Playing Adaptively Against Stealthy Opponents: A Reinforcement Learning Strategy for the FlipIt Security Game

Lisa Oakley and Alina Oprea
Khoury College of Computer Sciences, Northeastern University, Boston MA, USA

Abstract. A rise in Advanced Persistent Threats (APTs) has introduced a need for robustness against long-running, stealthy attacks which circumvent existing cryptographic security guarantees. FlipIt is a security game that models the attacker-defender interactions in advanced scenarios such as APTs. Previous work analyzed extensively non-adaptive strategies in FlipIt, but adaptive strategies rise naturally in practical interactions as players receive feedback during the game. We model the FlipIt game as a Markov Decision Process and use reinforcement learning algorithms to design adaptive strategies. We prove theoretical results on the convergence of our new strategy against an opponent playing with a Periodic strategy. We confirm our analysis experimentally by extensive evaluation of the strategy against specific opponents. Our strategies converge to the optimal adaptive strategy for Periodic and Exponential opponents. Finally, we introduce a generalized Q-Learning strategy with composite states that outperforms a Greedy-based strategy for several distributions, including Periodic and Uniform, without prior knowledge of the opponent’s strategy.

Keywords: Security games · FlipIt · Reinforcement learning · Adaptive strategies · Markov Decision Processes.

1 Introduction

Motivated by sophisticated cyber-attacks such as Advanced Persistent Threats (APT), the FlipIt game was introduced by van Dijk et al. as a model of cyber-interactions in APT-like scenarios [3]. FlipIt is a two-player cybersecurity game in which the attacker and defender contend for control of a sensitive resource (for instance a password, cryptographic key, computer system, or network). Compared to other game-theoretical models, FlipIt has the unique characteristic of stealthiness, meaning that players are not notified about the exact state of the resource during the game. Thus, players need to schedule moves during the game with minimal information about the opponent’s strategy. The challenge of determining the optimal strategy is in finding the best move times to take back resource control, while at the same time minimizing the overall number of moves (as players pay a cost upon moving). FlipIt is a repeated, continuous game, in
which players can move at any time and benefits are calculated according to the
asymptotic control of the resource minus the move cost.

The original FlipIt paper performed a detailed analysis of non-adaptive strate-
gies in which players move according to a renewal process selected at the begin-
ning of the game. Non-adaptive strategies are randomized, but do not benefit
from feedback received during the game. In the real world, players naturally get
information about the game and the opponent’s strategy as the game progresses.
For instance, if detailed logging and monitoring is performed in an organization,
an attacker might determine the time of the last key rotation or machine refresh
upon system takeover. van Dijk et al. defined adaptive strategies that consider
various amounts of information received during gameplay, such as the time since
the last opponent move. However, analysis and experimentation in the adaptive
case has remained largely unexplored. In a theoretical inspection, van Dijk et al.
prove that the optimal Last Move adaptive strategy against Periodic and Expo-
nential opponents is a Periodic strategy. They also introduce an adaptive Greedy
strategy that selects moves to maximize local benefit. However, the Greedy strat-
egy requires extensive prior knowledge about the opponent (the exact probability
distribution of the renewal process), and does not always result in the optimal
strategy [3]. Other extensions of FlipIt analyzed modified versions of the game
[13,5,19,10,6], but mostly considered non-adaptive strategies.

In this paper, we tackle the challenge of analyzing the two-player FlipIt game
with one adaptive player and one non-adaptive renewal player. We limit the
adaptive player’s knowledge to the opponent’s last move time and show how
this version of the game can be modeled as an agent interacting with a Markov
Decision Process (MDP). We then propose for the first time the use of temporal-
difference reinforcement learning for designing adaptive strategies in the FlipIt
game. We introduce a Q-Learning based adaptive strategy that plays the game
by leveraging information about the opponent’s last move times. We explore in
this context the instantiation of various reward and state options to maximize
the benefit of the Q-Learning strategy against a variety of opponents.

We start our analysis of the Q-Learning algorithm by considering an oppo-
nent playing with the Periodic with random phase strategy, also studied by [3].
We demonstrate for this case that the Q-Learning strategy with states based on
the time since opponent’s last move converges to the optimal adaptive strategy
(playing immediately after the opponent with the same period). We provide a
theoretical analysis of the convergence of the Q-Learning strategy against this
Periodic opponent. Additionally, we perform detailed experiments in the Ope-
nAI Gym framework, demonstrating fast convergence for a range of parameters
determining the exploration strategy and learning decay. Next, we perform an
analysis of the Q-Learning adaptive strategy against an Exponential opponent,
for which van Dijk et al. determined the optimal strategy [3]. We show experi-
mentally that Q-Learning with states based on the player’s own move converges
to the optimal strategy and the time to convergence depends largely on the
adaptive player’s move cost and the Exponential player’s distribution parame-
ters. Finally, we propose a generalized, composite strategy that uses as states
the time since last moves for both players. We show that the composite strategy converges to the optimal strategy for Periodic and Exponential. Remarkably, our Q-Learning algorithm has no prior information about the opponent strategy at the beginning of the game, and most of the time outperforms the Greedy algorithm (which leverages information about the opponent strategy). For instance, Q-Learning achieves average benefit between 5% and 50% better than Greedy against Periodic and 15% better than Greedy against a Uniform player.

