + i(T - N_1 + 1), \ldots, T + i(T - N_1 + 1)\}_{i=0}^j \right|
\]

\[
= T - N_1 - N_2 + 1.
\]

Using the chain rule, we have

\[
H \left( s_0, s_1, \ldots, s_{T-N_2+j-1}(T-N_2+1) \right) \left\{ X_i(T-N_2+1), X_1+i(T-N_2+1), \ldots, X_{T-N_1-N_2+i(T-N_2+1)} \right\}_{i=0}^j
\]

\[
= \sum_{\ell=0}^{T-N_1+1} (j-1)(T-N_2+1) H \left( s_\ell \left| \{X_i(T-N_2+1), X_1+i(T-N_2+1), \ldots, X_{T+N_i+1}(T-N_1+1)\}_{i=0}^j, s_0, s_1, \ldots, s_{\ell-1} \right. \right)
\]

\[
\leq 0
\]

where the inequality is due to (72) and (27).

**Derivation of** (30): Since the \((N_1, N_2)\)-achievable \((n, m, k, T)\) streaming code restricted to channel \((r, d)\) can be viewed as an \(N_2\)-achievable point-to-point \((m, k, T - N_1)\)-code that can correct the periodic erasure sequence \(\hat{e}^\infty\) illustrated in Figure 3, it follows from the arguments in [16, IV-A] that (28) holds. For the sake of
completeness, we present a rigorous proof below.

Using (24), we have

$$|F|^{k \times j(T - N_2 + 1)} \leq |F|^{n \times (j + 1)(T - N_2 - N_1 + 1)},$$

(76)

because \(j(T - N_2 + 1)\) source messages can take \(|F|^{k \times j(T - N_2 + 1)}\) values and \((j + 1)(T - N_2 - N_1 + 1)\) source packets can take at most \(|F|^{n \times (j + 1)(T - N_2 - N_1 + 1)}\) values for each \(j\). Taking logarithm on both sides of (76) followed by dividing both sides by \(j\), we have

$$k(T - N_2 + 1) \leq n(1 + 1/j)(T - N_1 - N_2 + 1).$$

(77)

Since (77) holds for all \(j \in \mathbb{N}\), it follows that (30) holds.

\[\square\]

**APPENDIX B**

**PROOF OF LEMMA 4**

Fix a natural number \(k\) and a delay spectrum \(\Delta = (\Delta_0, \Delta_1, \ldots, \Delta_{k-1})\). Suppose we are given an \(N\)-achievable point-to-point \((n, k, \Delta)\)-block code over \((u, v)\), and let

$$G = [I_k \ P] \in \mathbb{F}^{k \times n}$$

(78)

be the generator matrix. By Definition 15, the \((n, k, \Delta)\)-block code has the following properties:

(i) The length of the block code is \(n\).

(ii) From time 0 to \(k - 1\), the source symbols

$$[x[0] \ x[1] \ \cdots \ x[k - 1]] = [s[0] \ s[1] \ \cdots \ s[k - 1]]$$

(79)

are transmitted.

(iii) From time \(k\) to \(n - 1\), the parity-check symbols

$$[x[k] \ x[k + 1] \ \cdots \ x[n - 1]] = [s[0] \ s[1] \ \cdots \ s[k - 1]] \ P$$

(80)

are transmitted.

(iv) Upon receiving

$$[y[0] \ y[1] \ \cdots \ y[\min\{\ell + \Delta_\ell, n - 1\}]]$$

$$= [g_1(x[0], e_0) \ g_1(x[1], e_1) \ \cdots \ g_1(x[\min\{\ell + \Delta_\ell, n - 1\}], e_{\min\{\ell + \Delta_\ell, n - 1\}})],$$

(81)

the destination can perfectly recover \(s[\ell]\) by time \(\min\{\ell + \Delta_\ell, n - 1\}\) for each \(\ell \in \{0, 1, \ldots, k - 1\}\) as long as \(e^\infty \in \Omega_N\).
In order to construct an $N$-achievable point-to-point $(n, k, \Delta)$-streaming code (cf. Definition 16), we first let $\{u_i\}_{i=0}^\infty$ denote a sequence of length-$k$ packets and let $u_i[\ell]$ denote the $(\ell + 1)^{th}$ element of $u_i$ such that

$$u_i \triangleq [u_i[0] \ u_i[1] \ \cdots \ u_i[k-1]] \quad (82)$$

for all $i \in \mathbb{Z}_+$. Then, construct

$$[x_i[0] \ x_{i+1}[1] \ \cdots \ x_{i+n-1}[n-1]] \triangleq [u_i[0] \ u_{i+1}[1] \ \cdots \ u_{i+k-1}[k-1]] \mathbf{G} \quad (83)$$

for each $i \in \mathbb{Z}_+$ where $\mathbf{G}$ is the generator matrix of the $N$-achievable $(n, k, T)$-block code. In other words, we are coding $u_i$ diagonally as illustrated in Table 5. At each time $i \in \mathbb{Z}_+$, node $u$ transmits

$$x_i^{(u)} \triangleq [x_i[0] \ x_i[1] \ \cdots \ x_i[n-1]]. \quad (84)$$

Based on the $N$-achievable $(n, k, \Delta)$-block code which satisfies Properties (i) to (iv) as stated at the beginning of this proof, we construct an $(n, k, \Delta)$-streaming code where $u_i$ and $x_i^{(u)}$ satisfy (82), (83) and (84). Our goal is to show that the streaming code is $N$-achievable. To this end, we fix any $i \in \mathbb{Z}_+$ and any $e^\infty \in \Omega_N$, and would like to show that node $v$ can perfectly recover $u_i = [u_i[0] \ u_i[1] \ \cdots \ u_i[k-1]]$ based on

$$[y_0^{(v)} \ y_1^{(v)} \ \cdots \ y_{i+T}^{(v)}] = [g_n(x_0^{(u)}, e_0) \ g_n(x_1^{(u)}, e_1) \ \cdots \ g_n(x_{i+1}^{(u)}, e_{i+T})]. \quad (85)$$

