Interaction-Transformation Evolutionary Algorithm for Symbolic Regression

Fabricio Olivetti de Franca, Member, IEEE, and Guilherme Seidyo Imai Aldeia

Abstract—The Interaction-Transformation (IT) is a new representation for Symbolic Regression that restricts the search space into simpler, but expressive, function forms. This representation has the advantage of creating a smoother search space unlike the space generated by Expression Trees, the common representation used in Genetic Programming. This paper introduces an Evolutionary Algorithm capable of evolving a population of IT expressions supported only by the mutation operator. The results show that this representation is capable of finding better approximations to real-world data sets when compared to traditional approaches and a state-of-the-art Genetic Programming algorithm.

Keywords—Symbolic Regression, Interaction-Transformation, evolutionary algorithms.

I. INTRODUCTION

Regression analysis has the objective of describing the relationship between measurable variables [1]. This analysis can be used to make predictions of not yet observed samples, to study a system’s behavior or to calculate the statistical properties of such system.

This concept can be formalized (In this paper we will adopt uppercase letters for matrices, lowercase bold or greek letters for vectors and lowercase letters for scalars) as, given a set of \( n \) \( d \)-dimensional samples in the form of a matrix \( X \in \mathbb{R}^{n \times d} \), denoted dependent variables, and a set of scalars in the form of a vector \( y \in \mathbb{R}^n \), named independent variables. Our goals is to find a mapping \( \mathbb{R}^d \rightarrow \mathbb{R} \) that maps any sampled \( x \in X \) to the corresponding measured \( y \in y \).

In other words, we wish to obtain \( f(x) \approx y \). Most commonly, this is performed by parametric models in which the function form is defined \textit{a priori} and the mapping is found by adjusting a set of free parameters \( \beta \). In such case, the function becomes \( f(x, \beta) \) with the goal of finding the optimal beta (\( \beta^* \)) that minimizes the approximation error of the model.

A simple example of parametric model is the \textbf{linear regression} that assumes a parametric function of the form:

\[
f(x, \beta) = \beta \cdot x,
\]

This model assumes that the relationship between independent and dependent variables is linear, an assumption that does not hold with many data sets. Despite that, this model is frequently used as it is descriptive and easy to understand how the variables interact with the system being studied.

Another famous example of a parametric model is the \textbf{Multi-layer Perceptron} (MLP), that may assume different forms similar to:

\[
\hat{y} = f(x, \beta, \gamma) = \gamma \cdot g(B \cdot x),
\]
where \( g(\cdot) \) is a vector of functions called activation functions. The activation function is usually a non-linear sigmoid function.

This model has the property of being an universal approximator [2]. Given the correct dimensions and values for \( B \) and \( \gamma \), it is possible to approximate any given function with a small error \( \epsilon \).

The models that are either difficult or impossible to interpret are called black box because they do not make the relationships between variables explicit.

Another regression model, commonly studied in the field of evolutionary algorithms, is the symbolic regression [3]. This approach searches for the function form that best fit the input data, introducing some flexibility to the model.

Often this is performed by means of genetic programming algorithms [4] a population based search algorithm that evolves expression trees with the goal of minimizing the approximation error.

A common problem related to the exploration of Expression Trees is the occurrence of potentially infinite number of expressions that are actually the same or equivalent in a given domain. For example, consider the following expressions:

\[
\begin{align*}
  f(x) &= \frac{x^3}{6} + \frac{x^5}{120} + \frac{x^7}{5040} \\
  f(x) &= \frac{16x(\pi - x)}{5\pi^2 - 4x(\pi - x)} \\
  f(x) &= \sin x.
\end{align*}
\]

Assuming that the function described in Eq. 3 is the one that describes the generating process, the other two functions can be considered reasonable approximations within a restricted domain. If we consider that the main objective of our study is to understand the behavior of the measured data, the third function is the only one that can be readily understood by the practitioner.

A solution to this problem is being treated by including simplicity as a secondary objective, either in the form of penalization or in a multi-objective approach [5, 6].

Recently, the Interaction-Transformation representation for expressions in the context of Symbolic Regression was introduced in [7]. The basic idea is that a mathematical expression should be described as a linear combination of nonlinear transformations of different interactions between the original variables.

Basically, this representation creates a new set of transformed variables that hopefully express a linear relationship with the target variable.

Together with this representation, the author in [7] also introduced a simple local search algorithm called SymTree. When tested on a simple set of benchmark functions (with up to five variables), this algorithm was capable of finding better approximations than state-of-the-art Genetic Programming approaches and traditional regression analysis algorithms.