The implications of our findings are that reinforcement learning is a promising avenue for designing optimal learning-based strategies in cybersecurity games. Practically, our results also reveal that protecting systems against adaptive adversaries is a difficult task and defenders need to become adaptive and agile in face of advanced attackers. To summarize, our contributions in the paper are:

– We model the FlipIt game with an adaptive player competing against a renewal opponent as an MDP.
– We propose a versatile generalized Q-Learning based adaptive strategy for FlipIt that does not require prior information about the opponent strategy.
– We prove our strategy converges to the optimal against a Periodic opponent.
– We demonstrate experimentally that the Q-Learning strategy converges to the optimal strategy and outperforms the Greedy strategy for a range of opponent renewal strategies.

Paper organization. We start with surveying the Related Work in Section 2. Then we introduce the FlipIt game in Section 3 and describe our MDP modeling of FlipIt and the Q-Learning algorithm in Section 4. We analyze Q-Learning against a Periodic opponent theoretically in Section 5. We perform experimental evaluation of Periodic and Exponential strategies in Section 6. We evaluate the generalized composite Q-Learning strategy against four distributions in Section 7, and conclude in Section 8.

2 Related Work

FlipIt, introduced by van Dijk et al. [3], is a non-zero-sum cybersecurity game where two players compete for control over a shared resource. The game distinguishes itself by its stealthy nature, as moves are not immediately revealed to players during the game. Finding an optimal (or dominant) strategy in FlipIt implies that a player can schedule its defensive (or attack) actions most effectively against stealthy opponents. van Dijk et al. proposed multiple non-adaptive strategies and proved results about their strongly dominant opponents and Nash Equilibria [3]. They also introduce the Greedy adaptive strategy and show that it results in a dominant strategy against Periodic and Exponential players, but it is not always optimal. The original paper left many open questions about designing general adaptive strategies for FlipIt. van Dijk et al. [1] analyzed the applications of the game in real-world scenarios such as password and key management.
Additionally, several FlipIt extensions have been proposed and analyzed. These extensions focus on modifying the game itself, adding additional players [10,6], additional resources [13], and additional move types [19]. FlipLeakage considers a different version of FlipIt in which information leakage is gradual and ownership of resource is obtained incrementally [5]. Zhang et al. consider limited resources with an upper bound on the frequency of moves and analyze Nash Equilibria in this setting [25]. Several games study human defender players against automated attackers using Periodic strategies [20,8,18]. All of this work uses exclusively non-adaptive players, often limiting analysis to solely opponents playing periodically. The only previous work that considers adaptive strategies is by Laszka et al. [15,14], but in a modified version of the original game with non-stealthy defenders. Our Q-Learning strategy can be generalized to play adaptively in these extensions and we leave that to future work.

Reinforcement learning (RL) is an area of machine learning in which an agent takes action on an environment, receiving feedback in the form of a numerical reward, and adapting its action policy over time in order to maximize its cumulative reward. Traditional methods are based primarily on monte carlo and temporal difference Q-Learning [22]. Recently, approximate methods based on deep neural networks have proved effective at complex games such as Backgammon, Atari and AlphaGo [23,17,21].

RL has emerged in security games in recent years. Han et al. use RL for adaptive cyber-defense in a Software-Defined Networking setting and consider adversarial poisoning attacks against the RL training process [9]. Hu et al. proposes the idea of using Q-Learning as a defensive strategy in a cybersecurity game for detecting APT attacks in IoT systems [11]. Motivated by HeartBleed, Zhu et al. consider an attacker-defender model in which both parties synchronously adjust their actions, with limited information on their opponent [26]. Other RL applications include network security [4], spatial security games [12], security monitoring [2], and crowdsensing [24]. Markov modeling for moving target defense has also been proposed [7,16].

To the best of our knowledge, our work presents the first application of RL to stealthy security games, resulting in the most effective adaptive FlipIt strategy.

3 Background on the FlipIt Game

FlipIt is a two-player game introduced by van Dijk et al. to model APT-like scenarios [3]. In FlipIt, players move at any time to take control of a resource. In practice, the resource might correspond to a password, cryptographic key, or computer system that both attacker and defender wish to control. Upon moving, players pay a move cost (different for each player). Success of a player in the game is measured by the asymptotic amount of resource control minus the move cost. The game is infinite, and we consider a discrete version of the game in which players can move at discrete times. Figure 1 shows an example of the FlipIt game, and Table 1 provides relevant notation we will use in the paper.
Playing Adaptively Against Stealthy Opponents

Fig. 1: Example of FlipIt game between Last-Move adaptive Player 1 and Player 0 using a Renewal strategy. Rounded arrows indicate player moves. The first move of Player 1 is flipping, and the second move is consecutive. $\tau_t$ is the time since Player 0's last known move at time $t$ and $\text{LM}_i$ is Player $i$'s actual last move at time $t$. Due to the stealthy nature of the game, $\tau_t \geq t - \text{LM}_0$.

