Key words: Nonequilibrium Green’s functions, second-Born self-energy, numerical algorithm

\(^\ast\) Corresponding author: e-mail gianluca.stefanucci@roma2.infn.it

We describe an algorithm to efficiently compute the second-Born self-energy of many-body perturbation theory. The core idea consists in dissecting the set of all four-index Coulomb integrals into properly chosen subsets, thus avoiding to loop over those indices for which the Coulomb integrals are zero or negligible. The scaling properties of the algorithm with the number of basis functions is discussed. The computational gain is demonstrated in the case of one-particle Kohn-Sham basis for organic molecules.

1 Introduction At the beginning of the new century the computational capabilities were powerful enough to implement the nonlinear integro-differential Kadanoff-Baym equations (KBE) put forward in the sixties [1–4]. The first KBE calculation dates back to 2000 and deals with plasma oscillations in the homogeneous electron gas [5]. KBE calculations of inhomogeneous systems like atoms and diatomic molecules driven out of equilibrium by external laser fields appeared in 2007 [6]. Since then the number of groups working on efficient implementations of the KBE has grown, and the interest has progressively moved toward nonequilibrium properties of model Hamiltonians. Among the pioneering works we mention Refs. [7–15].

Despite the aforementioned advances, the KBE have not yet been combined with ab initio schemes for the investigation of nonequilibrium properties of realistic systems. In fact, the propagation of a two-times object like the Green’s function is still too burdensome, even for most modern supercomputers. An enormous simplification to the numerical solution of the KBE occurs when evaluating the collision integral using the Generalized Kadanoff-Baym Ansatz (GKBA) [16]. For this reason there has been a considerable effort in assessing the reliability of the GKBA [17–20] and in combining it with ab initio methods [21–28] over the last years. Through the GKBA the nonequilibrium Green’s function formalism is converted into a time-dependent density-matrix functional theory [29–31] with the advantage that correlation effects can be included through diagrammatic approximation to the self-energy.

As pointed out in a recent work [32], the GKBA is an ansatz for the Green’s function and the computational gain with respect to a full KBE simulation is limited to self-energies up to the second Born (2B) level, with first- and second-order exchange diagrams evaluated using either the bare Coulomb interaction \(v\) or the statically or partially dynamically screened interaction \(W\). The 2B approximation well reproduces equilibrium spectral properties [33] and total energies [34] of molecular systems. Furthermore, benchmarks against numerically exact simulations in 1D atoms and molecules [13], quantum wells [14], weakly correlated Hubbard and extended Hubbard nanoclusters [15,17,19,35–37], the Anderson model at finite bias [38] and photo-excited donor-acceptor tight-binding Hamiltonians [20] indicate that the 2B approximation remains accurate even out of equilibrium. The GKBA implementation of more sophisticated approximations like the self-consistent GW or T-matrix self-energies would scale like the original KBE unless a GKBA-like expression for the fully dynamically screened interaction \(W\) or T-matrix \(T\) is provided.

The special role played by the 2B diagrams (with \(v\) or \(W\) interaction lines) in the GKBA scheme has triggered the search for efficient algorithms to compute the 2B self-energy. In an electronic system with \(N\) one-particle de-
degrees of freedom the computational cost of a naive implementation would scale like $N^5$. Such an unfavourable scaling makes first principles simulations of systems with more than two or three light atoms numerically expensive. In this work we describe a *dissection algorithm* which takes the maximum advantage of vanishing or very small Coulomb integrals. The dissection algorithm is currently implemented in the CHEERS code [39] and it allows for first principles simulations of systems with tens of active electrons like, e.g., organic molecules, up to tens of femtoseconds [28]. We emphasize that the algorithm does not make any use of the GKBA and, therefore, it can also be implemented to simulate time-dependent quantum phenomena within the full KBE dynamics.

