Abstract Multiple logic-based reconstructions of conceptual data modelling languages such as EER, UML Class Diagrams, and ORM exist. They mainly cover various fragments of the languages and none are formalised such that the logic applies simultaneously for all three modelling language families as unifying mechanism. This hampers interchangeability, interoperability, and tooling support. In addition, due to the lack of a systematic design process of the logic used for the formalisation, hidden choices permeate the formalisations that have rendered them incompatible. We aim to address these problems, first, by structuring the logic design process in a methodological way. We generalise and extend the DSL design process to apply to logic language design more generally and, in particular, by incorporating an ontological analysis of language features in the process. Second, we specify minimal logic profiles availing of this extended process, including the ontological commitments embedded in the languages, of evidence gathered of language feature usage, and of computational complexity insights from Description Logics (DL). The profiles characterise the essential logic structure needed to handle the semantics of conceptual models, therewith enabling the development of interoperability tools. There is no known DL language that matches exactly the features of those profiles and the common core is small (in the tractable DL $\mathcal{ALNI}$). Although hardly any inconsistencies can be derived with the profiles, it is promising for scalable runtime use of conceptual data models.

Keywords Conceptual modelling · modelling languages · language profiles · modelling language use

1 Introduction

Conceptual data models were proposed in the 1970s as a vehicle to describe what has to be stored or processed in the prospective information system or database, aiming to separate those ‘what’ aspects from the design of the ‘how’ to achieve that. Many conceptual data modelling languages (CDMLs) have been proposed over the past 40 years by several research communities (notably, originating from relational databases, object-oriented software) and for a range of motivations, such as spatial entities in geographic information systems, ontology-driven or not, and aiming for simplicity and leanness vs expressiveness. Assessing the modelling features of CDMLs over time, it exhibits a general trend toward an increase in modelling features; e.g., UML has identifiers since v2.4.1 [80], ORM 2 has more ring constraints than ORM [51,52], and EER also supports entity type subsumption and disjointness cf. ER [91,93]. Opinion varies about this feature richness and its relation to model quality [76] and fidelity of capturing all the constraints specified by the customer, and asking modellers and domain experts which features they think they use, actually use, and need showed discrepancies between them [1]. From the quantitative viewpoint, it has been shown that advanced features are being used somewhere by someone, but they are used relatively very few times,
as both the quantitative analysis of CDML feature usage in 168 ORM diagrams [89], and 101 EER, UML, and ORM diagrams have shown [67]. With such insight into feature usage, it is possible to define an appropriate logic as underlying foundation of a CDML so as to not only clarify semantics but also use it for computational tasks. Logic-based reconstructions open up the opportunity for, among others, automated reasoning over a model to improve its quality (e.g., [10,85]) and runtime usage of the models, such as conceptual and visual query formulation [24,26,92] and optimisation of query compilation [96].

Concerning the ‘appropriate’ logic, many logic-based reconstructions have been proposed over the years (discussed below), which can be grouped into either the Description Logics (DL)-based approach that propose logics from viewpoint of computational complexity, rather than needs and usages by modellers, or the as-expressive-as-needed approach, such as in full first-order predicate logic. Neither of these proposals, however, has taken a methodological approach to language design and brush over several thorny details of CDMLs, such as which core types of elements to formalise with their own semantics (aggregation, association ends), whether to include n-aries (when \(n \geq 2\), not \(n = 2\)), and various advanced constraints. This has resulted into an embarrassment of the riches of logic-based reconstructions, which is hampering the actual use of logic-based conceptual data models in information systems and there-with risk sliding into disuse. These problems with the multitude of incompatible ad hoc formalisations raise the questions of

i. How should one design a logic methodologically?

ii. What would be a compatible set of logics for CDMLs that do take into account model feature usage and ontological commitments of CDMLs?

We aim to address these problems and answer these questions in this paper, specifically for the structural fragment of the most widely used CDMLs, because this features most prominently as a core interoperability issue in system integration and needs to be resolved before harmonising any ‘dynamic’ components such as methods. First, we will adapt and extend Frank’s [41] domain-specific language (DSL) design methodology into one suitable for language design more broadly, including conceptual data modelling languages, and informed by language design decision points emanating from ontology. Such ontology-driven language design decisions include, among others, positionalism of relations, the conceptual/computational trade-off and 3-dimensionalist vs. 4-dimensionalist. To the best of our knowledge, this is the first inventarisation of parameters of ontological commitments of language design of information and knowledge representation languages. Second, we apply this to the design of logics for several conceptual data modelling languages that is informed by the language feature usage reported in [67]. These logic ‘profiles’ cover the most often appearing features used, containing those features that cover about 99% of the features used in conceptual data models. The outcome is a so-called ‘positionalist’ and a ‘standard view’ core profile, and three language family profiles formalised in a DL, most of which have a remarkable low computational complexity.

An example of a model in UML Class Diagram notation that can be fully reconstructed into the standard view core profile (more precisely: \(DC_p\)) is included in Fig. 1. It has a logical underpinning thanks to the knowledge base construction rules and three algorithms we propose in this paper, and therewith also has grounded equivalents in EER and ORM notation.

This paper builds upon several previous papers on this topic [66,67,68,65,67]. The main novel contributions in this paper are: i) methodological language design, including ontological aspects involved in it; ii) a new positional core profile; and iii) the profiles have been defined with a formal syntax and semantics. The remainder of the paper is structured as follows. The state of the art and related works are discussed in Section 4. Section 3 presents our first contribution, which is a first inventarisation and discussion of ontological issues that affect language design. Our second main contribution is the logic-based profiles, which are described in Section ii. We close with a discussion in Section 5 and conclusions in Section 6.

2 Related work

Many conceptual data modelling languages have been proposed over the past 40 years; e.g., UML [80], EER [27,91,93] and its flavours such as Barker ER and 1E notation, ORM [50,52] and its flavours such as CogniAM and FCO-IM, MADS [83], and Telos [78]. Some of those are minor variants in notation, whereas others have to a greater or lesser extent a different number of features. Some ‘families’ of languages can be identified, which basically still run along the lines from which subfield it was originally developed. Notably, ER and EER originate from the relational database community [27], UML Class Diagrams from object-oriented programming [80], and ORM [52] bears similarities with semantic networks and can be used for conceptual modelling for both database and object-oriented programming, and more recently also business rules. Each ‘family’ has their own set of preferred tools and community of users.
Evidence-based lean conceptual data modelling languages

Besides these three main groups, some CDMLs have been developed specifically for additional features (e.g., temporal extensions) or somewhat revised graphical notations of the elements, such as different colours and a so-called ‘craw’s feet’ icon vs .n or ..* for ‘many’ multiplicity/cardinality. We will not address this here, but instead will focus on the underlying language features from a logic-based perspective to which the best graphical elements could be attached as ‘syntactic sugar’ (see, e.g., [25,62] for this approach), and language design.

2.1 Logic-based reconstructions of CDMLs

A lot of effort has gone into trying to formalise conceptual models for two principal motivations: 1) to be more precise to improve a model’s quality and 2) runtime usage of conceptual models. Most works are within the scope of the first motivation. Notably, various DLs have been used for giving the graphical elements a formal semantics and for automated reasoning over them, such as [2,10,50,51,53,56], although also other logics are being used, including OCL [55], CLIF [52], Alloy [13], and Z [56]. There are also different approaches, which are more interested in the verification problem, notably using some variant of constraint programming [16,17].

Zooming in on DLs, the ALUNI language has been used for a partial unification of CDMLs [25], whereas other languages are used for particular modelling language formalisations, such as DL-Lite and DCRL for ER [2] and UML [10], and OWL for ORM and UML [99]. These logic-based reconstructions are typically incomplete with respect to the CDML features they cover, such as omitting ER’s identifiers (‘keys’) [25] or n-aries [2,99], among many variants. Also, multiple formalisations in multiple logics for one conceptual modelling language have been published. ORM formalisations can be found in, among others, [10,50,54,58,86], noting that full ORM and ORM2 (henceforth abbreviated as ‘ORM/2’) is undecidable due to arbitrary projections over n-aries and the acyclic role constraints (and probably antisymmetry). Even for the more widely-used ER and EER (henceforth abbreviated as ‘(E)ER’), multiple logic-based reconstructions exist from the modeller’s viewpoints [27,91,93] and from the logician’s vantage points with the DLR family [20,21,22] and DL-Lite family [23] of languages.