</table>

An interesting aspect of FlipIt is that the players do not automatically learn the opponent’s moves in the game. In other words, moves are stealthy, and players need to move without knowing the state of the resource. There are two main classes of strategies defined for FlipIt:

Non-adaptive Strategies. Here, players do not receive any feedback upon moving. Non-adaptive strategies are determined at the beginning of the game, but they might employ randomization to select the exact move times. Renewal strategies are non-adaptive strategies that generate the intervals between consecutive moves according to a renewal process. The inter-arrival times between moves are independent and identically distributed random variables chosen from a probability density function (PDF). Examples of renewal strategies include:

- Periodic with random phase ($P_\delta$): The player first moves uniformly at random with phase $R_\delta \in (0, \delta)$, with each subsequent move occurring periodically, i.e., exactly at $\delta$ time units after the previous move.
- Exponential: The inter-arrival time is distributed according to an exponential (memoryless) distribution $E_\lambda$ with rate $\lambda$. The probability density function for $E_\lambda$ is $f_{E_\lambda}(x) = \lambda e^{-\lambda x}$, for $x > 0$, and 0 otherwise.
- Uniform: The inter-arrival time is distributed according to an uniform distribution $U_{\delta,u}$ with parameters $\delta$ and $u$. The probability density function for $U_{\delta,u}$ is $f_{U_{\delta,u}}(x) = 1/u$, for $x \in [\delta - u/2, \delta + u/2]$, and 0 otherwise.
– Normal: The inter-arrival time is distributed according to a normal distribution $N_{\mu,\sigma}$ with mean $\mu$ and standard deviation $\sigma$. The probability density function for $N_{\mu,\sigma}$ is $f_{N_{\mu,\sigma}}(x) = \frac{1}{\sqrt{2\pi\sigma^2}}e^{-(x-\mu)^2/2\sigma^2}$, for $x \in \mathbb{R}$.

**Adaptive Strategies.** In these strategies, players receive feedback during the game and can adaptively change their subsequent moves. In *Last Move (LM)* strategies, players receive information about the opponent’s last move upon moving in the game. This is the most restrictive subset of adaptive players, so we only focus on LM adaptive strategies here.

Theoretical analysis of the optimal LM strategy against specific Renewal strategies has been shown [3]. For the Periodic strategy, the optimal LM strategy is to move right after the Periodic player (whose moves can be determined from the LM feedback received during the game). The memoryless property of the exponential distribution implies that the probability of moving at any time is independent of the time elapsed since the last player’s move. Thus, an LM player that knows the Exponential opponent’s last move time has no advantage over a non-adaptive player. Accordingly, the dominant LM strategy against an Exponential player is still a Periodic strategy, with the period depending on the player’s move cost and the rate of the Exponential opponent.

**Greedy Strategy.** To the best of our knowledge, the only existing adaptive strategy against general Renewal players is the “Greedy” strategy [3]. Greedy calculates the “local benefit”, $L(z)$ of a given move time, $z$, as:

$$L(z) = \frac{1}{z} \left[ \int_0^z x f_0(x) dx + z \int_z^{\infty} \hat{f}_0(x) dx - k_1 \right],$$

(1)

where $\hat{f}_0(x) = f_0(\tau + x)/(1 - F_0(\tau))$, $f_0$ is the PDF of the opponent’s strategy, $F_0$ is the corresponding cumulative density function (CDF), and $\tau$ is the interval since the opponent’s last move. Greedy finds the move time, $\hat{z}$, which maximizes this local benefit, and schedules a move at $\hat{z}$ if the maximum local benefit is positive. In contrast, if the local benefit is negative, Greedy chooses not to move, dropping out of the game.

Although the Greedy strategy is general and able to compete with any Renewal strategy, it is dependent on knowledge of the opponent’s strategy. van Dijk et al. showed that Greedy is optimal against Periodic and Exponential players [3]. However, they showed an example strategy for which Greedy is not optimal. This motivates us to look into other general adaptive strategies that *achieve higher benefit than Greedy* and *require less knowledge about the opponent’s strategy*.

4 **New Adaptive Strategy for Flipt**

Our main insight is to apply traditional reinforcement learning (RL) strategies to the Flipt security game to create a Last Move adaptive strategy that outperforms existing adaptive strategies. We find that modeling Flipt as a *Markov Decision
1. Estimate value of $a_t$ in $s_t$
2. Store estimated value in $Q(s_t, a_t)$
3. Choose $a_{t+1}$ (with exploration)

(see Algorithm 1 for details)

Agent (Adaptive Player) \hspace{1cm} Environment (FlipIt game history)

Process (MDP) and defining an LM Q-Learning strategy is non-trivial, as the stealthy nature of the game resists learning. We consider the most challenging setting, in which the adaptive player has no prior knowledge on the opponent’s strategy. In this section, we present a strategy which is able to overcome those challenges and elegantly compete against any Renewal opponent.

### 4.1 Modeling FlipIt as an MDP

Correctly modeling the game of two-player FlipIt as an MDP is as important to our strategy’s success as the RL algorithm itself. In our model, player 1 is an agent interacting with an environment defined by the control history of the FlipIt resource as depicted in Figure 2.

We consider the infinite but discrete version of FlipIt and say that at every time step, $t \in \{1, 2, \ldots \}$, the game is in some state $s_t \in S$ where $S$ is a set of observed state values dependent on the history of the environment. At each time $t$, the agent chooses an action $a_t \in A = \{0, 1\}$ where 0 indicates waiting, and 1 indicates moving. The environment updates accordingly and sends the agent state $s_{t+1}$ and reward $r_{t+1}$ defined in Table 2 and Equation (3), respectively.