The paper is organized as follows. In Section 2 we introduce the equation of motion for the one-particle density matrix and write down the explicit form of the 2B self-energy. The equation of motion for the one-particle density matrix in the full KBE dynamics. In Section 3 we illustrate the dissection algorithm as currently implemented in the dissection algorithm [39] and can easily be generalized. The one-particle density matrix $\rho$ is diagonal in spin space and the matrix element $\rho_{ij}$ between $\varphi_i$ and $\varphi_j$ is independent of the spin orientation. The equation of motion for the $N \times N$ matrix $\rho$ reads [18,23,20,28]

$$\frac{d}{dt} \rho_{ij}(t) + i[h_{HF}(t),\rho(t)]_{ij} = -I_{ij}(t) + \text{H.c.},$$

where $h_{HF}(t)$ is the time-dependent HF Hamiltonian and $I(t)$ is the collision integral, written in terms of the greater and lesser self-energy and Green’s function [3]

$$I(t) = \int_0^t dt' [\Sigma^>(t,t')G^<(t',t) - \Sigma^<(t,t')G^>(t',t)].$$

In the 2B approximation the self-energy $\Sigma$ reads

$$\Sigma_{ij} = \sum_{pq} v_{pqij} G_{pq} G_{sp} \sum_m [2v_{mqjs} G_{nm} - v_{mqjs} G_{nm}],$$

where we used the short-hand notation

$$\Sigma \equiv \Sigma^>(t,t') \quad G \equiv G^>(t,t') \quad \bar{G} \equiv G^<(t',t).$$

For real one-particle basis the Coulomb integrals in Eq. (3) are given by

$$v_{ijmn} \equiv \int d\mathbf{r} d\mathbf{r}' \frac{\varphi_i(\mathbf{r}) \varphi_j(\mathbf{r}') \varphi_m(\mathbf{r}') \varphi_n(\mathbf{r})}{|\mathbf{r} - \mathbf{r}'|},$$

and have the symmetry properties

$$v_{ijmn} = v_{ijnm} = v_{pjim} = v_{mjpi}.$$  

The computational cost for evaluating $\Sigma$ for a given pair of times $t, t'$ depends on how much the tensor of Coulomb integrals $v_{ijmn}$ is sparse. Recalling that $N$ is the dimension of the one-particle basis, the cost can vary from $N^2$ for a Hubbard-like interaction, i.e., $v_{ijmn} \propto \delta_{ij} \delta_{bm} \delta_{in}$, to $N^5$ when all $v_{ijmn}$’s are nonvanishing. In the latter case, however, several Coulomb integrals may be order of magnitude smaller than others [23,28], and the calculation of the r.h.s. of Eq. (3) remains accurate by considering only those $v_{ijmn}$ larger than a certain cutoff $A$. In fact, the 2B self-energy is quadratic in $v$ and therefore $A$ can generally be chosen larger than the cutoff of a typical Hartree-Fock (HF) calculation (the HF self-energy is linear in $v$). Therefore, the effective scaling with $N$ can be considerably reduced if one manages to sum over only those indices for which $|v_{ijmn}| > A$. The basic idea consists in dissecting the set of all Coulomb integrals in properly chosen subsets.

**3 Dissection algorithm** In this Section we illustrate an efficient algorithm to calculate the r.h.s. of Eq. (3) with $v_{ijmn} \rightarrow v_{ijmn} \theta(|v_{ijmn}| - A)$. We begin by noticing that the first term in the square bracket is nonvanishing only if the pair $(qs)$ belongs to

$$\mathcal{L} = \{(qs): |v_{mqjs}| > A \text{ for some } (mj)\},$$

and that the second term in the square bracket is nonvanishing only if the pair $(qs)$ belongs to

$$\mathcal{L}_x = \{(qs): |v_{mqjs}| > A \text{ for some } (mj)\}.$$  

Let $D$ and $D_x$ be the dimension of the sets $\mathcal{L}$ and $\mathcal{L}_x$ respectively. Given $\alpha = 1,\ldots,D$ we establish a map to extract the couple $q = q(\alpha)$ and $s = s(\alpha)$ similarly. Given $\beta = 1,\ldots,D_x$ we establish a map to extract the couple $q = q(\beta)$ and $s = s(\beta)$. Once these maps are defined we introduce a superindex $I = 1,\ldots,N \times D$ from which to extract $n = \text{Int}[I/D] + 1$ varying between 1 and $N$ and $\alpha = I - (n - 1)D$ varying from 1 to $D$. Similarly we introduce a superindex $J = 1,\ldots,N \times D_x$ from which to extract $n = \text{Int}[J/D_x] + 1$ varying between 1 and $N$ and $\beta = J - (n - 1)D_x$ varying from 1 to $D_x$. We use these superindices to rewrite the terms in the square brackets as