The second principal reason for formal foundations of CDMLs, runtime usage, comprises a separate track of works, which looks as very lean fragments. The driver for language design here is computational complexity and scalability, and the model is relegated to so-called ‘background knowledge’ of the system, rather than the prime starting point for software development. Some of the typical runtime usages are: scalable test data generation for verification and validation [77,89] and ontology-mediated query answering that involves, among others, user-oriented design and execution of queries [11,12,20,22], querying databases during the stage of query compilation [96], and recent spatio-temporal stream queries that avail of ontology-based data access [57,61,81].

In sum, many logics are used for many fragments of the common CDMLs, where the fragments have been chosen for complexity or availability reasons rather than for which features a modeller actually uses.
2.2 Language design

The design of a modelling or knowledge representation language may be considered as an engineering task, involving several steps and decision points among alternatives. For instance, a requirement could be that the language has to be decidable in subsumption reasoning or that it needs to have n-ary relations, that one can use it for at least the use cases specified upfront, and that it has to have a graphical syntax. Systematic approaches to language design have been developed, especially the design pipeline of Frank [41] and noting others that either focus on one aspect only (e.g., the requirements engineering step [71]) or offer guidelines applicable to one class of modelling language specifically (e.g., domain-specific languages [59]). We include here a summary of Frank’s waterfall model for domains-cvatively (e.g., domain-specific languages [59]). We include here a summary of Frank’s waterfall model for domains-specific modelling languages [41], as shown in Figure 2, with the steps we focus on in this paper highlighted. We will step through these stages briefly and with respect to applicability and related works on CDML design.

For step 1, the scope is conceptual data modelling languages, and the goals are at least model interoperability and, at least to some extent if feasible, runtime use of conceptual models for so-called ‘intelligent systems’ or ontology or conceptual-model driven information systems.

Regarding steps 2 and 3, to the best of our knowledge, there is no requirements catalogue for CDMLs (step 2/3a), but several use cases (step 2/3b) have been reported in scientific literature; e.g., the term-banks for multiple languages requiring interoperability among ER and UML [65] and runtime integration of information about food in the Roman Empire with ORM [28]. Assigning priorities (step 2/3c) has been done for several languages, but mostly not explicitly. For instance, a priority may be the computational complexity of the problem of satisfiability checking, scalability in the presence of large amounts of data (e.g., the OWL 2 QL modelling language) or a scalable model (e.g., OWL 2 EL) [76], or to have many language features to cover corner cases such as the “narcissist” as the single example for the need for local reflexivity (in SROIQ [55]). Tables with alternative sets of conflicting requirements are available, such as the pros and cons of several logics for formalising conceptual models [36] and trade-offs for representing the KEGMT mereotopology in various logics [60]. For the CDMLs, it has yet to be decided how to assign priorities. One could survey industry [72], but it has been shown in at least one survey that modellers do not know the features well enough to be a reliable source [1]. Thus, existing works fall short on providing answers to steps 2 and 3.

There are many papers describing a language specification (step 4), with the DLs the most popular by number of papers. Most of these papers do not have a metamodel, however. Regarding existing metamodels one may be able to reuse for the language specification: there are proposals essentially in the conceptual modelling community, spanning theoretical accounts (e.g., [53, 58]), academic proof-of-concept implementations [6, 12, 88], and industry-level applications, such as in the Eclipse Modeling Framework [1]. The UML diagrams in the OWL and UML standards [77, 50] are essentially metamodels as well. To enable a comparison between CDMLs, a unified metamodel is required, which reduces the choice to [61, 12, 88]. The most recent metamodel [88] covers all the static structural components in unifying UML Class Diagrams, ER and EER, and ORM and ORM2 at the metamodel layer cf. the subsets in [61, 12, 88], and has both a glossary of elements and the constraints among them. It was developed in UML Class Diagram notation for communication [68] and formalised for precision [35].

Step 5 in the language design pipeline—design of a graphical notation—is straightforward for the current scope, for it will be mapped onto the graphical notation of UML Class diagrams, EER, and ORM2. The architecture of the tool (step 6) is being worked on [37, 14], and only after that can one do step 7, which is thus outside of the current scope.

While the 7-step waterfall process for domain-specific languages is generally applicable for logic-based CDML design as well, some ontological analysis during steps 2-4 should improve the outcome, to which we shall return in Section 3. The case for, and benefits of, using insights from ontology (analytic philosophy) to advance the modelling has been well-documented [43, 44], with many papers detailing improvements on precision of representing the information; e.g., deploying the UFO foundational ontology to improve the UML 2.0 metamodel [39] and examining the nature of relationships [61, 48], and more general philosophical assessments about conceptual models, such as regarding concepts [84] and 3D versus 4D conceptual models [100].

Thus, current resources fall short especially on a clear requirements specification and priority-setting for CDMLs and on ontology-driven language design. We will contribute to filling these gaps in the following two sections.

2.3 Quantitative assessments on language feature use

To the best of our knowledge, there are only two studies with a quantitative approach to CDML feature usage, which examined ORM diagrams that are used in industry and were developed by one modeller [89] and examined publicly available EER, UML, and ORM diagrams [67], whose ORM data are similar to those reported in [89]. The diagrams in the dataset of [67] were analysed using a unified metamodel [68], which facilitated cross-language comparisons and categorisation of entities in those languages into the harmonised terminology. A relevant selection of the terminology across the languages is included in Table 1. This metamodel’s top-type is Entity that has four immediate subclasses: Relationship with 11 subclasses, Role, Entity type with 9 subclasses, and Constraint that has 49 subclasses (i.e., across the three CDML families, there are 49 different types of constraint). In addition to the hierarchy, the entities have constraints declared among them to constrain their use; e.g., each relationship must have at least two roles and a disjoint object type constraint is only declared on class subsumptions. This metamodel was used to classify the entities of the diagrams in a set of 101 UML, (E)ER, and ORM/2 models that were publicly available from online sources, published papers, and textbooks[2]. The average size of the diagram (vocabulary+subsumption) was found to be about 50 entities/diagram, totalling to 8036 entities, of which 5191 (i.e., 64%) were entities that were classified in an entity (language feature) that is included in all three language families and 1108 (13.8%) in ones that are unique to a language family (e.g., UML’s aggregation) [67]. The feature usage results are described and discussed in [67], where it is noted that while most features of each language family is typically used somewhere, both expected and unexpected high or low frequencies have been observed; e.g., disjoint and covering constraints are used sparingly throughout the models, as are ring constraints in ORM and n-aries or association classes in UML. The obtained usage frequency for each entity, together with the design choices described in Section 3, sustain the logic profiles that will be introduced in Section 4.

3 Design choices for logic-based profiles

One could take the evidence of which CDML features are used most, and design a logic for it, or pick a logic one likes and make the best out of a logic-based reconstruction. This has resulted in an ‘embarrassment of the riches’ in the plethora of logic-based reconstructions, and even more so when the formalisations are examined in detail, for none is the same. The reason for this is that there are several design choices that each can result in a different logic of different computational complexity, using different reconstruction algorithms, with varying tooling support. Such choices have not been stated upfront, but they have to be piecemeal reconstructed by anyone interested in logic foundations for conceptual models, because such decisions are sparsely

---

[11] Fig. 2 Language design, adapted from [11], where the focus of this paper is highlighted in bold and shared (green). The “234. Ontological analysis of language features” has been added to the 7-step process, which is elaborated on in Section 3.

[67] The models, their respective provenance, and raw data analysis are available from [http://www.meteck.org/swdsont.html](http://www.meteck.org/swdsont.html) which is not within the scope of this paper. That experiment design, results, and discussion are described in [67].

discussed in the literature. This brings us to the “4” of the “234. Ontological analysis of language features” extension to Frank’s waterfall procedure [41] for language development (recall Fig. 2 in Section 2.2). The step 4, “language specification”, concerns affordances and features of the logic, such as 1) the ability to represent the conceptualisation more or less precisely with more or less constraints [3] and 2) whether the representation language contributes to support, or even shape, the conceptualisation and one’s data analysis for the conceptual data model for an information system, or embeds certain philosophical assumptions and positions. Regarding the latter, we identified several decision points, which may not yet be an exhaustive list, but it is the first and most comprehensive list to date. They are as follows, and explained and discussed for CDMLs afterward:

1. Should the CDML be ‘truly conceptual’ irrespective of the design and implementation or also somewhat computational? That is, whether the language should be constrained to permit representation of only the what of the universe of discourse vs. not only what but also some how in the prospective system. The typical example is whether to include data types for attributes or not.