Defining optimal state values and reward functions is essential to generating an effective RL algorithm. In a stealthy game with an unknown opponent, this is a non-trivial task that we will investigate in the next two sections.

**Modeling State.** At each time step $t$, the LM player knows two main pieces of information: her own last move time ($LM_1$), and the time since her opponent’s last known move ($\tau_t$). The observed state can therefore depend on one or both of these values. We define three observation schemes in Table 2. We compare these observation schemes against various opponents in the following sections.

**Modeling Reward.** Temporal difference learning algorithms leverage incremental updates from rewards at each time tick, and therefore require the environment

</tbody>
</table>

To transmit meaningful reward values. A good reward should be flexible, independent of prior knowledge of opponent strategy, and most importantly promote the ultimate goal of achieving high benefit. We divide actions into three resulting categories: flipping, consecutive, and no-play based on the type of action and the state of the environment as depicted in Table 3.

The most straightforward reward after each action is a resulting benefit

\[
\beta_1^{(\alpha_t, s_t)} = I_1^{(\alpha_t, s_t)} - k_1
\]

where \( I_1^{(\alpha_t, s_t)} \) is the resulting gain, or Player 1’s additional time in control between time \( t \) and the opponent’s next move as a result of taking action \( \alpha_t \) in state \( s_t \). These rewards would sum to equal Player 1’s total benefit over the course of the game, therefore exactly matching the goal of maximized benefit.

For consecutive moves, \( \beta_1^{(\alpha_t, s_t)} = -k_1 \), as Player 1 is already in control, so she attains no additional gain, resulting in a wasted move. For no-plays, \( \beta_1^{(\alpha_t, s_t)} = 0 \), as not moving guarantees no additional gain and incurs no cost.

The main challenge here comes from determining reward for flipping moves. It is impossible to retroactively calculate an accurate \( \beta_1^{(\alpha_t, s_t)} \) in the case that Player 0 moves more than once between two of Player 1’s moves because she cannot determine the exact time she lost control. Moreover, there is no way to calculate future gain from any move against a randomized opponent, as the opponent’s next move time is unknown.

There are a few approaches to circumvent these issues that prove ineffective. One is to give higher reward for lower resulting \( \tau_{t+1} \) values, meaning that Player 1 receives more reward when she moves soon after her opponent. While this works against a Periodic opponent, it does not work against an Exponential opponent, as moving closely after is not the optimal strategy. Another approach is a reward based on prior gain, rather than resulting gain. This can be difficult to calculate and ultimately rewards previous moves, rather than the current action.

In the end, we found that the best reward against an unknown opponent is a fixed constant related to the opponent’s move frequency. Player 1 has no prior knowledge of the opponent strategy or distribution parameters, so she must attain an estimate of this value. Playing often toward the beginning of the game and keeping track of the observed move times can provide a rough estimate of Player 0’s move frequency, \( \rho \). We then define the reward resulting from \( \alpha_t \) as
Playing Adaptively Against Stealthy Opponents

\[ r_{t+1} = \begin{cases} 
0 & \text{if no-play at time } t \\
-k_1 & \text{if consecutive move at time } t \\
\frac{a-k_2}{c} & \text{if flipping move at time } t
\end{cases} \]  

where \( c \) is a constant determined before gameplay (for normalization).

4.2 Q-Learning Based Adaptive Strategy

In this section we present a new LM adaptive strategy, \( Q \), based on existing temporal difference reinforcement learning techniques, using our model of FlipIt from Section 4.1. While optimized to play against Renewal opponents, a \( Q \) player can still compete against an adaptive or otherwise defined strategy as she does not require knowledge of the opponent’s strategy. To the best of our knowledge, \( Q \) is the first adaptive strategy which can play FlipIt against any opponent without having any prior knowledge about their strategy.

**Value Estimation.** We want \( Q \) to use the feedback attained from the environment after each move and the information gathered during gameplay to estimate the value of action \( a_t \) in state \( s_t \). Player 1 does not have prior knowledge of the opponent’s strategy, therefore must learn an optimal strategy in real-time. We adopt an on-line temporal difference model of value estimation where \( Q(s_t, a_t) \) is the expected value of taking action \( a_t \) in state \( s_t \) as in [22].

We start by defining the actual value of an action \( a_t \) in state \( s_t \) as a combination of the immediate reward and potential future value as

\[ V_{s_t,a_t} = r_{t+1} + \gamma \cdot \max_{a' \in A} Q(s_{t+1}, a'). \]  

where \( 0 \leq \gamma \leq 1 \) is a constant discount to the estimated future value, and \( r_{t+1} \) is the environment-provided reward from Equation (3).

After each tick, we update our value estimate by a discounted difference between estimated move value and actual move value as follows:

\[ Q_{\alpha+1}(s_t, a_t) = Q_\alpha(s_t, a_t) + \frac{1}{\alpha + 1} (V_{s_t,a_t} - Q_\alpha(s_t, a_t)) \]  

where \( \alpha \) is the number of times action \( a \) has been performed in state \( s \), and \( 1/\alpha \) is the step-size parameter, which discounts the change in estimate proportionally to the number of times this estimate has been modified.