The downside of this algorithm is that it does not scale well for higher dimensional problems.

In this paper we introduced an Evolutionary Algorithm for Symbolic Regression that evolves an Interaction-Transformation expression. In order to validate this approach, the algorithm will be applied to a set of real-world benchmarks commonly used on Genetic Programming literature [7, 8] and compared to the performance of traditional and state-of-the art algorithms.

This paper is organized as follows. The next section details the Interaction-Transformation representation with a brief explanation of its seminal algorithm and what has been done so far. In Sec. III, we will introduce the Interaction-Transformation Evolutionary Algorithm giving implementation details sufficient for reproducibility. Following, in Sec. IV, we will explain the methodology adopted in this paper and the experimental results obtained with the introduced algorithm. Finally, in Sec. V, we conclude this paper with some final comments regarding the results and perspectives.
for future research.

II. INTERACTION-TRANSFORMATION REPRESENTATION

In [7] a constrained representation, called Interaction-Transformation (IT), was proposed in such a way that it disallowed complex expressions and avoided redundancy in the search space. An IT expression is any function with the form:

$$f(x) = \sum_{i} w_i \cdot g_i(x),$$  \hspace{1cm} (4)

where $w_i$ is the $i$-th coefficient of a linear combination, hereafter referred to as \textit{weight}, and $g_i(.)$ is the $i$-th function that transforms the original variables to a new one.

The function $g(.)$ is described as the composition of two functions $g(.) = t(.) \circ p(.)$, with $t : \mathbb{R} \rightarrow \mathbb{R}$ a one-dimensional \textit{transformation} function and $p : \mathbb{R}^d \rightarrow \mathbb{R}$ a $d$-dimensional \textit{interaction} function. The interaction function has the form:

$$p(x) = \prod_{i=1}^{d} x_i^{k_i},$$  \hspace{1cm} (5)

where $k_i \in \mathbb{Z}$ is the exponent of the $i$-th variable, called the \textit{strength} of the interaction.

This representation has the advantage of restricting the search space to simple expressions such as:

$$f(x) = 3.5 \sin(x_1^2 \cdot x_2) + 5 \log(x_2^3/x_1),$$  \hspace{1cm} (6)

while not allowing more complicated function forms such as those with function chaining:

$$f(x) = \tanh(\tanh(\tanh(w \cdot x))).$$

Computationally, an IT expression can be represented as a tuple $(T, F, W)$ each one encapsulating the list of strengths for each term, the list of functions to be applied to each term and a list of weights.

For example, the expression in Eq. 6 can be represented as:

$$T = \{[2, 1], [-1, 3]\},$$
$$F = [\sin, \log],$$
$$W = [3.5, 5.0].$$

A. Symbolic Regression Search Tree

In [7], the Symbolic Regression Search Tree algorithm (SymTree) was introduced as a seminal algorithm to benchmark the potential of the IT expressions.

This algorithm is similar to a Breadth-first search in which the root state is the IT expression representing a simple linear regression.

At every step of the algorithm, each leaf node is expanded by performing a greedy search operation that creates a set of candidate terms that are either the combination of two terms of the parent node expression or a copy of one term from the parent node with a new transformation function.

The combination of terms is equivalent to multiplying or dividing two interactions of variables. For example, a combination of the terms $x_1^2 \cdot x_2$ and $x_1^{-1} \cdot x_2^3$ would generate the interaction $x_1 \cdot x_2^4$.

Given a set of candidate terms $\{t_1, t_2, t_3\}$, the power set would be $\{\emptyset, \{t_1\}, \{t_2\}, \{t_3\}, \{t_1, t_2\}, \{t_1, t_3\}, \{t_2, t_3\}, \{t_1, t_2, t_3\}\}$. This power set is split into two subsets: the set of solutions that improve the parent solution, called \textit{candidate solutions}, and the complement of this set, called \textit{terminal states} that no longer will be expanded.

For more details, we refer the reader to the seminal paper [7].

III. INTERACTION-TRANSFORMATION Evolutionary Algorithm

The Interaction-Transformation Evolutionary Algorithm (ITEA) proposed in this paper follows a basic
Algorithm 1: Interaction-Transformation Evolutionary Algorithm.

input: data points $X$ and corresponding set of target variable $y$.
output: symbolic function $f$

$\text{pop} \leftarrow \text{GenRandom}();$

while criteria not met do

$\text{children} \leftarrow \{\text{Mutate}(\text{child}) \text{ for child } \in \text{children}\};$

$\text{pop} \leftarrow \text{Select}(\text{pop}, \text{children});$

return $\text{arg max pop};$

mutation-based evolutionary algorithm as briefly described in Alg. 1.