2. Are the roles that objects play fundamental components of relationships, i.e., should roles be elements of the language?

3. Will refinements of the kinds of general elements—that then have their own representation element—result in a different (better) conceptual model? For instance,
   (a) to have not just Relationship but also an extra element for, say, parthood;
   (b) to have not just Object type but also refinements thereof so as to indicate ontological distinctions between the kind of entities, such as between a rigid object type and the role it plays (e.g., Person vs Student, respectively, as being of a different kind);
   (c) if only binary relationships are allowed, the modeller may assume there are only binary relations in the world and reifications of n-aries vs the existence of n-aries (\(n \geq 2\)) proper;
   (d) if only object types are allowed, the modeller may assume everything is a countable object in the world, though one may argue that ‘stuff’, such as Wise and Gold, is disjoint from object, and thus would have to be represented with a different element.

4. Does one have a 4-dimensionalist view on the world (space-time worms) and thus a language catering for that or are there only 3-dimensional objects with, perhaps, a temporal extension?

5. What must be named? The act of naming or labelling something amounts to identifying it and its relevance; conversely, if it is not named, perhaps it is redundant.

Little is known about what effects the different decisions may have. The data analysis of [67] indicates that binaries vs n-aries (Item 3c) and just plain relationship vs also with aggregation (Item 3a) does indeed make a difference at least for UML vs (E)ER and ORM/2. UML class diagrams have disproportionately fewer n-aries and more aggregation associations than (E)ER and ORM/2. Regarding the former, it is known that n-aries in UML class diagrams are hard to read due to the look-across notation [88] and it uses a different visual element (diamond vs line), compared to (E)ER and ORM/2 that use the same notation for both binaries and n-aries; an investigation into the ‘syntactic sugar’ of the graphical elements is outside the current scope. The other options in Item 3 are philosophically

---

3 this is distinct from subject domain coverage; to illustrate the difference: being able to represent, say, “has part =2 eyes” vs only “has part ≥ 1 eyes” concerns precision, whereas omitting information about the eyes concerns coverage.
interesting, but unambiguous industry requirements for
them are sparse, except for ‘stuff’, because quantities
of amounts of matter are essential to traceability of in-
gredients in, among others, the food production process
and pills and vaccines production (e.g., {30,90}). In this
case, distinguishing between a countable object and a
specific quantity of an amount of matter can more pre-
cisely relate, say, a specific, numbered, capsule of liquid
medicine and the stock that the medicine came from,
which, could aid investigations in case of contamination
(e.g., the capsule was not cleaned properly vs a contam-
inated batch of liquid). To date, there is no CDML that
includes this distinction other than one proposal for a
UML stereotype by {17} and a set of relations for stuffs
that could refine UML’s aggregation association by {69}.

Continuing with the analysis of Item 3, regarding
Object Type refinements (Item {19}), principled ideas
have been proposed by {19} that avails of notions from
philosophy such as rigidity that then leads to types of
Object Types, like “type” for the kind of objects that
supply an identity criterion (the Person) and “role” that
an object plays (the Student). This has been applied to
UML class diagrams in OntoUML by means of stereот
types {10}. More generally, one could take a founda-
tional ontology, such as UFO, GFO, or DOLCE, and use
those core categories to refine Object Type (and, anal-
ogously, the relationships). Choosing one foundational
ontology may result in the situation where one’s concep-
tual data modelling language—hence, the diagrams—
turns out to be incompatible with one that adheres to
another foundational ontology {69}. At the time of writ-
ing, it is not clear where or how exactly such refine-
ments provide benefits, other than the typical example
of preventing bad hierarchies that OntoClean {15} seeks to
resolve. For instance, to not declare, say, Person as
a subclass of Employee, because the former is a sortal
and the latter is a role that the former plays for a lim-
ited duration. Instead, it either should be the other way
around (Employee is a Person) or sideways (Employee is a
role played by Person). Declaring each Object Type with
their respective category and firing ontological rules,
such as ‘a sortal cannot be subsumed by a role’, could
then detect automatically such quality issues in a dia-
gram. From the viewpoint of logics and formalising
it, something like this can be done with second-order
logic, many-valued logics, or have the elements in the
diagrams be subsumed by the entities in a foundational
ontology.

The identified decision points are now explained in
the following paragraphs.

Conceputal models and features for implementation de-
cisions (Item {7}) It is known theoretically at least that
incorporating design and implementation decisions into
a model reduces potential for interoperability and in-
tegration with other systems. Two common examples
are declaring data types of attributes (in UML and
ORM/2) and entity type-specific attributes (in (E)ER
and UML) vs value types that can be shared among
entity types (ORM). ER and EER do not have data
types, and its selection is pushed down to the design
or implementation stage in the waterfall methodology
of database development; e.g., whether some attribute
length should be recorded in integer or float is irre-
evant in the data analysis stage. ORM’s Value Types,
in contrast to attributes, can be reused by multiple en-
tity types and can easily be reverted into entity types
with minimal disruption to the diagram; e.g., a value
type length means the same thing regardless whether
it is used for the length of a Sofa or a Table for some
furniture database. Of course, one can convert between
attributes and value types {30}, but a Value Type ele-
ment in the language enables extra analysis regarding
common semantics in a model and constraint specifi-
cation.

Practically, for the design of a logic, the inclusion
of value types entails that one has two types of object
types: one that can relate only to other object types
and another, disjoint, one that relates to a data type.
The inclusion of attributes affects the language insofar
as one wants to create, or already has, a type of rela-
tion that relates an object type to a data type, such as
OWL’s Data Property.

Ontological commitments for relationships (Item {3}) To
determine whether one would want ‘roles’ in the lan-
guage, let us first illustrate the possible decisions that
Item {2} asks for. Irrespective of the representation de-
cision, there is some relationship, say, teach that holds
between Professor and Course. One can take the decision
of ‘just predicates’, which means that there is assumed
to be no teach relationship, or at least not represented
as such, but there would be at least one predicate, teaches
or taught by in which Professor and Course participate
in that specific order or in the reverse, respectively. An
alternative decision is to choose for the ‘there are roles
too’-option. Here, Professor plays a role, say, [lecturer],
in the relationship teach and Course plays the role [sub-
ject] in the relationship teach; hence, role is an element
in the language and deemed to be part of the so-called
‘fundamental furniture’ of the universe. This distinction
between predicates-only and roles-too has been inves-
tigated by philosophers, and are there called standard
view and positivist, respectively. It has been argued
that the positivist commitment with roles (argument
places) is ontologically a better way characterising rela-
tions than the standard view that enforces an artificial ordering of the elements in the relation and requires inverses, and it is also deemed better with respect to natural language interaction and expressing more types of constraints.

This has been discussed at some length in [30] from a computational perspective, because the main issue is that the CDMLs are all positionalist, yet most logics use predicates with the standard view. This is not to say one cannot define roles in, say, FOL, but the notion of role as a component of an n-ary predicate is not an element of FOL (it just has predicates, functions, and constants), i.e., FOL adheres to the standard view by design. An example of a positionalist logic is DLR and its related logics in the DLR family, where the syntax does include a “DL role component” for the DL roles and it has a corresponding semantics; e.g., an aggregation relationship could then be specified as \( \text{aggregate} \subseteq [\text{part}]C \times [\text{whole}]D \) where concept \( C \) plays the role of part in the binary \( \text{aggregate} \) and \( D \) plays the role of the whole in that relationship.

To address the impasse between CDMLs on the one hand and most logics on the other, there are several options. One could commit to a logic-based reconstruction into a positionalist language, such as those in the DLR family, which are used for partial reconstructions of ER, UML class diagrams, and ORM include roles in the Z formalisation, or one that is yet to be designed. One also could deny positionalism in some way and force it into a standard view logic. For instance, one could change the \{lecturer\} and \{subject\} roles into a \{teaches\} and/or a \{taught by\} predicate and declare them as inverses if both are included in the vocabulary, or pick one of the two and represent the other implicitly through \{taught by\} or \{teaches\}, respectively. Sampling decisions made in related works showed that, e.g., Pan and Liu use a hybrid of both roles and predicates for ORM and its reading labels also may be “promoted” to relationships, the original ORM formalisation was without roles in the language, and ORM’s association ends are sometimes ignored as well (e.g., [11,84]), but not always [10].