This update policy uses the estimate error to step toward the optimal value estimate at each state. Note that, if \( \gamma = 0 \), we play with no consideration of the future, and \( Q_\alpha(s, a) \) is just an average of the environment-provided rewards over all times action \( a \) was performed in state \( s \).

**Action Choice (Exploration).** A key element of any reinforcement learning algorithm is balancing exploitation of learned value estimation with exploration of new states and actions to avoid getting stuck in local maxima. We employ a modified decaying-\( \epsilon \)-greedy exploration strategy from [22] as
Algorithm 1

1: Estimate rate of play $\rho$ of opponent and drop out if $k_1 \geq \rho$
2: Initialize 2D table $Q$ with all zeros
3: Initialize $s_0$ according to observation type (see section 4.1)
4: for $t \in \{1, 2, \ldots \}$ do
5: if $Q(s_t, 0) = Q(s_t, 1)$ then
6: $a_t \leftarrow 0$ with probability $p$, else $a_t \leftarrow 1$
7: else
8: Choose action $a_t$ according to equation (6)
9: Simulate action $a_t$ on environment, and observe $s_{t+1}, r_{t+1}$
10: Update $Q(s_t, a_t)$ according to equation (5)

5 Theoretical Analysis for Periodic Opponent

We consider first an opponent playing periodically with random phase. Previous work has concluded that $P_\delta$ is the optimal strategy in most gameplay situations [3,15,14,6]. We first show theoretically that our Q-Learning LM strategy eventually learns to play optimally against a Periodic opponent when the future discount $\gamma$ is set at 0. We employ this restriction because, when $\gamma > 0$, the actual value of $a_t$ in $s_t$ ($V_{s_t, a_t}$) depends on the maximum estimated value in $s_{t+1}$, which changes concurrently with $Q(s_t, a_t)$. Additionally, Section 6.2 shows experimentally that changing $\gamma$ does not have much effect on benefit.

In the discrete version of FlipIt a player using the Periodic strategy $P_\delta$ plays first at some uniformly random $R_\delta \in \{0, \ldots, \delta\}$, then plays every $\delta$ ticks for all
subsequent moves. In this case, the optimal LM strategy is to play immediately after the opponent. Our main result is the following theorem, showing that the Q-Learning strategy converges to the optimal strategy with high probability.

**Theorem 1.** Playing against a $P_δ$ opponent with $γ = 0$, $k_1 < δ$, and using the ownLM observation scheme, $Q$ converges to the optimal LM strategy as $t → ∞$.

We will prove this theorem by first showing that $Q$ visits state $δ + 1$ infinitely often, then claiming that $Q$ will eventually play once in state $δ + 1$. We conclude by proving $Q$ eventually learns to play in state $δ + 1$ and no other state. This is exactly the optimal strategy of playing right after the opponent. Because the $P_δ$ strategy is deterministic after the random phase, we can model Player 1’s known state and transitions according to the actual state of the game as in Figure 3. We prove several lemmas and finally the main theorem below.

![Fig. 3: Q using oppLM states against $P_δ$. Arrows indicate state transitions. Red means $a_t = 1$, green means $a_t = 0$, and yellow means either $a_t = 0$ or $a_t = 1$.](image)

**Lemma 1.** If $t > R_δ$ and $a_t = 1$, $Q$ will visit state $δ + 1$ in at most $δ$ additional time steps.

**Proof.** We want to show that, for any $s_t$, with $t > R_δ$, choosing $a_t = 1$ means that $Q$ will visit state $δ + 1$ again in at most $δ$ additional time steps.

**Case 1:** Assume $1 < s_t < δ + 1$. We see from Figure 3 that $s_{t+1} = s_t + 1$, for all $a_t$ when $−1 < s_t < δ + 1$. Therefore, $Q$ will reach state $δ + 1$ in $δ + 1 − s_t < δ$ additional time steps.

**Case 2:** Assume $s_t ≥ δ + 1$. The opponent is $P_δ$, so $LM_1 < LM_0$ at time $t$. Given $a_t = 1$, Table 3 gives $s_{t+1} = t − LM_0 < δ + 1$, returning to Case 1.

**Case 3:** Assume $s_t = −1$ and $Q$ chooses $a_t = 1$. From Tables 2 and 3, we have that $s_{t+1} = t − LM_0 < δ + 1$, returning again to Case 1.

**Lemma 2.** Playing against a $P_δ$ opponent with $γ = 0$, $0 ≤ p < 1$ and $k_1 < δ$, $Q$ visits state $δ + 1$ infinitely often.

**Proof.** We prove by induction on the number of visits, $n$, to state $δ + 1$ that $Q$ visits state $δ + 1$ infinitely often.

**Base of Induction:** We show that, starting from $s_0 = −1$, $Q$ will reach $s_t = δ + 1$ with probability converging to 1. If $Q$ chooses $a_t = 1$ when $R_δ < t ≤ δ$,
this is a flipping move, putting $Q$ in state $s_{t+1} < \delta + 1$. If not, $t > \delta \ge R_{\alpha}$. When $s_t = -1$, $Q$ chooses $a_t = 0$ with probability $p$ and $a_t = 1$ with probability $1 - p$. Therefore

$$P[Q \text{ not flipping after } v \text{ visits to } s = -1] = p^v.$$  

(7)

This implies that $Q$ will flip with probability $1 - p^v \to 1$ as $t = v \to \infty$. By Lemma 1, $Q$ will reach state $\delta + 1$ in a finite number of steps with probability 1.