$$\sum_n v_{mqjs} G_{nm} \equiv \tilde{V}_{I,j}$$

for all $(qs) \in \mathcal{L}$ and

$$\sum_n v_{mqjs} G_{nm} \equiv \tilde{V}_x^I_{j,j}$$

for all $(qs) \in \mathcal{L}_x$. 

for all \((qs) \in \mathcal{L}_s\). In general, these quantities can be zero
for several \(j's\) since for a fixed pair \((qs)\) the values of
\(|v_{mjs}|\) or \(|v_{njs}|\) may be smaller than \(A\). To minimize
the number of quantities to store we found convenient to
define the sets
\[
\mathcal{S}(qs) = \{j : |v_{mqs}| > A \text{ for some } m\},
\]
\[
\mathcal{S}_x(qs) = \{j : |v_{nqs}| > A \text{ for some } m\}.
\]

Let \(d(qs)\) and \(d_x(qs)\) be the dimension of \(\mathcal{S}(qs)\) and
\(\mathcal{S}_x(qs)\) respectively. For any given couple \((qs)\) we con-
struct the map which associates to the integer \(\sigma = 1, \ldots, d(qs)\) the index \(j(\sigma) \in \mathcal{S}(qs)\) and to the integer
\(\tau = 1, \ldots, d_x(qs)\) the index \(j(\tau) \in \mathcal{S}_x(qs)\). Then, for
every \(j \in \mathcal{S}(qs)\) we define
\[
V_{I,\sigma} \equiv \tilde{V}_{I,j(\sigma)},
\]
and for every \(j \in \mathcal{S}_x(qs)\) we define
\[
V_{I,\tau}^x \equiv \tilde{V}_{I,j(\tau)},
\]
We observe that for a fixed superindex \(I = (\alpha, n)\) (or \(J = (\beta, n)\)) the length of the array \(V_{I,\sigma}\) (or \(V_{I,\tau}^x\)) depends
on the pair \((q(\alpha), s(\alpha)) \in \mathcal{L} (or \(q(\beta), s(\beta)) \in \mathcal{L}_s\). To caculate \(V\) and \(V^x\) we define two more sets
\[
\mathcal{L}(qs) = \{(mj) : |v_{mqs}| > A\}
\]
\[
\mathcal{L}_x(qs) = \{(mj) : |v_{nqs}| > A\}
\]