Exploring the conversion strategies brings one to the computational complexity of the logic. Mostly, adding inverses does not change the worst-case computational complexity of a language; e.g., ALCQ and ALCQIQ are both ExpTime-complete under GCIs. A notable exception is the OWL 2 EL profile that does not have inverse object properties.

3D vs. 4D (Item 4) The 3-dimensionalist approach takes objects to be 3-dimensional in space where the objects are wholly present at each point in time (i.e., they do not have temporal parts). Statements are true at the ‘present’, whilst being ignorant of the object in the past and future. If one wants to deal with time, it is added as an orthogonal dimension, as in, e.g., [3]. The 4-dimensionalist approach, sometimes also called “fluent”, takes entities to exist in four dimensions, being space+time, they are not wholly present at each point in time, and do have temporal parts. Any statements can be about not only the present, but also the past and future (e.g., [9,100]). A typical example in favour of 4D is to represent as accurately possible the notion of a holding or supra-organisation, such as Alphabet and Nestlé: these companies exist for some time and keep their identity all the while they acquire and sell other (subsidiary) companies. In a 3D-only representation, one would have a record of which companies they own now, but not whether they are the same ones as last year (unless temporal information is added in some way; e.g., through database snapshots or time stamps).

The predominant choice of conceptual data modelling languages is 3D, although temporal extensions do exist especially for ER (e.g., [4,64]). We could not find any evidence that can explain why this is the case.

Naming things (Item 5) The act of naming things entails the interaction between natural language and ontology. We do not seek to discuss that millennia-old philosophical debate here, but one that is applied within the current context. Naming elements happens differently across the three CDML families. For instance, in UML Class Diagrams, the association ends must be named but the association does not necessarily have to be named, which typically is the other way around in (E)ER except for recursive relations, whereas ORM diagrams commonly only have reading labels of a relationship rather than naming either the roles or the relationship themselves. ORM thus clearly distinguishes between the conceptual layer and the natural language layer, but such workings are not taken into account explicitly in any of the formalisations, nor has it been explicitly decided whether it should be, other than in a model for roles in [63]. A systematic solution to this natural language ↔ ontology interaction has been investigated in the context of the Semantic Web, where the natural language dimension has its own extension on top of an OWL file [18], although it still relies on
naming classes and object properties. What the three CDML families do have in common is that object types are always named.

For designing a logic, this may not matter much, but it will have an effect on the algorithms to reconstruct the diagrams into a logical theory.

Engineering factors As opposed to principles for design with respect to ontological commitments of a logic, there are also practical considerations one may want to take into account. This refers principally to scalability for use of the logic in an intelligent information systems, and the tooling available for the logic for the various support activities, such as an automated reasoner. For instance, (full) first order predicate logic (FOL) is undecidable, unlike the myriad of FOL fragments in the DL family of languages that are typically more computationally well-behaved [8].

Automated reasoners offer various services, some of which are more relevant to the context of conceptual data modelling, such as class satisfiability and advanced querying of data, than others (e.g., proving a theorem). Other practical aspects are ease of use of a tool to design the model (theory), whether a language permits importing other models, and whether other systems are interoperable with it. For instance, OWL 2, by design, allows one to import other ontologies through its import statement [77]. Even more so with respect to modular approaches to design, is the Distributed Ontology, Model, and Specification Language DOL [6], which provides a metalanguage to link models in various logics, including up to second order logic; hence, interoperability with DOL may facilitate its practical use.

Assessment of popular languages and their commitments We assessed the relatively frequently occurring logics for formalising conceptual data models on whether it would be possible to choose a ‘best fit’ language. This comparison is included in Table 2. The first section of the table summarises the main design decisions discussed in the preceding paragraphs, whereas the second part takes into consideration non-ontological aspects with an eye on practicalities. Such practicalities include among others, scalability, tooling support, and whether it would be easily interoperable with other systems.

The first section in the table suggests $\mathcal{DL}_\text{R/ld}$ and FOL are good candidates for logic-based reconstructions of conceptual data models; the second section has more positive evaluations for $\mathcal{DL}$-Lite$\mathcal{A}$ and OWL 2 DL. Put differently: neither of them is ideal, so one may as well design one’s own language for the best fit.

4 Logic-based profiles for conceptual data modelling languages

We now proceed to define logics to characterise the model-theoretic semantics such that it is minimalist with respect to the most-used features for each of the three families of CDMLs. This takes into account the ontological considerations discussed in the previous section as well as the evidence from [67] and the requirement to have a coverage of around 99% of the used entities and constraint. Because of afore-mentioned ontological reasons in favour of roles as well as that all three CDML families are positionalist, a Positionalist Core is defined despite its current lack of implementation support (Section 4.1.1). Afterward, a standard view Standard Core and language-specific profiles are defined in Sections 4.1.2-4.1.5.

An overview of the upcoming definitions and algorithms is shown in Fig. 3. These profiles constitute a theoretical backbone for an interoperability tool between conceptual model expressed in different graphical languages and with different philosophical assumptions. The main distinction is the positionalist or the standard view, resulting in profiles $\mathcal{DC}_p$ and $\mathcal{DC}_s$, which each formalise the most widely used language features. The standard view profile is then extended into three different profiles one for each CDML, and serves as background knowledge to be exchanged between profiles. In order to interoperate from the positionalist and the standard view profiles some compromises must be taken, described mainly in Algorithm 1. Importing conceptual models into CDML may be carried out also with this theoretical structure, while exporting may be done by translating reasoner output into a suitable textual representation.

4.1 Profiles

Positionalism is the underlying commitment of the relational model and a database’s physical schema, as well as of the main CMDLs. It has been employed in Object-Role Modelling (ORM) and its precursor NIAM for the past 40 years [52]. UML Class Diagram notation requires association ends as roles, and Entity-Relationship (ER) Models have relationship components [36]. On the other hand, First Order Logic and most of its fragments, notably standard DLs [8], do not exhibit roles (DL role components) among its vocabulary. In order to be able to do reasoning, conceptual schemas
written in these CMDLs are generally translated into a DL by removing roles, and thus losing the connection that exists when the same role is played by different concepts, as the following example shows.

**Example 1** Consider de ER diagram shown in Figure 4 representing a (partial) conceptual model. In the rent relationship any person may rent any real state property, whereas in the house mortgage relationship any person living in a residential property may put a lien on it to obtain a loan from the bank. Both relationships involve the *occupant* role played by instances of the *Person* entity. This role name is relevant for querying, say, the real estate occupants in the database, so it is relevant for the model’s intended meaning. Following the translation procedure described in [3] to the DL-Lite DL family, the role *occupant* in the rent relationship is translated as

\[
\exists \text{occupant} \sqsubseteq \text{Person} \\
\exists \text{occupant}^{-} \sqsubseteq \text{RealStateProperty}
\]

The two formula state the domain and the range of the role. Similarly, the role *occupant* in the houseMortgage...
relationship is translated, including the functional constraint, as

\[
\exists \text{occupant} \sqsubseteq \text{Person} \\
\exists \text{occupant} \sqsubseteq \text{Residential} \\
\geq 2 \text{occupant} \sqsubseteq \bot
\]

In the case that both translations are merged into the same conceptual model formalisation, then unintended meaning is obtained. For example, that only houses may be rented, and that a person may rent only one property. The solution is to rename one of the roles, but then the connection between both roles is lost in the formalisation, the role is split, and therewith the intended meaning is weakened. This problem does not arise in the translation to the positionalist DLR.

Therefore, we consider it relevant to design a positionalist core profile that preserves roles as first class citizens among the DL vocabulary. In case reasoning over advanced modelling features is needed, it is possible to switch to the standard core profile with the cost of losing this connection. This translation is given in Algorithm 1 further below.

### 4.1.1 Positionalist Core Profile

In this section we define the DL fragments that describes the positionalist core profile. We use the standard DL syntax and semantics, as given in [8,10].

