NECK-PINCHING OF CP^1-STRUCTURES IN THE 
PSL(2, C)-CHARACTER VARIETY

SHINPEI BABA

Abstract. Let $S$ be a closed oriented surface of genus at least two. We consider a path of CP^1-structures $C_t$ on $S$ leaving every compact subset in the deformation space of (marked) CP^1-structures on $S$, such that its holonomy $\pi_1(S) \to \text{PSL}(2, \mathbb{C})$ converges in the PSL(2, C)-character variety. In this setting, it is known that the complex structure $X_t$ of $C_t$ also leaves every compact subset in the Teichmüller space.

In this paper, under the assumption that $X_t$ is pinched along a single loop $m$, we describe the limit of $C_t$ in terms of the developing maps, holomorphic quadratic differentials, and pleated surfaces. Moreover, we give an example of such a path $C_t$ whose the limit holonomy is the trivial representation in the character variety.

1. Introduction

Given a CP^1-structure on a (connected) closed oriented surface $S$ of genus at least two, its holonomy is a homomorphism $\pi_1(S) \to \text{PSL}(2, \mathbb{C})$, uniquely determined up to conjugation.
by PSL(2,\mathbb{C}). This correspondence yields the **holonomy map**

$$\text{Hol}: \mathcal{P} \to \chi,$$

where \(\mathcal{P}\) is the deformation space of all (marked) \(\mathbb{C}P^1\)-structures on \(S\) and \(\chi\) is the PSL(2,\mathbb{C})-character variety of \(S\).

Hejhal [Hej75] proved that \(\text{Hol}\) is a local homeomorphism (moreover, it is locally biholomorphic map [Hub81], [Ear81]); however it is not a covering map onto its image ([Hej75]). Thus a main problem of \(\mathbb{C}P^1\)-structures is to understand the global behavior of \(\text{Hol}\).

Throughout this paper, let \(C_t (t > 0)\) be a path of \(\mathbb{C}P^1\)-structures in \(\mathcal{P}\) such that

1. \(C_t\) leaves every compact subset in \(\mathcal{P}(\cong \mathbb{R}^{12g-12})\) at \(t \to \infty\), and
2. the holonomy \(\eta_t \in \chi\) of \(C_t\) converges to \(\eta_\infty \in \chi\) as \(t \to \infty\).

Kapovich [Kap95] raised the following problem: What is the asymptotic behavior of \(C_t\)? (See also [GKM00, Problem 12.5.1].)

In this paper, we give the answers to this question in a special case yet from different view points, creating a new type of degeneration. Although \(\eta_t\) is a strongly irreducible representation for each \(t \geq 0\), \(\eta_\infty\) may be reducible, or even, the identity representation, which we construct in §13. (It may be worth noting that we do not assume any regularity of the path \(\eta_t\) especially at \(t = \infty\).)

1.1. **Pinching loops on Riemann surfaces.** Let \(X_t\) be the complex structure of \(C_t\) for each \(t \geq 0\). Then, the conditions (1) and (2) imply that \(X_t\) must also leave every compact subset in the Teichmüller space \(T\) by the work of Kapovich and Tanigawa (see Corollary 2.2).

We focus on the following type of degeneration of \(X_t\). Given a path \(X_t \in T\), \(X_t\) is **pinched along a loop** \(m\) if

- \(\text{length}_{X_t} m \to 0\), and
- if an essential loop \(\ell\) in \(S \setminus m\) is not homotopic to \(m\), then \(\text{length}_{X_t} \ell\) is bounded between two positive numbers for all \(t \geq 0\).

Here “\(\text{length}_{X_t}\)” is either the extremal length of \(X_t\) or the hyperbolic length of the uniformization of \(X_t\). (In the augmented Teichmüller space, the above definition of pinching is equivalent to saying that \(X_t\) accumulates to a compact subset of the boundary stratum which corresponds to \(m\) having zero length.)

A **multiloop** is a union of disjoint finitely many essential simple closed curves. Then, similarly, we say that \(X_t\) is **pinched along a multiloop** \(M\) on \(S\), if, for each (essential) loop \(m\) of \(M\), \(\text{length}_{X_t} m \to 0\) as \(t \to \infty\) and for each loop \(\ell\) in \(S \setminus M\) not homotopic to a loop of \(M\), \(\text{length}_{X_t} \ell\) is bounded between two positive numbers for all \(t \geq 0\).