Let \(D(qs)\) and \(D_x(qs)\) be the dimension of the sets \(\mathcal{L}(qs)\) and
\(\mathcal{L}_x(qs)\) respectively. Given \(\mu = 1, \ldots, D(qs)\) we es-
lish a \((qs)\)-dependent map to extract the couple \((mj) =
(m(\mu)j(\mu))\). Similarly, given \(\nu = 1, \ldots, D_x(qs)\) we es-
lish a \((qs)\)-dependent map to extract the couple \((mj) =
(m(\nu)j(\nu))\). We then construct two two-dimensional arrays
\[
v_{\alpha j} \equiv v_{mqs},
\]
with \((qs) = (q(\alpha)s(\alpha)) \in \mathcal{L}\) and \((mj) = (m(\mu)j(\mu)) \in
\mathcal{L}(qs)\), and
\[
v_{\beta \nu}^x \equiv v_{nqs},
\]
with \((qs) = (q(\beta)s(\beta)) \in \mathcal{L}_x\) and \((mj) = (m(\nu)j(\nu)) \in
\mathcal{L}_x(qs)\). Notice that both \(v\) and \(v^x\) have rows of different
lengths. A code to fill up the array \(V\) would have the following
structure
\[
\text{DoLoop}[I = 1, D \times N] \{ \\
\alpha(1), n(1) \\
(qs) = (q(\alpha), s(\alpha)) \in \mathcal{L} \\
\text{DoLoop}[\mu = 1, D(qs)] \{ \\
(mj) = (m(\mu), j(\mu)) \in \mathcal{L}(qs) \\
V_{I,\sigma(j)} = V_{I,\sigma(j)} + v_{\alpha j}G_{mn} \\
\}
\}
\]
Similarly for \(V^x\) we have
\[
\text{DoLoop}[J = 1, D_x \times N] \{ \\
\beta(J), n(J) \\
(qs) = (q(\beta), s(\beta)) \in \mathcal{L}_x \\
\text{DoLoop}[\nu = 1, D_x(qs)] \{ \\
(mj) = (m(\nu), j(\nu)) \in \mathcal{L}_x(qs) \\
V_{I,\tau}^x = V_{I,\tau}^x + v_{\beta \nu}^xG_{mn} \\
\}
\}
\]
Once the arrays \(V\) and \(V^x\) are filled the calculation of the self-energy is reduced to calculate
\[
\Sigma_{ij} = 2B_{ij} + X_{ij},
\]
with the bubble term
\[
B_{ij(\sigma)} = \sum_{np} \sum_{\{qs\} \in \mathcal{L}} v_{npj}G_{pq}G_{sq}V_{I,\sigma},
\]
we recall that \(I = [\{qs\} \in \mathcal{L}, n]\) and the 2-nd exchange term
\[
X_{ij(\tau)} = \sum_{np} \sum_{\{qs\} \in \mathcal{L}_s} v_{npj}G_{pq}G_{sq}V_{I,\tau}^x
\]
we recall that \(J = [\{qs\} \in \mathcal{L}_x, n]\).
Next we observe that for a fixed \(i\) the sum over \(n\) in \(B\) and \(X\) can be restricted to those \(n\) for which the pair
\((ni) \in \mathcal{L}\) since \(v_{npj} = v_{npri}\). We then proceed as follows.
- Step 1) For any fixed \((ni) \in \mathcal{L}\) we construct the matrix
\[
H^{(ni)}_{sp} = \sum_{\tau} v_{npj}G_{sr}
\]
where the sum can be restricted to those \(\tau\) for which the pair
\((pr) \in \mathcal{L}(ni)\). In this way Eqs. (20,21) becomes
\[
B_{ij(\sigma)} = \sum_{np} \sum_{\{qs\} \in \mathcal{L}} G_{pq}H^{(ni)}_{sp}V_{I,\sigma},
\]
\[
X_{ij(\tau)} = \sum_{np} \sum_{\{qs\} \in \mathcal{L}_s} G_{pq}H^{(ni)}_{sp}V_{I,\tau}^x
\]
- Step 2) For any fixed \((qs) \in \mathcal{L}\) we extract the super-
index \(I = \{\{qs\}, n\}\) and construct the matrix
\[
Z_{i,1} = \sum_{p \in \mathcal{S}(ni)} G_{pq}H^{(ni)}_{sp}.
\]
Here the sum over \(p\) is restricted to \(\mathcal{S}(ni)\) since \(H^{(ni)}_{sp}\) van-
ishes for \(p \notin \mathcal{S}(ni)\). In terms of the \(Z\) matrix the bubble
term becomes
\[
B_{ij(\sigma)} = \sum_{l} Z_{i,1}V_{I,\sigma}
\]
Step 3) For any fixed \((qs) \in \mathcal{L}_x\) we extract the superindex \(J = [(qs), n]\) and construct the matrix

\[
Z_{i,j}^x = \sum_{p \in \mathcal{S}(qs)} G_{pq} H^{(ni)}_{sp}. \tag{27}
\]

In terms of the \(Z^x\) matrix the 2-nd order exchange term becomes

\[
X_{ij(\tau)} = \sum_j Z_{i,j}^x V_{j,\tau}^x \tag{28}
\]