Basically, the algorithm starts with a randomly generated population of solutions. After that, it performs two steps iteratively: mutation and selection. During the mutation step, each solution from the population is slightly modified, thus generating a new solution; the selection step chooses the next population with probability proportional to their quality.

Each one of these steps will be described in the following subsections together with some technical details of the implementation.

A. Representation

Each solution is an encapsulation of an IT expression together with the fitness value for that particular individual.

As such, each individual contains a list of terms, with each term represented by a list of interactions strength, a list of transformation functions, a list of weights, a variable representing the intercept of a linear regression, and a variable representing the fitness value.

For example, one individual representing Eq. 6 with a fitness of 0.001 would be encapsulated as the following structure:

<table>
<thead>
<tr>
<th>Individual</th>
</tr>
</thead>
<tbody>
<tr>
<td>terms = $[[2, 1], [-1, 3]]$;</td>
</tr>
<tr>
<td>funs = $[\sin, \log]$;</td>
</tr>
<tr>
<td>weights = $[3.5, 5.0]$;</td>
</tr>
<tr>
<td>intercept = 0.0;</td>
</tr>
<tr>
<td>fitness = $1e-3$;</td>
</tr>
</tbody>
</table>

B. Initial Population

In order to create a random initial population, each individual is created completely at random following certain rules:

- The IT expression must have at least one term and at most $k$ terms.
- The strength of each interaction for every term must be within a range $[lb, ub]$.
- The list of transformation functions must be sampled from a provided list of available functions.

After the terms and functions lists are created, the expression is fitted by using any Linear Regression algorithm providing the values for the weights, intercept and fitness.

C. Mutation

During the mutation step, each solution is modified by applying one out of six possible mutation algorithms chosen completely at random. Each mutation changes one aspect of the IT expression:

- **Drop term mutation**: removes one term from the expression. This is only applied if there is a minimum number of terms in the current expression.
- **Add term mutation**: adds a new random term to the expression. This is only applied if there is at most a certain number of terms in the current expression.
- **Replace interaction mutation**: replaces the interaction strength of a random term from the expression.
• **Replace transformation mutation**: replaces the transformation function of a random term from the expression.

• **Positive interaction mutation**: replaces a random term from the expression with the positive interaction with another random term. This changes the interaction strength by performing an element-wise addition of both strength lists.

• **Negative interaction mutation**: replaces a random term from the expression with the negative interaction with another random term. This changes the interaction strength by performing an element-wise subtraction of both strength lists.

After applying the mutation, the newly formed expression is fitted again using the linear regression algorithm chosen by the user, replacing the original list of weights, intercept and fitness.

Notice that when a new term is added, it may have no effect to the fitness if the corresponding weight is equal to zero.

**D. Selection**

The selection scheme should sample the solutions from the current and the mutated population forming a new population of solutions.

This sampling should favor the most fitted individuals but should also give a chance for diversification of the population.

**E. Evaluation exceptions**

Whenever the evaluation of a term generates invalid values such as infinity or *not a number*, the values for the entire column of such term is replaced by a constant value of zero and the term is removed afterwards.

**F. User-defined parameters**

In order to adjust the behavior of the algorithm and some aspects of the generated expression, ITEA allows for a wide range of user-defined parameters. These parameters should be set in order to better reflect the expectation for the final expression and, also, to reach a compromise between quality of solution and computational performance:

• **Population size** (*pop*): the size of the population. The higher this value, the larger the exploration of the search space but with a compromise of computational performance.

• **Set of Transformation functions** (*funcs*): the set of functions to be considered when creating an expression. This is domain-specific and should reflect the properties of the studied data set.

• **Stop criteria** (*stop*): when the algorithm should stop iterating. The criteria should allow the algorithm to stop whenever the population converges to a single solution or for as much computational budget they have.

• **Maximum number of terms** (*n_terms*): maximum number of terms when creating a random solution. A smaller number favors simpler solutions, but limits the search space.

• **Range of strength** (*lb*, *ub*): the range of the interaction strength when creating a random solution. Similar to the previous parameter, this controls the simplicity of the initial solutions and limits the search space.

• **Minimum length for drop mutation** (*min_drop*): the minimum number of terms to allow the application of the *drop* mutation. This parameter avoids the creation of trivial solutions with a small number of terms. Notice that it is still possible to create a solution with less than *min_drop* since the weight of the terms can be set to zero during the fitting step.