#### Definition 1

Given a conceptual model in any of the analysed CDMLs, we construct a knowledge base in \( \mathcal{DC}_p \) by applying the rules:

1. we take the set all of object types \( A \), binary relationships \( P \), datatypes \( T \) and attributes \( a \) in the model as the basic elements in the knowledge base.
2. for each binary relationship \( P \) formed by object types \( A \) and \( B \), we add to the knowledge base the assertions \( \geq 1[1]P \sqsubseteq A \) and \( \geq 1[2]P \sqsubseteq B \).
3. for each attribute \( a \) of datatype \( T \) within an object type \( A \), including the transformation of ORM’s Value Type following the rule given in [31], we add the assertion \( A \sqsubseteq \exists a.T \sqcap \leq 1a \).
4. subsumption between two object types \( A \) and \( B \) is represented by the assertion \( A \sqsubseteq B \).
5. for each object type cardinality \( m..n \) in relationship \( P \) with respect to its \( i \)-th component \( A \), we add the assertions \( A \sqsubseteq n[i]P \sqcap \geq m[i]P \).
6. we add for each mandatory constraints of a concept \( A \) in a relationship \( P \) the axiom \( A \sqsubseteq \geq 1[1]P \) or \( A \sqsubseteq \geq 1[2]P \) depending on the position played by \( A \) in \( P \). This is a special case of the previous one, with \( n = 1 \).
7. for each single identification in object type \( A \) with respect to an attribute \( a \) of datatype \( T \) we add the axiom \( \text{id} A a \).

This construction is linear in the number of elements in the original conceptual model, so the overall complexity of the process (translation and then reasoning) on the theory is the same as on the conceptual model. We restrict it to binary relationships only, because general \( n \)-ary relationships are rarely used in the whole set of analysed models. The (E)ER and ORM/2 models exhibit a somewhat higher incidence of \( n \)-aries, so they are included in the respective profiles (see below). Also, we allow only one such constraint for each component, as multiple cardinality constraints over the same component in a relationship are used very rarely.

\( \mathcal{DC}_p \) can be represented by the following DL syntax. Starting from atomic elements, we can construct binary relations \( R \), arbitrary concepts \( C \) and axioms \( X \) according to the rules:

\[
C \rightarrow T | A | \leq k[i]R | \geq k[i]R | \forall \exists a.T | \exists a.T | \leq 1a | C \sqcap D \\
R \rightarrow T_2 | P | (i : C) \\
X \rightarrow C \sqsubseteq D | \text{id} C a
\]

where \( i = 1, 2 \) and \( 0 < k \). For convenience of presentation, we generally use the numbers 1 and 2 to name the role places, but they can be any number or string and do not impose an order. Whenever necessary we note with \( U \) the set of all role names in the vocabulary, with \text{from,to} \in U fixed argument places for attributes such that \text{[from]} is the role played by the concept, and \text{[to]} the role played by the datatype. These names must be locally unique in each relationship/attribute.

Although this syntax represents all \( \mathcal{DC}_p \) knowledge bases, there are sets of formula following the syntactic rules that are not \( \mathcal{DC}_p \) knowledge bases since they are not result of any translation of a valid conceptual model. For example, the knowledge base \( \{ A \sqsubseteq \exists a.T \sqcap \leq 1a \sqcap \forall \exists a.T \} \) is not a \( \mathcal{DC}_p \) knowledge base, it can’t be obtained from the translation of any diagram.

Now we introduce the semantic characterisation.
Table 3 Semantics of DC_p.

Definition 2 An DC_p interpretation $I = (\mathcal{C}, $ $\mathcal{T}, $ $\mathcal{R})$ for a knowledge base in DC_p consists of a set of objects $\Delta^Z_c$, a set of datatype values $\Delta^Z$, and a function $f$ satisfying the constraints shown in Table 3. It is said that $I$ satisfies the assertion $C \subseteq D$ if $C^Z \subseteq D^Z$; and it satisfies the assertion id $C$ a if there exists $T$ such that $C^Z \subseteq (\exists a.T \cap \leq 1a\}^Z$ (mandatory 1) and for all $v \in T^Z$ it holds that $\# \{c \mid c \in \Delta^Z_c \land (c, v) \in a^2\} \leq 1$ (inverse functional).

In total, all the entities in the core profile sum up to 87.57% of the entities in all the analysed models, covering 91.88% of UML models, 73.29% of ORM models, and 94.64% of EE/EER models. Conversely, the following have been excluded from the core despite the feature overlap, due to their low incidence in the model set: Role (DL role component) and Relationship (DL role) Subsumption, and Completeness and Disjointness constraints. This means that it is not possible to express union and disjointness of concepts in a DC_p knowledge base obtained by formalising a conceptual model. Clearly they can be expressed by combinations of the constructors in DC_p, but this is not possible if we follow the previous construction rules. Since completeness and disjointness constraints are not present, reasoning in this core profile is quite simple.

This logic DC_p can be directly embedded into DLR (attributes are treated as binary relationships, and identification constraint over attributes can be represented as in [22]) which gives ExpTime worst case complexity for satisfiability and logical implication. A lower complexity would be expected due to the limitations in the expressiveness. For example, completeness and disjointness constraints are not present, and negation cannot be directly expressed. It is possible to code negation only with cardinality constraints [8 chapter 3], but then we need to reify each negated concept as a new idempotent role, which is not possible to get from the DC_p rules. Another form of getting contradiction in this context is by setting several cardinality constraints on the same relationship participation, which is also disallowed in the rules. In any case, the main reasoning problems on the conceptual model are only class subsumption and class equivalence on the given set of axioms.

In spite of all these limitations, no simpler positionalist DL has been introduced. In order to get lower complexity bounds we need to translate a DC_p TBox to a standard (non-positionalist) logic, like DC_s below.

Algorithm 1 Positionalist Core to Standard Core

1. $P$ an atomic binary relationship; $D_P$ domain of $P$; $R_P$ range of $P$
2. if $D_P \neq R_P$ then
   Rename $P$ to two ‘directional’ readings, $Pe_1$ and $Pe_2$
   Make $Pe_1$ and $Pe_2$ a DL relation (role)
   Type the relations with $\exists Pe_1 \subseteq \forall D_P$ and $\exists Pe_2 \subseteq R_P$
   Declare inverses with $Pe_1 \equiv Pe_2$
3. else if $D_P = R_P$ then
   if $i = 1, 2$ is named then
     $Pe_i \leftarrow i$
   else
     $Pe_i \leftarrow$ user-added label or auto generated label
   end if
   Make $Pe_i$, a DL relation (role)
   Type one $Pe_i$, i.e., $\exists Pe_i \subseteq D_P$ and $\exists Pe_i \subseteq R_P$
   Declare inverses with $Pe_i \equiv Pe_2$
4. end if

4.1.2 Standard Core Profile

Considering formalisation choices such as the positionalist of the relationships [61,72] and whether to use inverses or qualified cardinality constraints, a standard core profile has been specified [36]. In case the original context is a positionalist language, a translation into a standard (role-less) language is required. Algorithm [1] (adapted from [36]) does this work in linear time in the number of elements of the vocabulary. The main step involves recursive binary relations that generally do have their named relationship components vs ‘plain’ binaries that have only the relationship named.

Definition 3 Given a conceptual model in any of the analysed CDMLs, we construct a knowledge based in DC_s by applying algorithm 1 to its DC_p knowledge base.

Again, the algorithm is linear in the number of binary relationships in the knowledge base, not affecting complexity results when reasoning.

Once this conversion step is done, the formalisation of the standard core profile is described as follows. It includes inverse relations to keep connected both relationships generated by reifying roles. Take atomic binary relations ($P$), atomic concepts ($A$), and simple
attributes \((a)\) as the basic elements of the core profile language \(\mathcal{DC}_s\), which allows us to construct binary relations and arbitrary concepts according to the following syntax:

\[
C \rightarrow \top_1 \mid A \mid \forall R.A \mid \exists R.A \mid \leq k R \mid \geq k R \mid \forall a.T \mid \exists a.T \mid \leq 1 a.T \mid C \cap D
\]

\[R \rightarrow \top_2 \mid P \mid P^- \]

\[X \rightarrow C \subseteq D \mid id\ C\ a\]

**Definition 4** *\(\mathcal{DC}_s\) interpretation* for a knowledge base in \(\mathcal{DC}_s\) is given by \(I = (\mathcal{T}, \mathcal{F}, I^\mathcal{T})\), with \(\mathcal{T}^\mathcal{F}\) the domain of interpretation for concepts, \(\mathcal{T}^\mathcal{F}\) the domain of datatype values, and the interpretation function \(I^\mathcal{T}\) satisfying the conditions in Table 4. \(I\) satisfies an axiom \(X\) as in \(\mathcal{DC}_P\).