1.2. **Asymptotic behaviors.** One of our main results is that \(\text{tr} \eta_\infty (m)\) must be \(\pm 2\). In other words, the holonomy along \(m\) at \(t = \infty\) corresponds to either (i) a parabolic matrix or (ii) the identity matrix in PSL(2,\mathbb{C}). We will describe, in both Cases (i) and (ii), the asymptotic behavior of \(C_t\) from three different perspectives of \(\mathbb{C}P^1\)-structures:

(A) A holomorphic quadratic differential on a marked Riemann surface homeomorphic to \(S\) (Schwarzian parameters).
(B) A hyperbolic structure on \(S\) and a measured lamination, which induces an equivariant pleated surface \(\mathbb{H}^2 \to \mathbb{H}^3\) (Thurston parameters).
(C) A developing map $f : \hat{S} \to \mathbb{CP}^1$ and a holonomy representation $\rho : \pi_1(S) \to \text{PSL}(2, \mathbb{C})$.

The residue of a meromorphic quadratic differential $q$ at a pole is the integral of $\pm \sqrt{q}$ around the pole, which is well-defined up to sign (see [GW]). Given a pole of order two, letting $r$ be its residue, $q$ is expressed as $r^2/z^{-2}dz^2$ for an appropriate parametrization in a neighborhood of the pole (see [Str84, Theorem 6.3]).

Let $X$ be a nodal Riemann surface, and let $\hat{X}$ be the smooth part of $X$. Then the normalization $\overline{X}$ of $X$ is the smooth Riemann surface together with a continuous map $\xi : \overline{X} \to X$ such that $\xi$ is a biholomorphic in $\xi^{-1}(X)$ and for each node $p$ of $X$, $\xi^{-1}(p)$ consists of exactly two points. A regular quadratic differential on $X$ is a meromorphic quadratic differential $\tilde{q}$ on $\overline{X}$ such that

- each point of $\tilde{q}$ has an order at most two and it maps to a node of $X$, and
- if $z_1, z_2$ on $\overline{Z}$ map to the same node on $X$, then the residue around $z_1$ is equal to that of $z_2$

(see [Ber74] [LZ]).

For (A), the path $C_t$ corresponds to a path of pairs $(X_t, q_t)$, $t \geq 0$, where $X_t$ is a marked Riemann surface homeomorphic to $S$ and $q_t$ is a holomorphic quadratic differential $q_t$ on $X_t$ for all $t \geq 0$.

**Theorem A.** Suppose that $X_t$ is pinched along a loop $m$. Then exactly one of the following holds:

(i) $X_t$ converges to a nodal Riemann surface $X_\infty$ with a single node, and $q_t$ converges to a regular quadratic differential on $X_\infty$ such that the residue around the pole is a non-zero multiple of $\sqrt{2}\pi$ (Theorem 9.9.)

(ii) For every diverging sequence $0 \leq t_1 < t_2 < \ldots$, up to a subsequence, $X_{t_i}$ converges to a nodal Riemann surface $X_\infty$ with a single node and $q_{t_i}$ converges to a regular quadratic differential $q_\infty$ on $X_\infty$ such that the residue of each pole is a non-zero multiple of $\sqrt{2}\pi$. (Theorem 12.21.)

Suppose that $X_t$ is pinched along a multiloop $M$ consisting of $n$ loops. Then, for every diverging $t_1 < t_2 < \ldots$, there is a subsequence such that $X_{t_i}$ converges a nodal Riemann surface $X_\infty$ with $n$ nodes and $q_{t_i}$ converges to a meromorphic quadratic differential $q_\infty$ on $X_\infty$ which may has such that each node of $X_\infty$ is, at most, a pole of order two. (Corollary 7.4.)

The convergence of the holomorphic quadratic differential in Theorem A is normal convergence, and in particular, the $\mathbb{CP}^1$-structure $C_t$ converges to the $\mathbb{CP}^1$-structure corresponding to $(X_\infty, q_\infty)$ minus the node, uniformly on compact subset.

The character variety $\chi$ is the GIT-quotient of the space of homomorphisms $\pi_1(S) \to \text{PSL}(2, \mathbb{C})$, the representation variety (see §3). In order to have an equivariant object as a limit of $C_t$, we pick a lift $\rho_t : \pi_1(S) \to \text{PSL}(2, \mathbb{C})$ of $\eta_t \in \chi$, such that $\rho_t$ converges, as $t \to \infty$, to a homomorphism $\rho_\infty : \pi_1(S) \to \text{PSL}(2, \mathbb{C})$ which corresponds to $\eta_\infty$ (as $\eta_\infty$ may be an elementary representation, the existence of such a lift is not obvious); see Proposition 3.2. Let $N$ be a regular neighborhood of $m$ in $S$.