The structure of a code for the implementation of the above three steps would have the following structure

\[
\begin{align*}
&D\text{DoLoop}[(i_0, i_1, i_2)]\{ \\
&\quad \text{(in)} = (i(\alpha), n(\alpha)) \in \mathcal{L} \\
&\quad \text{DoLoop}[(\mu) = (i(\mu), p(\mu)) \in \mathcal{L}(\text{in})] \\
&\quad \text{DoLoop}[(s) = (i(\sigma), n(\sigma))] \\
&\quad H(s, p) = H(s, p) + v_{\alpha\mu} \delta_{sr} \\
&\quad \} \\
&\quad \text{Bubble} \{ \\
&\quad \text{DoLoop}[(\alpha') = (i(\alpha'), n(\alpha'))] \\
&\quad \text{DoLoop}[(\gamma) = (i(\gamma), n(\gamma))] \\
&\quad \text{DoLoop}[(\sigma) = (i(\sigma), n(\sigma))] \\
&\quad \text{DoLoop}[(\beta) = (i, n)] \\
&\quad (qs) = (q(\alpha), s(\alpha')) \in \mathcal{L} \\
&\quad I = I[(qs), n] \\
&\quad (qs) = (q(\alpha), s(\alpha')) \in \mathcal{L} \\
&\quad \text{DoLoop}[(\gamma) = (i(\gamma), n(\gamma))] \\
&\quad p = p(\gamma) \in S(\text{in}) \\
&\quad Z = Z + G_{pq} \delta_{sr} \\
&\quad \} \\
&\quad \text{Bubble} \{ \\
&\quad \text{DoLoop}[(\alpha') = (i(\alpha'), n(\alpha'))] \\
&\quad \text{DoLoop}[(\gamma) = (i(\gamma), n(\gamma))] \\
&\quad \text{DoLoop}[(\sigma) = (i(\sigma), n(\sigma))] \\
&\quad \text{DoLoop}[(\beta) = (i, n)] \\
&\quad (qs) = (q(\alpha), s(\alpha')) \in \mathcal{L}_x \\
&\quad J = J[(qs), n] \\
&\quad (qs) = (q(\beta), s(\beta)) \in \mathcal{L}_x \\
&\quad p = p(\gamma) \in S(\text{in}) \\
&\quad Z^x = Z^x + G_{pq} \delta_{sr} \\
&\quad \} \\
&\quad \text{DoLoop}[(\tau) = (i, n)] \\
&\quad \text{DoLoop}[(\tau) = (i, n)] \\
&\quad X(i, j) = X(i, j) + Z^x \delta_{s't} \\
&\quad \}
\end{align*}
\]

We observe that the above implementation of the 2B self-energy requires at most two-dimensional arrays.

4 Discussion on scaling In this section we show that the scaling of the dissection algorithm with \(N\) reduces with increasing number of vanishing Coulomb integrals. This means that it is possible to take advantage of the sparse nature of the \(v\) tensor without changing the implementation. Another advantage is that the convergence of a simulation can easily be checked by reducing the cutoff, see also below.

Let us first show that the algorithm scales like \(N^6\) when all Coulomb integrals are larger than \(\Lambda\). In this case both sets \(\mathcal{L}\) and \(\mathcal{L}_x\) have dimension \(D = D_x = N^2\) and, for any pair \((qs)\), the sets \(\mathcal{L}(qs)\) and \(\mathcal{L}_x(qs)\) have dimension \(D(qs) = D_x(qs) = N^2\). Thus the calculation of \(V\) and \(V^x\) involves an external loop of length \(N^3\) and an internal loop of length \(N^2\), resulting in a \(N^5\) scaling. For the calculation of the bubble and the 2-nd order exchange terms we have an external loop of length \(N^2\) followed by a cascade of two loops of lengths \(N^2\) and \(N\) respectively, hence again a \(N^5\) scaling, to build \(H^{(ni)}\). After closing these two loops, we have (for both \(B\) and \(X\)) the opening of a loop of length \(N^2\) followed by a sequence of two loops of length \(N\) since the dimension of the sets \(S(qs)\) and \(S_x(qs)\) is \(d(qs) = d_x(qs) = N\) for all \((qs)\). We conclude that the overall scaling of the algorithm is \(N^7\).