• **Maximum length for add mutation** (*max_add*): the maximum number of terms to allow the application of the *add* mutation. The opposite of the previous parameter, it avoids the creation of large
expressions.

- **Linear Regression fitting algorithm** (*model*): the algorithm that should be used to fit the linear coefficients of the expression.

- **Fitness measure** (*fitness*): the minimization objective-function to be used to evaluate the expression.

A sensitivity analysis of ITEA parameters is out of scope for this paper, as such, we will report the empirical parameters used during the experiments in Sec. IV.

### IV. Experimental Results

In this section we assess the performance of the proposed algorithm, ITEA, by following the experimental method described in [9]. These experiments will compare the obtained results against those obtained by different techniques, the complexity of the generated expressions when compared to a competent genetic programming algorithm, and the parallelization power of the algorithm when executed with multiple cores and processors.

Briefly, the main experimental setup consists of 8 real-world data sets taken from [10, 11]. Each data set was split into a 5-fold setup provided by the authors of [9] in order to allow a direct comparison with their reported results. Each algorithm is applied to each fold separation by adjusting the model with the training set and calculating the regression error against the training and test sets. For the stochastic algorithms, this experiment is repeated 6 times for each fold, totaling 30 runs for every data set. The deterministic algorithms are executed only once for each fold.

The regression error metric chosen was the Root Mean Squared Error calculated by:

\[
RMSE(y, \hat{y}) = \sqrt{\frac{1}{n} \sum_{i=1}^{n} (y_i - \hat{y}_i)^2},
\]

where \(\hat{y}\) is the vector of predicted values for each sample.

A brief description of the data sets are given in Table I. As we can see, the chosen data sets have a varying number of samples and features. Notice that Symbolic Regression algorithms are usually not tested against high-dimensional data sets as because they often demands an exponentially larger tree size. In this paper we will conform to this pattern and leave such tests for future research.

The obtained results are compared with some standard linear and nonlinear regression algorithms, with the GSGP proposed in [9] and with the seminal IT-based algorithm. Briefly, these algorithms and their corresponding reference names (in parentheses) are:

- **Ordinary Least Squares (OLS)**: linear regression using ordinary least square algorithm.
- **Ordinary Least Square with Ridge regularization (Ridge)**: the same as ols but with an \(l_2\) regularization term.
- **Coordinate Descent with Lasso regularization (Lasso)**: the coordinate descent algorithm with \(l_1\) regularization.
- **Least Angle Regression (LARS)**: another algorithm for linear regression with \(l_1\) regularization.
- **Elastic Net (ElNet)**: Coordinate Descent with a balance between \(l_1\) and \(l_2\) regularization.
- **Multi Layer Perceptron (MLP)**: a feed forward...
multi-layered neural network.

- **Gradient Boosted Regression Trees (GBRT):** a boosting algorithm for regression trees that incrementally adds weak models to complement the current boosted model.

- **Symbolic Regression Tree (SymTree):** the seminal algorithm introduced with the Interaction-Transformation representation (see Sec. II).

- **Geometric Semantic Genetic Programming (GSGP):** a variation of Genetic Programming in which the crossover and mutation operators take into account the semantics of the individual, thus leading to a smoother change. The version used here for the comparisons is the one introduced in [9] that applies an aggregation and expansion operators in order to reduce the size of the expression tree.

For all these algorithms, with the exception of SymTree, GSGP and ITEA, we have used the implementation provided by the Scikit-Learn Python library [12] version 0.20. The SymTree and ITEA algorithms were developed in Python 3.6.5 with the regression models also provided by the Scikit-Learn library.

### A. Parameters setup

All of the reported results for each algorithm was obtained through a Grid Search Cross Validation process. In this process the training set is split into 2-folds and then each combination of the parameters set is tested. The best set of parameters is then used to fit the model in the original training data.

The only two exceptions for this methodology were the GSGP algorithm, in which we have transcribed the reported results from [9], and ITEA in which we have used empirical parameters setup with sampled runs due to the extensive number of possible combinations. Specifically for the ITEA, a proper study of the parameters influence will be left to a future research paper.

For the MLP, we have tested one-hidden layer with \{50, 100, 500\} neurons and two-hidden layers with \{(50, 50), (100, 50), (500, 50)\} neurons. Also, we have considered both hyperbolic tangent and ReLU activation functions.

The Gradient Tree Boosting parameters set was a combination of \{10, 50, 100, 200, 300\} estimators, a maximum depth of \{2, 3, 4\} and learning rates of \{0.001, 0.01, 0.1, 1, 10\}.