For $t \geq 0$, let $C_t \cong (\tau_t, L_t)$ be Thurston parameters, where $\tau_t$ is a path of marked hyperbolic structures on $S$ and $L_t$ is a path of measured laminations on $S$ (2.1.2). Fixing a marking $\iota_t : S \to \tau$ in its isotopy class, $(\tau_t, L_t)$ yields to a $\rho_t$-equivariant pleated surface
\( \beta_1: \tilde{S} \cong \mathbb{H}^2 \to \mathbb{H}^3 \), which changes continuously in \( t \geq 0 \). Then, in fact, \( \beta_t \) converges to a continuous map, in Case (ii), up to a subsequence:

**Theorem B.** Suppose that \( X_t \) is pinched along a loop \( m \). Then, by taking an appropriate path of markings \( \iota_t: S \to \tau_t \), exactly one of the following holds:

1. \( \rho_\infty(m) \in PSL(2, \mathbb{C}) \) is parabolic, and \( \beta_1: \tilde{S} \to \mathbb{H}^2 \) converges to a \( \rho_\infty \)-equivariant continuous map \( \beta_\infty: \tilde{S} \to \mathbb{H}^3 \cup \mathbb{C}P^1 \) uniformly on compact subset, such that \( \beta_\infty^{-1}(\mathbb{C}P^1) \) descends to \( m \) (Theorem 9.3).
2. \( \rho_\infty(m) \) is the identity in \( PSL(2, \mathbb{C}) \), and, for every diverging sequence \( t_1 < t_2 < \ldots \), there is a subsequence so that \( \beta_t: \tilde{S} \to \mathbb{H}^3 \) converges to a \( \rho_\infty \)-equivariant continuous map \( \beta_\infty: \tilde{S} \to \mathbb{H}^3 \cup \mathbb{C}P^1 \) such that \( \beta_\infty^{-1}(\mathbb{C}P^1) \) descends either to the loop \( m \) or to a subsurface isotopic to one or two components of \( S \setminus N \) (§12.0.1).

\( f_t: \tilde{S} \to \mathbb{C}P^1 \) be the developing map of \( C_t \) which is a \( \rho_t \)-equivariant continuous local homeomorphisms, and \( f_t \) changes continuously in \( t \geq 0 \). Let \( N \) be a regular neighborhood of \( m \). For each component \( \tilde{N} \) of \( \phi^{-1}(N) \), by abuse of notation, we regard the loop \( m \) also as the element of \( \pi_1(S) \) which preserves \( \tilde{N} \). We show that the developing map \( f_t \) converges in the complement of \( \phi^{-1}(N) \), and the asymptotic behavior on \( \partial\phi^{-1}(N) \) is well controlled by the holonomy of \( \rho_t(m) \). t Hyperbolic structures are in particular \( \mathbb{C}P^1 \)-structures. If a hyperbolic surface has a cusp, it has a neighborhood obtained by quotienting a horodisk in \( \mathbb{H}^2 \) by the cyclic group generated by a parabolic holonomy around the puncture. If a general \( \mathbb{C}P^1 \)-structure has a cusp, its neighborhood is either a horodisk quotient (uniformizable) or a grafting of a horodisk quotient. (See Proposition 5.2.)