The previous discussion helps in determining how the algorithm scales in the general case. Let

\[
M = \frac{1}{D} \sum_{(qs) \in \mathcal{L}} D(qs), \tag{29}
\]

\[
M_x = \frac{1}{D_x} \sum_{(qs) \in \mathcal{L}_x} D_x(qs). \tag{30}
\]

Then, the calculation of \(V\) scales like \(D \times N \times M\) whereas the calculation of \(V^x\) scales like \(D \times N \times M_x\), see the loop structure below Eq. (18). From the loop structure below Eq. (28) we infer that the calculation of \(H^{(ni)}\) scales like \(V\). To determine the scaling of \(B\) and \(X\) we need to introduce two more integers

\[
m = \frac{1}{D} \sum_{(qs) \in \mathcal{L}} d(qs), \tag{31}
\]

\[
m_x = \frac{1}{D_x} \sum_{(qs) \in \mathcal{L}_x} d_x(qs). \tag{32}
\]

We then see that \(B\) scales like \(D^2 \times 2m\) whereas \(X\) scales like \(D \times D_x \times (m + m_x)\). We conclude that the dissection algorithm scales like

\[
S_{\text{da}} = DN(2M + M_x) + 2mD + (m + m_x)D_x. \tag{33}
\]

This number should be compared with the scaling \(7N^5\) of an algorithm blind to the magnitude of the Coulomb integrals.
Let us consider a few examples. For an extended Hubbard interaction \( v_{ijmn} \propto \delta_{im} \delta_{jn} \). In this case \( D = N \), \( D_s = 2N^2 \), \( M = N \), \( M_x = 2 \), \( m = N \) and \( m_x = 1 \) and the overall calculations scales like \( 2N^4 \). For a Hubbard like interaction \( v_{ijmn} \propto \delta_{im} \delta_{jm} \delta_{ij} \). In this case \( D = N \), \( D_s = N \), \( M = 1 \), \( M_x = 1 \), \( m = 1 \) and \( m_x = 1 \) and the overall calculation scales like \( 7N^2 \). More generally, the dissection algorithm minimize the scaling by exploiting the sparsity of the four-index Coulomb tensor. In Table 1 we report the scaling for four different organic molecules (first column). The second column shows the number \( N \) of bound Kohn-Sham states (either occupied or unoccupied) calculated using the Quantum Espresso package [40] whereas the third column shows the number of electrons \( N_{el} \) per spin of the charge neutral molecule. We calculated the Coulomb integrals in the bound sector using the Yambo code [41] and performed convergence tests on the time-dependent charge density put in motion by a weak attosecond laser pulse using the CHEERS code [39]. In all cases we found that the results converge by setting the cutoff \( \Lambda = 0.01 \) a.u. (the maximum value of the Coulomb integrals is about 0.5 a.u.). For all four molecules we calculated \( D, D_s, M, M_x, m \) and \( m_x \) and report the scaling \( S_{da} \) of Eq. (33) in the fourth column. This should be compared with the scaling \( 7N^5 \) in the fifth column. The gain factor \( g \equiv 7N^5 / S_{da} \) is reported in the last column.

## 5 Conclusions
We have described an algorithm to calculate the 2B self-energy appearing in the collision integral of the KBE and the GKBA equation. The basic idea consists in dissecting the set of Coulomb integrals in properly chosen (overlapping) subsets to exploit the sparsity of the Coulomb tensor. We have shown that the scaling of the computational cost reduces to \( N^4 \) for density-density type interactions and to \( N^2 \) for Hubbard-like interactions. For systems like atoms and molecules the net gain with respect to a \( N^5 \) scaling depends on the nature of the atoms. Our empirical evidence is that the gain factor increases with increasing the ratio \( N/N_{el} \), see Table 1.

The dissection algorithm as currently implemented in CHEERS [39] is further optimized by exploiting the symmetries in Eq. (6). This leads to a reduction by a factor of 2 of the dimension of the sets \( L \) and \( L(qs) \). The entire procedure can easily be generalized to complex (already implemented in CHEERS) and spin-dependent basis functions.