**Inductive Step:** Assume $Q$ visits state $\delta + 1$ $n$ times. Because we are considering an infinite game, at any time $t$ there are infinitely many states that have not been visited. Therefore $\exists m \ge \delta + 1$ such that $\forall s > m, Q(s) = (0,0)$.

If $Q$ flips at state $s_t \in \{\delta + 1, ..., m\}$, she will reach $\delta + 1$ again in a finite number of additional steps by Lemma 1.

If $Q$ does not flip at state $s_t \in \{\delta + 1, ..., m\}$, we have

$$P[Q \text{ does not move after } z \text{ steps}] = p^z. \tag{8}$$

By Lemma 2, we know that $Q$ visits state $\delta + 1$ infinitely often. Therefore, probability that $Q$ moves in state $\delta + 1$ is $1 - p^v \to 1$ as $v \to \infty$.

\[\square\]

**Lemma 3.** If $\gamma = 0$ and $k_1 < \delta$, $Q$ will eventually choose to move in state $\delta + 1$ with probability 1.

**Proof.** If $Q$ flips in any visit to state $\delta + 1$, the conclusion follows.

Assume $Q$ does not flip in state $s = \delta + 1$. Since $\gamma = 0$, from Equation (4), $V_{s_t, a_t} = 0$ for $a_t = 0$. Therefore $Q(s) = (0,0)$ and we have

$$P[Q \text{ does not flip after } v \text{ visits to state } \delta + 1] = p^v. \tag{9}$$

By Lemma 2, we know that $Q$ visits state $\delta + 1$ infinitely often. Therefore, probability that $Q$ moves in state $\delta + 1$ is $1 - p^v \to 1$ as $v \to \infty$. \[\square\]

**Proof of Theorem 1** We will now prove the original theorem, using these lemmas. To prove that $Q$ plays optimally against $P_\delta$, we must show that it will eventually (1) play at $s = \delta + 1$ at each visit and (2) not play at $s \neq \delta + 1$ at any visit. Assuming $\gamma = 0$, we have from section 2.5 of [22] that

$$Q_{\alpha+1}(s,a) = Q_{\alpha}(s,a) + \frac{1}{\alpha + 1} \cdot (r_{\alpha+1} - Q_{\alpha}(s,a)) = \frac{1}{\alpha + 1} \sum_{\alpha_1}^{\alpha+1} r_i. \tag{10}$$

Here we denote by $r_i$ the reward obtained the $i$-th time state $s$ was visited and action $a$ was taken. Additionally, $P_\delta$ plays every $\delta$ time steps after the random phase. Therefore we derive from Equation (3):

$$r_i = \begin{cases} 0 & \text{if } a_i = 0 \\ -k_1 & \text{if } a_i = 1 \text{ and } 1 \le s_i \le \delta \\ \delta - k_1 & \text{if } a_i = 1 \text{ and } s_i \ge \delta + 1 \end{cases} \tag{11}$$
By Equations (10) and (11), we have for all states $s$,

$$Q_\alpha(s, 0) = \frac{1}{\alpha} \sum_{i=1}^{\alpha} 0 = 0.$$  \hspace{1cm} (12)

First we show that $Q$ will eventually choose $a_t = 0$ in all states $1 < s_t < \delta + 1$. Consider some $s_t$ such that $1 < s < \delta + 1$. If $Q$ never chooses $a_t = 1$ in this state, we are done. Assume $Q$ plays at least once in this state, $\alpha > 0$, then

$$Q_\alpha(s, 1) = \frac{1}{\alpha} \sum_{i=1}^{\alpha} -k_1 = -k_1 < 0 = Q_\alpha(s, 0).$$  \hspace{1cm} (13)

since $k_1 > 0$. Therefore $\arg\max_{a \in A} Q(s, a) = 0$. Because $\epsilon' = \epsilon \cdot e^{-d \cdot v}$, and $0 \leq \epsilon, d < 1$, as $v \to \infty$ we have that $\epsilon' \to 0$. Therefore $P[Q$ does not play at $s] \to 1$ for $1 \leq s \leq \delta$ as desired.

Next we show that $Q$ will eventually play at state $\delta + 1$ at each visit. From Lemma 3, we know that $Q$ will play once at $s = \delta + 1$ with probability 1, meaning $\alpha > 0$ with probability 1. By Equations (10) and (11) we have for $\alpha > 0$ and $s = \delta + 1$,

$$Q_\alpha(s, 1) = \frac{1}{\alpha} \sum_{i=1}^{\alpha} \frac{\delta - k_A}{c} = \frac{\delta - k_A}{c} > 0 = Q_\alpha(s, 0).$$  \hspace{1cm} (14)

Now $\arg\max_{a \in A} Q(s, a) = 1$, so as $\epsilon' \to 0$, $P[Q$ plays at $s = \delta + 1] \to 1$.