From the perspective of reasoning over \(\mathcal{DC}_s\), this is rather simple and little can be deduced: negation cannot be directly expressed here either, as discussed for \(\mathcal{DC}_P\). This leaves the main reasoning problem of class subsumption and class equivalence here as well. At most the DL \(\mathcal{ALNI}\) (called \(\mathcal{PL}_2\) in [29]) is expressive enough to represent this profile, since we only need \(\top, \cap, \neg\) and cardinality constraints; \(\mathcal{PL}_2\) has polynomial subsumption, but its data complexity is unknown. That said, using a similar encoding of conceptual models as given in Section 4.1.1, the language can be reduced further to \(\mathcal{DL-Lite}_{\text{core}}\) which is NLogSpace with some restrictions on the interaction between role inclusions and number restrictions, and the Unique name Assumption (UNA). Observe that the \(\mathcal{DL-Lite}_{\text{core}}\) fragment is also enough to include class disjointness in NLogSpace, and jumps to NP including disjoint covering [3].

### 4.1.3 UML Class diagram Profile

The profile for UML Class Diagrams strictly extends \(\mathcal{DC}_s\). It was presented extensively in [36] and succinctly formally specified here.

**Definition 5** *A knowledge base in \(\mathcal{DC}_{\text{UML}}\) from a given conceptual model in UML is obtained by adding to its \(\mathcal{DC}_s\) knowledge base the following formulas and axioms:

1. for each attribute cardinality \(m..n\) in an attribute \(a\) of datatype \(T\) within an object type \(A\) we add the assertion \(A \subseteq a.T \cap T^\mathcal{F} \geq m.a.T\).
2. for each binary relationship subsumption between relationships \(R\) and \(S\) we add the axiom \(R \subseteq S\).

The syntax is as in \(\mathcal{DC}_s\), with the additions highlighted in bold face for easy comparison:

\[
C \rightarrow \top_1 \mid A \mid \forall R.A \mid \exists R.A \mid \leq k R \mid \geq k R \mid \forall a.T \mid \exists a.T \mid \leq 1 a.T \mid C \cap D
\]

\[R \rightarrow \top_2 \mid P \mid P^- \]

\[X \rightarrow C \subseteq D \mid id\ C\ a\]

With this profile, we cover 99.44% of all the elements in the UML models of the test set. Absence of rarely used UML-specific modelling elements, such as the qualified association (relationship), completeness and disjointness among subclasses does limit the formal meaning of their models. On the positive side from a computational viewpoint, however, is that adding them to the language bumps up the complexity of reasoning over the models (to ExpTime-hardness [10]); or: the advantage of their rare use is that reasoning over such limited diagrams has just becomes much more efficient than previously assumed to be needed.

**Definition 6** *\(\mathcal{DC}_{\text{UML}}\) interpretation* for a \(\mathcal{DC}_{\text{UML}}\) knowledge base is a \(\mathcal{DC}_s\) interpretation \(I\) that also satisfies \(R \subseteq S\) if and only if \(R^\mathcal{T} \subseteq S^\mathcal{T}\), with \((\leq k a.T)^\mathcal{T} = \{c \in \mathcal{T}^\mathcal{F} \mid \#\{a \in T^S\mid (c, a) \in a.T\} \leq k\}\) and \((\geq k a.T)^\mathcal{T} = \{c \in \mathcal{T}^\mathcal{F} \mid \#\{a \in T^S\mid (c, a) \in a.T\} \geq k\}\).

Compared to \(\mathcal{DC}_s\), role hierarchies have to be added to the \(\mathcal{ALNI}\) logic of the Core Profile, which yields the logic \(\mathcal{ACNH}\). To the best of our knowledge, this language has not been studied yet. If we adjust it a little by assuming unique names and some, from the conceptual modelling point of view, reasonable restrictions on the interaction between role inclusions and cardinality constraints, then the UML profile can be represented in the known \(\mathcal{DL-Lite}_{\text{core}}^{(\mathcal{ACN})}\), which is NLogSpace for subsumption and \(\mathcal{ACN}\) for data complexity [3]. Also, if one wants to add attribute value constraints to this profile then reasoning over concrete domains is necessary. The interaction of inverse roles and concrete domains
is known to be highly intractable, just adding them to \(\mathcal{ALC}\) gives ExpTime-hard concept satisfiability \([7]\).

### 4.1.4 ER and EER Profile

The profile for ER and EER Diagrams also extends \(\mathcal{DC}_s\).

**Definition 7** A knowledge base in \(\mathcal{DC}_{\text{EER}}\) from a given conceptual model in EER is obtained by adding to its \(\mathcal{DC}_s\) knowledge base the following formulas and axioms:

1. we include atomic ternary relationships in the basic vocabulary.
2. for each attribute cardinality \(m.n\) in an attribute \(a\) of datatype \(T\) within an object type \(A\), we add the assertion \(A \subseteq n.a.T \cap m.a.T\).
3. for each weak identification of object type \(A\) through relationship \(P\) in which it participates as the \(i_3\)-th component, we add the assertion \(\text{fd } R_{i_1,i_2} \rightarrow i_3\), such that \(1 \leq i_1, i_2, i_3 \leq 3\) and are all different.
4. associative object types are formalised by the reification of the association as a new DL concept with two binary relationships.
5. multi-attribute identification is formalised as a new composite attribute with single identification.

This profile was presented extensively in [36] and is here recast in shorthand DL notation. The syntax is as in \(\mathcal{DC}_s\), with the additions highlighted in bold face for easy comparison:

\[
C \rightarrow \top | A | \forall R.A | \exists R.A | \leq k R | \geq k R | \forall a.T | \exists a.T
\]

\[
R \rightarrow \top_n | P | P^-
\]

\[
X \rightarrow C \subseteq D | \text{id } C.a | \text{fd } R_{i_1,i_2} \rightarrow i_3
\]

where \(n = 2, 3\) and all \(i_j = 1, 2, 3\) and different.

**Definition 8** An interpretation \(I\) satisfies a knowledge base in \(\mathcal{DC}_{\text{EER}}\) is it is a \(\mathcal{DC}_s\) interpretation, and satisfies \(\text{fd } R_{i_1,i_2} \rightarrow i_3\) iff for all \(r, s \in R^T\) it holds that if \([i_1]r = [i_1]s\) and \([i_2]r = [i_2]s\) then \([i_3]r = [i_3]s\), with 

\[
(\leq k a.T)^T = \{c \in \Delta^T_2 | \#\{a \in T^2 | (c,a) \in a^2\} \leq k\}
\]

and 

\[
(\geq k a.T)^T = \{c \in \Delta^T_2 | \#\{a \in T^2 | (c,a) \in a^2\} \geq k\}
\]

This profile covers relative frequent EER modelling entities such as composite and multivalued attributes, weak object types and weak identification, ternary relationships, associated object types and multiattribute identification in addition to those of the standard core profile. This profile can capture 99.06% of all the elements in the set of (E)ER models. Multivalued attributes can be represented with attribute cardinality constraints, and composite attributes with the inclusion of the union datatype derivation operator. Each object type (entity type) in (E)ER is assumed by default to have at least one identification constraint. In order to represent external identification (weak object types), we can use functionality constraints on roles as in \(\mathcal{DLR}_{\mathrm{id}}\) \([22]\) and its close relative \(\mathcal{DLR}^+\) \([4]\) or in \(\text{CFD}\) \([23]\). Ternary relationships are explicitly added to the profile. If we want to preserve the identity of these relationships in the DL semantics, then we need to restrict to logics in the \(\mathcal{DLR}\) family. Otherwise, it is possible to convert ternaries into concepts by reification, as described in Algorithm 2 using three traditional DL roles and therefore allowing the translation into logics such as \(\text{CFD}\). Since associative object types do not impose new static constraints on the models, they are formalised by reification of the association as a new DL concept with two binary relationships. Finally, multiattribute identification can be represented as a new composite attribute with single identification.