According to (84), for each $i \in \mathbb{Z}_+$, $[x_i[0] \ x_{i+1}[1] \ \cdots \ x_{i+n-1}[n-1]]$ are transmitted from time $i$ to $i + n - 1$. Therefore, it follows from (83), Property (iv) and (85) that for each $i \in \mathbb{Z}_+$ and each $\ell \in \{0, 1, \ldots, k-1\}$, the destination can perfectly recover $u_i[\ell]$ by time $i + \Delta_\ell$ based on $[y_1^{(v)} \ y_{i+1}^{(v)} \ \cdots \ y_{i+\Delta_\ell}^{(v)}]$. Consequently, for any $i \in \mathbb{Z}_+$ and any $e^\infty \in \Omega_N$, the destination can perfectly recover $u_i[\ell]$ by time $i + \Delta_\ell$ for each $\ell \in \{0, 1, \ldots, k-1\}$, which implies by Corollary 2 that the $(n, k, \Delta)$-convolutional code is $N$-achievable.

**APPENDIX C**

**PROOF OF LEMMA 5**

Suppose we are given an $N_1$-achievable point-to-point $(n, k, t)$-code and an $N_2$-achievable point-to-point $(m, k, \Delta)$-code where $t = (t_0, t_1, \ldots, t_{k-1})$ and $\Delta = (\Delta_0, \Delta_1, \ldots, \Delta_{k-1})$. We would like to concatenate the two codes over the three-node relay network such that the $(n, k, t)$-code and the $(m, k, \Delta)$ are used over $(s, r)$ and $(r, d)$ respectively. To this end, we first let $\{f_s^{(t)}\}_{i\in \mathbb{Z}_+}$ and $\{f_r^{(r)}\}_{i\in \mathbb{Z}_+}$ be the encoding functions of the $(n, k, t)$-code and the $(m, k, \Delta)$-code respectively. Consider the following symbol-wise DF scheme constructed by concatenating the two point-to-point codes.

For each time $i \in \mathbb{Z}_+$, let $s_i = [s_i[0] \ s_i[1] \ \cdots \ s_i[k-1]]$ denote the $k$ symbols transmitted by node $s_i$ let

$$x_i^{(s)} \triangleq f_s^{(s)}(s_0, s_1, \ldots, s_i) \quad (86)$$

be the length-$n$ source packet generated by the $(n, k, t)$-code, and let

$$s_i^{(r)} \triangleq [\hat{s}_i^{(r)}_{-t_0} \ \hat{s}_i^{(r)}_{-t_1} \ \cdots \ \hat{s}_i^{(r)}_{-t_{k-1}} [k-1]] \quad (87)$$
be the \( k \) estimates for \( s_{1-t_0}[0], s_{1-t_1}[1], \ldots, s_{1-t_k}[k-1] \) constructed by the \((n, k, t)\)-code.

In addition, let
\[
\hat{x}_i^{(r)} = f_i^{(r)}(s_0^{(r)}, s_1^{(r)}, \ldots, s_i^{(r)})
\]  
(88)
be the length-\( m \) relay transmitted packet generated by the \((m, k, \Delta)\)-code, and let
\[
\hat{s}_i^{(d)} = \left[ \hat{s}_{i-t_0-\Delta_0}[0], \hat{s}_{i-t_1-\Delta_1}[1], \ldots, \hat{s}_{i-t_k-\Delta_k}[k-1] \right]
\]  
(89)
be the \( k \) estimates for \( s_{1-t_0}[0], s_{1-t_1}[1], \ldots, s_{1-t_k}[k-1] \) constructed by the \((m, k, \Delta)\)-code.

Fix any erasure sequences \( e^\infty \in \Omega_{N_1} \) and \( e^\infty \in \Omega_{N_2} \). Since the \((n, k, t)\)-code is \( N_1 \)-achievable,
\[
\hat{s}_i^{(r)}[\ell] = s_{1-t_\ell}
\]  
(90)
for all \( i \in \mathbb{Z}_+ \) and all \( \ell \in \{0, 1, \ldots, k-1\} \). Similarly, since the \((m, k, \Delta)\)-code is \( N_2 \)-achievable,
\[
\hat{s}_i^{(d)}[\ell] = \hat{s}_{i-t_\ell}[\ell]
\]  
(91)
for all \( i \in \mathbb{Z}_+ \) and all \( \ell \in \{0, 1, \ldots, k-1\} \). Combining (90) and (91), we have
\[
\hat{s}_i^{(d)}[\ell] = s_{i-t_\ell}[\ell]
\]  
(92)
for all \( i \in \mathbb{Z}_+ \) and all \( \ell \in \{0, 1, \ldots, k-1\} \). Since (92) holds for any \( e^\infty \in \Omega_{N_1} \) and \( e^\infty \in \Omega_{N_2} \), the resultant concatenated code is an \((N_1, N_2)\)-achievable \((\max\{n, m\}, k, d)\)-code where \( d \) is as defined in (48).