If $Q$ plays at state $\delta + 1$, it will not reach states $s > \delta + 1$, and thus cannot play in those states. Therefore, as $t \to \infty$, $P[Q$ plays optimally] $\to 1$.

\[ \square \]

6 Q-Learning Strategies for Periodic and Exponential Opponents

In this section we show experimentally that $Q$ can learn to play optimally against $P_\delta$ and $E_\lambda$ opponents. Here, we assume that $Q$ has minimal information about the opponent. For the Periodic strategy, feedback about the opponent’s last move is useful in learning the optimal strategy. In contrast, for the Exponential strategy, information about the opponent’s moves is not needed due to the memoryless property of the exponential distribution. $Q$ thus needs to know which observation scheme to employ. We use the oppLM observation against $P_\delta$ and the ownLM observation against $E_\lambda$, but set other parameters of $Q$ identically. Next section, we generalize $Q$ to the setting of no prior information about the opponent.

6.1 Implementation

All experiments are run using a Python 3.5 simulation (https://github.com/lisaokley/flipit-simulation) with a custom OpenAI Gym environment.
Fig. 4: Player’s 1 average benefit for different $\epsilon$ and $p$ parameters at three time ticks. Here $Q$ plays with oppLM, $\gamma = 0$ and $k_1 = 25$ against a $P_\delta$ opponent with $\delta = 50$, averaged over 10 runs. Darker purples mean higher average benefit. $Q$ converges to optimal (.48), improving more quickly with low exploration.

(https://github.com/lisaoakley/gym-flipit) for FlipIt. We ran each experiment over a range of costs and Player 0 parameters within the constraint that $k_1 < \rho$, as other values have an optimal drop out strategy. For consistency, we calculated $\rho$ from the distribution parameters before running simulations. We report averages across multiple runs, choosing the number of runs and duration of each run to ensure convergence. For calculating integrals we used the quad function from the scipy.integrate library. For Greedy’s maximization step we used the minimize function from the scipy.optimize with the default “BFGS” algorithm.

Our algorithm can run against a variety of opponents with minimal configuration. Our algorithm is robust to the choice of opponent’s strategy, and thus all $Q$ hyper-parameters are the same across experiments, with $\gamma = 0.8$, $\epsilon = 0.5$, $d = 0.05$, $c = 5$, and $p = 0.7$ unless otherwise noted.

6.2 $Q$ vs. Periodic

In Section 5 we proved that $Q$ will eventually play optimally against $P_\delta$ when future discount $\gamma$ is 0 and $k_1 < \delta$. In this section, we show experimentally that most configurations of $Q$ using oppLM quickly lead to an optimal strategy. Additionally, we show there is little difference in benefit when $\gamma > 0$.

**Learning Speed.** When $\gamma = 0$, Equation (4) reduces to $V_{s,a} = r_{t+1}$. In this case we verify that $Q$ learns an optimal strategy for all exploration parameters, but that lower exploration rates cause $Q$ to reach optimal benefit more quickly. Against a Periodic opponent, $Q_{\alpha}(s,a)$ is constant after $Q$ takes action $a$ in state $s$ at least once ($\alpha > 0$). Thus, exploring leads to erroneous moves. When the probability of moving for the first time in state $s$ is low ($p$ is high), $Q$ makes fewer costly incorrect moves in states $s < \delta + 1$ leading to higher benefit. When $p = 1$, $Q$ never plays and $\beta_1 = 0$. Figure 4 displays Player 1’s average benefit
Playing Adaptively Against Stealthy Opponents

(a) Learning over time averaged over 50 runs per configuration. Optimal benefit vs. $P_\delta$ with $\delta = 50$ and $k_1 = 25$ in a discrete game is 0.48

(b) Statistics over 50 runs. “Non-optimal” runs have average benefit > .02 less than optimal (.48) after 500,000 ticks.

Fig. 5: $Q$ using oppLM with $k_1 = 25$ playing against $P_\delta$ with $\delta = 50$.

for different values of $p$ and $\epsilon$. $Q$ achieves close to optimal benefit after 64,000 ticks with high exploration rates $\epsilon$ and high probability of playing in new states $(1 - p)$, and in as little as 8,000 ticks with no exploration ($\epsilon = 0$) and low $1 - p$.

Varied Configurations. When $\gamma > 0$, $V_{s_t,a_t}$ factors in the estimated value of state $s_{t+1}$ allowing $Q$ to attain positive reward for choosing not to move in state $\delta + 1$. The resulting values in the $Q$ table can negatively impact learning. Figure 5 shows the average benefit over time (left) and the number of non-optimal runs (right) for different $\epsilon$ and $\gamma$ values. We observe that $Q$ performs non-optimally on 38% of runs with $\gamma = 0.8$ and $\epsilon = 0$ but has low benefit variation between runs. However, increasing $\epsilon$ even to 0.1 compensates for this and allows $Q$ to play comparably on average with future estimated value ($\gamma > 0$) as with no future estimated value ($\gamma = 0$). This result allows us flexibility in configuring $Q$ which we will leverage to maintain hyper-parameter consistency against all opponents. In the rest of the paper we set $\gamma = 0.8$, $\epsilon = 0.5$, and $p = 0.7$.