This profile presents an interesting challenge regarding existing languages. The only DL language family that has arbitrary \(n\)-aries and the advanced identification constraints needed for the weak entity types is the positionalist \(\mathcal{DLR}_{\mathrm{id}}\). However, \(\mathcal{DLR}_{\mathrm{id}}\) also offers DL role components that are not strictly needed for (E)ER, so one could pursue a binary or \(n\)-ary DL without DL role components but with identification constraints, the latter being needed of itself and for reification of a \(n\)-ary into a binary (Algorithm 2). The \(\text{CFD}\) family of languages may seem more suitable, then. Using Algorithm 2’s translation, and since we do not have covering constraints in the profile, we can represent the (E)ER Profile in the description logic \(\mathcal{DL}-\mathcal{Lite}_{\text{core}}\) \([3]\) which has complexity NLogSpace for the satisfiability problem. This low complexity is in no small part thanks to its UNA, whereas most logics operate under no unique name assumption. A similar result is found in [2] for \(\text{ER}_{\text{eif}}\), but it excludes composite attributes and weak object types.

**Algorithm 2** Equivalence-preserving \(n\)-ary into a binary conversion

\[
\nu_D^P: \text{domain of } P; R_P \text{ range of } P; n \text{ set of } P\text{-components}
\]

Reify \(P\) into \(P' \subseteq \top\)

for all \(i, 3 \geq i \geq n \) do

- \(\text{Re}_i \leftarrow \text{user-added label or auto generated label}\)

Make \(\text{Re}_i\) a DL role,

- Type \(\text{Re}_i\) as \(\exists \text{Re}_i \subseteq P'\) and \(\exists \text{Re}_i^- \subseteq R_P\), where \(R_P\) is the player ((E)ER entity type) in \(n\)

Add \(P' \subseteq \exists \text{Re}_i \cdot \top\) and \(P'' \subseteq \leq 1 \text{Re}_i \cdot \top\)

end for

Add external identifier \(\top \leq (\cup_i \text{Re}_i)^- \cdot P'\)
4.1.5 ORM and ORM2 Profile

Unlike for the ER and EER profile, there is no good way to avoid the ORM roles (DL role components), as they are used for several constraints that have to be included. Therefore, to realise this profile, we must transform the ORM positionalist commitment into a standard view, as we did in Algorithm 1. This is motivated by the observation that typically fact type readings are provided, not user-named ORM role names, and only 9.5% of all ORM roles in the 33 ORM diagrams in our dataset had a user-defined name, with a median of 0. We process the fact type (relationship $P$) readings and ignore the role names following Algorithm 3.

**Algorithm 3 ORM/2 to standard view and common core.**

- $P$ an atomic relationship
- If $P$ is binary then
  - Take fact type readings $F$
  - If there is only one fact type reading then
    - Reify $F$
    - Type $Re_1$ with domain and range
    - Create $Re_2$
    - Declare $Re_1$ and $Re_2$ inverses
  - else
    - Assign one reading to $Re_1$ and the other to $Re_2$
    - Type $Re_1$ with domain and range accordingly
    - Declare $Re_1$ and $Re_2$ inverses
  - end if
- Else
  - $P$ is $n$-ary with $n > 2$
  - Reify $P$ into $P' \subseteq \top$, like in Algorithm 2
  - with the for the $n$ binaries using the fact type readings as above
- end if

The profile for ORM/2 Diagrams was presented in [35], and a more detailed version including a text-based mapping as a restricted “ORM2@” was developed in [33] using $\mathcal{CFDT}$s as underlying logic, yet that could cover only just over 96% of the elements in the set of ORM models, whereas this one reaches 98.69% coverage.

**Definition 9** A knowledge base in $\mathcal{DC}_\text{ORM}$ from a given conceptual model in ORM2 is obtained by adding to its $\mathcal{DC}_2$ knowledge base the following formulas and axioms:

1. Each $n$-ary relationship is reified as in Algorithm 3.
2. Each unary role is formalised as a boolean attribute.
3. Add pairwise disjoint axioms for each pair of relationships with different arity.
4. Each subsumption between roles $R, S$ is represented by the formula $R \subseteq S$.
5. Each subsumption between relationships $R, S$ is represented by the subsumption between the reified concepts, $R' \subseteq S'$, and the subsumption of each of the $n$ components of the relationships, $R_{ei} \subseteq S_{ei}, 1 \leq i \leq n$.
6. Each disjoint constraint between roles $R$ and $S$ is formalised as two inclusion axioms for roles: $R \subseteq \neg S$ and $S \subseteq \neg R$.
7. Each nested object type is represented by the reified concept of the relationship.
8. Each value constraint is represented by a new datatype that constraint.
9. Each disjunctive mandatory constraint for object type $A$ in roles $R_i$ is formalised as the inclusion axiom $A \subseteq \lor_i R_i$.
10. Each internal uniqueness constraint for roles $R_i, 1 \leq i \leq n$ over relationship objectified with object type $A$ is represented by $\text{id} A | R_1 \ldots, 1 R_n$.
11. Each external uniqueness constraint between roles $R_i, 1 < i \leq n$ not belonging to the same relationship is represented by $\text{id} A | 1 R_1, \ldots, 1 R_n$, where $A$ is the connected object type between all the $R_i$, if it exists, or otherwise a new object type representing the reification of a new $n$-ary relationship between the participating roles.
12. Each external identification is represented as the previous one, with the exception that we are now sure such $A$ exists. (i.e., the mandatoryness is added cf. simple uniqueness).

This slightly more comprehensive language is here recast in shorthand DL notation, with the additions highlighted in bold face for easy comparison:

$$C \rightarrow \top_1 | A \lor R.A | \exists R.A | k R | k R \lor \forall a.T | \exists a.T | \leq 1 a \vdash$$

$$C \rightarrow C \cap D | C \cup D$$

$$R \rightarrow \top_2 | P | P^- | \neg R$$

$$X \rightarrow C \subseteq D | R \subseteq S | \text{id} C | \text{id} \text{ R}_1 \ldots \text{ R}_n$$

**Definition 10** A $\mathcal{DC}_\text{ORM}$ interpretation for a $\mathcal{DC}_\text{ORM}$ knowledge base is a $\mathcal{DC}_\text{2}$ interpretation $I$ with the constraints that $(C \cup D)^I = C^I \cup D^I$, and $(\neg R)^I = \top_2 \setminus R^I$. $I$ satisfies the assertion $R \subseteq S$ iff $(R \subseteq S)^I = R^I \subseteq S^I$, and the assertion $\text{id} C | R_1 \ldots R_n$ iff $C^I \subseteq \cap_i (3 R_i \subseteq 1 R_i)^I$ and for all objects $d_1, \ldots, d_n \in T^I$ it holds that $\#\{c | c \in C^I \land (c, d_i) \in R_i^I, 1 \leq i \leq n\} \leq 1$. 

4.2 Example application of the construction rules

Let us now return to the claim in the introduction about the sample UML Class Diagram in Fig. 1 that it has a logical underpinning in $\mathcal{DC}_s$ and therewith also has grounded equivalents in EER and ORM notation. The equivalents in EER and ORM are shown in Fig. 5.

The first step is to note that the $\mathcal{DC}_s$ reconstruction is obtained from $\mathcal{DC}_p$ + Algorithm 1 (by Definition 3). By the $\mathcal{DC}_p$ rules from Definition 1, we obtain the set of object types $\{\text{Person}, \text{Affiliation}, \ldots, \text{Publisher}\}$ and of data types $\{\text{Name}, \ldots, \text{VAT reg no}\}$. For the relationships, we need to use Algorithm 1 which we illustrate here for the association between $\text{Person}$ and $\text{Affiliation}$: 1) bump up the association end names, has member and has, to DL roles; 2) type the relationships with:

- $\top \sqsubseteq \forall\text{hasMember.Affiliation} \sqcap \exists\text{Person} \sqcap \forall\text{has.Affiliation}$
- $\top \sqsubseteq \forall\text{Person} \sqcap \exists\text{hasMember} \equiv \forall\text{hasMember.} .\text{Person}$

and 3) declare inverses, $\text{hasMember} \equiv \text{has}$−. After doing this for each association in the diagram, we continue with step 3 of Definition 1 being the attributes. For instance, the $\text{Person}'s$ Name we obtain the axiom

$\text{Person} \sqsubseteq \exists\text{Name.String} \sqcap \leq 1 \text{name}$

and likewise for the other attributes. Step 4 takes care of the subsumptions; among others $\text{Popular.science.book} \sqsubseteq \text{Book}$ is added to the $\mathcal{DC}_s$ knowledge base. Then cardinalities are processed in steps 5 and 6 (noting the algorithmic conversion from positionalist to standard view applies in this step), so that, for the membership association illustrated above, the following axioms are added to the knowledge base: $\text{Affiliation} \sqsubseteq 1 \text{ has member}$ (mandatory participation) whereas for, say, the scientist, it will be $\text{Scientist} \sqsubseteq 3 \text{ has}$. Finally, any identifiers are processed, such as $\text{ISBN}$ for $\text{Book}$, generating the addition of the $\text{id Book ISBN}$ to the $\mathcal{DC}_s$ knowledge base.