In the case of the regularized linear regression algorithms, we have varied the \(\alpha = \{0.001, 0.01, 0.1, 1, 10\}\) and whether the data set was normalized prior fitting or not.

Finally, the SymTree algorithm was tested with significance thresholds of \{1e-3, 1e-4, 1e-5, 1e-6\}.

The parameters chosen for ITEA were \(\text{pop} = 500, \text{funcs} = \{\text{id, sin, cos, tanh}, \sqrt{\log, \log (x + 1), \exp}\}, \text{stop} = 500 \text{ iterations, n_terms} = 4, \text{lb} = 0, \text{ub} = 4, \text{min_drop} = 3, \text{max_add} = 10, \text{model} = \text{OLS, fitness} = \text{RMSE}\).  

### B. Results

The median of the RMSE for the training set is given by Tab. III. This table, and the following, is divided into three sections, the top section refers to Symbolic Regression algorithms, the middle section contains the nonlinear regression algorithms and the linear regression algorithms are at the bottom section.

From this table we can see that, with the exception of Tower Data, ITEA presented much better results than the linear regression approaches. This indicates that the proposed algorithm can return a significantly better result than basic benchmark.

With respect to the nonlinear approaches it was interesting to notice that ITEA results were much better than those obtained by MLP but significantly worse than XGBoost. It is expected that the black box approaches are more capable of achieving better results due to
their universal approximation nature and convergence properties.

Finally, when comparing to the Symbolic Regression approaches, ITEA was consistently better than GSGP but worse than SymTree, with the exception of Wine White in which SymTree was incapable of finding a result due to a memory error. Even though ITEA did not obtained the best results (ranked in third from all the tested algorithms) it was the one algorithm with the smaller expressions as we will see later.

From Table IV we can see the same median of the RMSE when applying the best model to the test set. These results are consistent with the previous table and the same observations are still valid. One thing to notice though, is that XGBoost was the only algorithm from this set affected by overfitting, having a significant difference in results from training to test sets. Despite this difference, it is still ranked as first among the algorithms.

Another important aspect of the Symbolic Regression algorithms is the expression size. It is usually argued that, even though the errors obtained by Symbolic Regression models are higher than state-of-the-art black box regression models, they compensate it by generating expressive models that can be analyzed by the practitioner.

In order to compare the three Symbolic Regression approaches, Tab. II reports the average number of nodes of the expression tree of the final expressions.

As we can see from this table, expressions generated by ITEA are more than $10\times$ smaller than GSGP and up to $9\times$ smaller than SymTree (with the exception of Yacht, in which SymTree found a smaller expression).

This contrast happens since, while the expressions generated by ITEA have a size constraint, disallowing the insertion of new terms whenever the expression already contains $n\_terms$, both GSGP and SymTree are free to insert how many terms they need to improve the solution.

V. CONCLUSION

The Interaction-Transformation representation is a recently conceived expression representation for regression models that simplify the expressions search space to an additive model of non-linear terms w.r.t. the original variable space.

This representation was shown to be effective in Symbolic Regression scenario when tested with popular artificial benchmarks.

In this paper we have introduced a mutation-based evolutionary algorithm with the purpose of evolving IT-expressions, which we named ITEA. The algorithm is composed of two simple steps: i) mutation and; ii) selection.

The mutation operator is composed of a selection of six different mutations chosen at random for a particular individual. Each one of these mutations change a structural component of the expression by adding or removing a term, changing a nonlinear function, replace part of the expression, or combining two terms through the interaction of variables.

For evaluation purposes, The algorithm was tested on 8 different real-world data sets and the obtained results were compared against those obtained by linear, nonlinear and black-box, and symbolic regression approaches.

The results indicated that ITEA is ranked third, losing only to XGBoost and SymTree, being particularly close to the second in rank. But, ITEA stands out on the size
of the generated expressions, being much smaller than SymTree and GSGP.

As for future research, we have different aspects of the algorithm that deserve a detailed investigation. For instance, a sensibility analysis of the parameters will help to verify which ones should be considered during a grid search or which ones could be fixed.

Also, we intend to propose a set of crossover operators which is expected to improve the convergence towards an optimal solution. Following this proposal, we will investigate the potentials of a multi-population approach running on a distributive environment to deal with higher dimensional data sets.

Finally, other bio-inspired approaches will be considered by adapting their core characteristics to the evolution of IT-expressions.

ACKNOWLEDGMENT

The authors would like to thank Luiz Otavio V. B. Oliveira, Ph.d. for gently providing the data sets to help the reproducibility in their experiments. Also, the experiments made use of Intel®AI DevCloud, which Intel® provided free access.