Comparison to Greedy. Assuming the Greedy strategy against $P_\delta$ plays first at time $\delta$, it will play optimally with probability $1 - k_1/\delta$. However, with probability $k_1/\delta$, Greedy will drop out after its first adaptive move [3]. We compare $Q$ and Greedy against $P_\delta$ for $\delta = 50$ across many costs in Figure 6. $Q$ consistently achieves better average benefit across runs, playing close to optimally on average. Additionally, Player 0 with $k_0 = 1$ attains more benefit on average against a Greedy opponent as a result of these erroneous drop-outs. For $k_1 < 45$, $Q$ attains benefit between 5% and 50% better than Greedy on average.
6.3 $Q$ vs. Exponential

The optimal LM strategy against an $E_\lambda$ opponent is proven in [3] to be Periodic with random phase on some fixed period, $\delta$. This $\delta$ is completely independent of $\tau$ as the Exponential distribution is memoryless, thus time since the opponent’s last move is irrelevant. Instead, optimal $Q$ moves $\delta$ steps after its own last move, regardless of the opponent’s last move time. $Q$ therefore uses the ownLM observation space from Table 2, rather than the oppLM space used against Periodic.

For $Q$ to learn any Periodic strategy, it must visit states $s < \delta$ many times. Table 4 shows that the optimal $\delta$ against an Exponential opponent grows quickly as $k_1$ increases. Therefore, as the optimal period increases, $Q$ takes additional time to learn. Figure 7 (a) shows the average benefit versus cost after running the algorithm for up to 4.096 million ticks for rate of the Exponential distribution $\lambda = 1/100$. Interestingly, for small costs, $Q$ learns to play optimally within a

very short time (16,000 ticks). As the move cost increases, $Q$ naturally takes longer to converge. We verified this for other values of $\lambda$ as well. Figure 7 (b) shows how the benefit varies by time for various move costs. Given enough time, $Q$ converges to a near-optimal Periodic strategy for all costs (even as high as $k_1 = 100$, which results in drop out for $\lambda = 1/100$).

7 Generalized Strategy

Previous sections show that $Q$ converges to optimal using the oppLM and ownLM observation schemes for the $P_\delta$ and $\mathcal{E}_\lambda$ opponents respectively. In this section we show that $Q$ using a composite observation scheme can play optimally against $P_\delta$ and $\mathcal{E}_\lambda$, and perform well against other Renewal strategies without any knowledge of the opponent’s strategy. The composite strategy uses as states both Player 1’s own last move time ($L_{\text{M}1}$), and the time since her opponent’s last known move ($\tau_t$), as described in Table 2. The composite strategy is the first general adaptive FlipIt strategy that has no prior information on the opponent.

Fig. 8: $Q$ with $k_1 = 10$ averaged over 10 runs. $Q$ converges to optimal against $P_\delta$ and $\mathcal{E}_\lambda$ using oppLM and ownLM observation schemes respectively, and plays close to optimally against both with composite observation scheme.
Fig. 9: Q’s average benefit by time for Uniform (left) and Normal (right) distributions with $k_1 = 10$. Q with oppLM and composite observations outperforms Greedy against $U_{\delta,u}$ averaged over 10 runs. Against both opponents, composite converges to oppLM as time increases.

7.1 Playing against $P_\delta$ and $E_\lambda$ Opponents

Figure 8 shows that Q’s average benefit eventually converges to optimal against both $E_\lambda$ and $P_\delta$ when using a composite observation scheme. We note that it takes significantly longer to converge to optimal when using the composite scheme. This is natural, as Q has an enlarged state space (quadratic compared to oppLM and ownLM observation schemes) and now visits each state less frequently. We leave approximation methods to expedite learning to future work.

7.2 Playing Against Other Renewal Opponents

The composite strategy results in flexibility against multiple opponents. We evaluate Q using composite observations against Uniform and Normal Renewal opponents in Figure 9. Q attains 15% better average benefit than Greedy against $U_{\delta,u}$. Figure 9 also shows that Q attains a high average benefit of 0.76 against a $N_{\mu,\sigma}$ opponent. We do not compare $N_{\mu,\sigma}$ to Greedy as the numerical packages we used were unable to find the maximum local benefit from Equation (1). Q using oppLM performs best against both opponents. Additionally, Q using composite attains average benefit within 0.01 of Q using oppLM against both opponents after 10 million time steps.

8 Conclusions

We considered the problem of playing the FlipIt security game with adaptive strategies. We designed a novel adaptive strategy based on temporal difference Q-Learning, instantiated with three different observations schemes. We showed theoretically that Q-Learning plays optimally against a Periodic Renewal opponent using the oppLM observation. We confirmed experimentally that our
Q-Learning strategy converges for a range of parameters against Periodic and Exponential opponents. For Exponential Renewal strategies, Q-Learning uses the ownLM observation. Finally, we designed a generalized Q-Learning algorithm with composite observation that can play well against a range of Renewal opponents, including Periodic, Exponential, Uniform, and Normal. Our composite strategy is the first adaptive strategy with no prior knowledge on the opponent.

We performed detailed experimental evaluation of our three observation schemes for a range of distributions parameters and move costs. Interestingly, we showed that certain hyper-parameter configurations for the amount of exploration ($\epsilon$ and $d$), future reward discount ($\gamma$), and probability of moving in new states ($1 - p$) are applicable against a range of Renewal strategies. Thus, our algorithm has the advantage of requiring minimal configuration.

In future work, we plan to consider extensions of the FlipIt game, such as multiple resources and different types of moves. We are interested in analyzing other non-adaptive strategies besides the class of Renewal strategies. Finally, approximation methods from reinforcement learning have the potential to make our composite strategy faster to converge and we plan to explore them in depth.