The process for the EER diagram is the same except that the name of the relationship can be used directly cf. bumping up the role names to relationship names. The reconstruction into ORM has two permutations cf. the UML one, which are covered by step 3 in Definition 1 being the conversion algorithm from ORM's value types to attributes as described in [34], and it passes through the second else statement of Algorithm 1 cf. the first if statement that we used for UML when going from positionalist to standard view.

Diagram construction rules, i.e., going in the direction from the logic-based profile to a graphical notation, can follow the same process in reverse. This can be achieved automatically, except where labels have to be generated. For instance, if one were to have a scenario on an interoperability tool of “UML diagram $\rightarrow \mathcal{DC}_s \rightarrow$ ORM diagram” and one wants to have the fact type readings, they will have to be added, which a user could write herself or it could be generated by one of the extant realisation engines for the controlled natural language$^7$ similar to OWL verbalisation [87] or SimpleNLG for natural language generation [42].

5 Discussion

The methodological approach proposed is expected to be of use for similar research to inform better the language design process and elucidate ontological commitments that are otherwise mostly hidden. The five profiles form an orchestrated network of compatible logics, which serve as the logic-based reconstructions of fragments of the three main CDMLs that include their most used features. In the remainder of the section, we discuss language design and computational complexity, and take a look ahead at applicability.

Language design To the best of our knowledge, there is no 'cookbook process' for logic or conceptual data modelling language design. Frank’s waterfall process [41] provided useful initial guidance for a methodological approach. In our experience in designing the profiles, we deemed our proposed extension with “Ontological analysis of language features” necessary for the conceptual modelling and knowledge representation languages setting cf. Frank’s domain-specific languages. An alternative option we considered beforehand was [59]'s list of 26 guidelines, but they are too specific to DSLs to be

\footnote{It would have rules that render, e.g., a $\text{has member}$ into ... $\text{has member}$ and a $\text{has member}$− into ... $\text{member of}$ ...}
amenable to CDML design, such as the DSL’s distinction between abstract and concrete syntax and their corresponding guidelines.

Zooming into the extra “Ontological analysis of language features” step, we had identified five decision points for language design with respect to ontology and several practical factors that are listed in Table 2 in Section 3. To the best of our knowledge, it is the first attempt to scope this component of language/logic design systematically and it may spur further research into it. Our contribution in that regard should be seen as a starting point for a broader systematic investigation into this hitherto neglected aspect. In making choices, we had to accommodate alternative design choices and the need to achieve high coverage. This was addressed by designing two alternative cores—positionalist and standard view (item 2 in Section 3)—and, importantly, three algorithms to achieve that level of compatibility. More precisely, Algorithm 1 provides the conversion option for item 2—roles or not—in a generic way, Algorithm 2 takes case of the binaries vs n-aries (item 3a), and Algorithm 3 is a specific adaptation of Algorithm 2. All profiles have data types (item 1 in Section 3), for they are present in UML Class Diagrams and ORM/2,
noting that it simply can be set to \texttt{xsd:anyType} and thus have no influence, which is the case for (E)ER. Further, if the intended semantics of the aggregation association were to have been more specific in the UML standard, it would have merited inclusion in its profile (item 3b in Section 3), with then the onus on the DL community to find a way to add it as a primitive to a DL. If included, it would likely also be possible to design a conversion algorithm between the new primitive and a plain DL role with properties. Regarding adding more types of entity types to the language (item 3c), like sortal and phase: the one proposal in Section 3 is not in widespread use and therewith did not meet the evidence-based threshold for inclusion. It is also not clear how to represent in a decidable language such notions that are essentially based on OntoClean [45] that requires modality and higher-order predicates, nor how an equivalence-preserving algorithm would look like, if possible at all.

**Complexity considerations for the profiles** Traditionally, the DL research community has strived for identifying more and more expressive DLs for which reasoning is still decidable. The introduced profiles show that high expressivity is not necessary for representing most of the semantics of conceptual models, independently of the chosen modelling language. They thus are ‘lean’, evidence-based, profiles that, while not covering all corners of modelling issues, do have those features that are used most in practice. We summarise the complexity of each profile by immersion into a DL language in Table 5. The “Approximate DL” column is not an exact match for each profile, and often involves some extra assumptions that explains the different complexities. Low complexities are achievable by the standard profiles (i.e., those that give up on positionalism), due to the existence of a more accurate matching logic. Recall that \(\mathcal{DC}_s\) is included in \(\mathcal{DC}_{UML}, \mathcal{DC}_{EER}\), and \(\mathcal{DC}_{ORM}\). The biggest gap between the profiles and the matching DLs is given in \(\mathcal{DC}_s\), showing more work on positionalist DLs is necessary, especially with respect to reasoning algorithms.

An outstanding issue is whether object types in the diagrams are by default disjoint when not in a hierarchy, or not. Some research are convinced they are, and some are not; most formalisations and tools do not include it. Because of the lack of agreement, we have not included it. Note further that if this assumption were to be added, i.e., full negation in the profiles, it would affect the computational complexity of the profiles negatively.

It is also interesting to analyse at which point increasing expressiveness by adding new features to the language is worthwhile from the point of view of the modeller. If the feature is present, at least one modeller will use it, though mostly only occasionally. It is not clear if this is due to them being corner cases, a lack of experience on representing advanced constraints by modelers, tooling, or another reason. On the other hand UML’s aggregation as ‘extra’ feature cf. (E)ER’s and ORM/2’s plain relationships is being used disproportionally more often than part-whole relations in (E)ER and ORM/2. It remains to be investigated why exactly this is the case.

**Toward applicability** The presented profiles may be applied as the back-end of CASE tools using the compatible profiles as unifying logics and orchestration of corresponding optimised reasoners for, say, Ontology-Based Data Access such that it focusses on the perceived language needs of the modelers (cf. the logic and technology, as in, e.g., [19,81]), whilst still keeping it tractable. The current conceptual modelling tools that have a logic back-end are still sparse [32,33,15], and allow a modeller to model in only one language, rather than being allowed to switch between language families.

Using the common core for model interoperability by mapping each graphical element into a construct in \(\mathcal{DC}_s\) is an option. However, one also would want to be precise and therefore use more language features than those in the common core, and when linking models, ‘mismatch’ links would still need to be managed, and wrong ones discarded. To solve this, an interoperability approach with equivalence, transformation, and approximation rules that is guided by the metamodel is possible [54,50]. There, one can have two models with an intermodel assertion; e.g., between a UML association and an ORM fact type. The entities are first classified/mapped into entities of the metamodel, any relevant rules are executed, and out comes the result, being either a valid or an invalid link. The ‘any relevant rules are executed’ is coordinated by the metamodel; e.g., the metamodel states that each Relationship has to have two or more Roles, which, in turn, have to have attached to it either an Object Type or Value Type, so those mapping and transformation rules are called as well during the checking of the link. The MIST EER tool [28] has a similar goal, though currently it supports only EER and its translation to SQL and therewith is complementary to our work presented here.

The formal foundation presented here would enable such an interface were either multiple graphical rendering in different modelling language families could be generated, or link models represented in different languages in a system integration scenario.

6 Conclusions

A systematic logic design process was proposed that generalises and extends the DSL design process to be more broadly applicable by incorporating an ontological analysis of language features in the process. This first compilation of ontological commitments embedded in a logic design process includes, among others, the ontology of relations, the conceptual vs design features trade-off, and 3-dimensionalist vs. 4-dimensionalist commitments.

Based on this extended process with explicit ontological distinctions and the evidence of the prevalence of the features in the models, different characteristic profiles for the three conceptual data modelling language families were specified into a suitable Description Logic, which also brought with it insights into their computational complexity. The common core profile is of relatively low computational complexity, being in the tractable \( \mathcal{ALNI} \). Without the negation, hardly any inconsistencies can be derived with the profiles, with as flip side that it is promising for scalable runtime use of conceptual data models.

We are looking into several avenues for future work, including ongoing tool development and more precise complexity results for the profiles so that it would allow special, conceptual data model-optimised, reasoners.