**Theorem C.** Suppose that \( X_t \) is pinched along a loop \( m \). Then exactly one of the following two holds.

1. \( \rho_\infty(m) \) is parabolic,
   - the restriction of \( f_t: \tilde{S} \to \mathbb{C}P^1 \) to \( \tilde{S} \setminus \phi^{-1}(N) \) converges to a \( \rho_\infty \)-equivariant continuous map \( f_\infty: \tilde{S} \setminus \phi^{-1}(N) \to \mathbb{C}P^1 \), such that the boundary components of \( \tilde{S} \setminus \phi^{-1}(N) \) map to its corresponding parabolic fixed point (Theorem 9.3), and
   - moreover, if the cusps of \( C_\infty \) have horodisk quotient neighborhoods, then \( f_t: \tilde{S} \to \mathbb{C}P^1 \) converges to a \( \rho_\infty \)-equivariant continuous map \( f_\infty: \tilde{S} \to \mathbb{C}P^1 \), and, in fact, there is a multiloop \( M \) which is a union of finitely many parallel copies of \( m \) such that \( f_\infty \) is a local homeomorphism exactly on \( \tilde{S} \setminus \phi^{-1}(M) \), and \( f_\infty \) takes each component \( \tilde{m} \) of \( \phi^{-1}(M) \) to its corresponding parabolic fixed point (Theorem 9.6).
2. \( \rho_\infty(m) = I \), and for every diverging sequence \( t_1 < t_2 < \ldots \), there is a subsequence such that
   - the restriction of \( f_t \) to \( \tilde{S} \setminus \phi^{-1}(N) \) converges to a \( \rho_\infty \)-equivariant continuous map \( f_\infty: \tilde{S} \setminus \phi^{-1}(N) \to \mathbb{C}P^1 \), and
   - \( \text{Axis}(\rho_t(m)) \) converges to a geodesic in \( \mathbb{H}^3 \) or a point in \( \mathbb{C}P^1 \) so that \( f_\infty \) takes the boundary components of \( \tilde{N}_m \) onto the ideal points (in \( \mathbb{C}P^1 \)) of \( \lim_{i \to \infty} \text{Axis}(\rho_t(m)) \) (Theorem 12.1).

(See Definition 3.6 for the axes of matrices in \( PSL(2, \mathbb{C}) \).)

**Remark 1.1.** A \((2\pi\text{-})\)grafting is a (cut-and-paste) operation of a \( \mathbb{C}P^1 \)-structure, and it yields a new \( \mathbb{C}P^1 \)-structure with the same holonomy, by inserting an appropriate cylinder along an (admissible) loop (Gol87, see also Kap01, Bab). In the second part of (i) in Theorem C, each component of the multiloop (except one) corresponds to a \( 2\pi \)-grafting along
m. To be more precise, there is a continuous family of admissible loops $m_t$ on $C_t$ homotopic to $m$ for sufficiently large $t > 0$, such that the grafting $Gr_{m_t}C_t$ of $C$ along $m_t$ yields a very similar diverging path in $P$ except that the number of the loops of $M$ increases by one.

In fact, Cases (i) and (ii) in Theorem A, Theorem B, and Theorem C correspond. In particular the Type (i) degeneration occurs on the boundary of the quasi-Fuchsian space, by pinching a loop on a Bers slice.

On the other hand, the Type (ii) degeneration is new indeed. In particular $\eta_t$ must be non-discrete representation for all sufficiently large $t > 0$, possibly except at $t = \infty$ (Theorem 12.22). Notice that if the peripheral loop of a cups of a $\mathbb{CP}^1$-structure has trivial holonomy, then the $\mathbb{CP}^1$-structure can be deformed without changing the holonomy (of the entire surface), by moving the cusp (c.f. Theorem 5.7). Then, since $\rho_\infty(m) = I$, therefore it is necessarily to take a subsequence. In §13, we give examples of Type (ii) degenerations.

The integration of $\sqrt{q_t}$ yields a singular Euclidean structure $E_t$ on $X_t$ (see for example, [FM12]). A main step to the proof of the main theorem is to give a upper bound for the injectivity radius of $E_t$ for all $t \geq 0$ (Theorem 6.1). The existence of such an upper bound is equivalent to the upper bound of $L^\infty$-norm of $q_t$. Such an upper bound yields a certain bound for $C_t$.

Recall that the holonomy map Hol is a local homeomorphism for the closed surface $S$. However, in this paper, we also consider $\mathbb{CP}^1$-structure with cups, such the punctures are at most poles of order two. The holonomy theorem is proved for typical $\mathbb{CP}^1$-surfaces cusps by Luo ([Luo93]). (For higher order poles, see a recent preprint [AB]). However, in their theorems, the holonomy around the punctures are non-trivial (in their words, no “apparent” singularities. ) In order to have a convergence of $C_t$ in its thick part, we prove a holonomy theorem (Theorem 5.7) for the developing pairs of $\mathbb{CP}^1$-structures allowing trivial holonomy around punctures.

Gallo, Kapovich, and Marden algebraically characterized the image of Hol, and it is almost onto one of the two components of $\chi$ ([GKM00]). To be more precise, $\rho: \pi_1(S) \to$ PSL(2, $\mathbb{C}$) $\in \text{Im Hol}$ if and only if $\text{Im } \rho$ is non-elementary and $\rho$ lifts to a homomorphism from $\pi_1(S)$ into SL(2, $\mathbb{C}$). As an example of Type (ii) degeneration, we construct a path $C_t$ whose holonomy limits to an elementary representation, or even to the trivial representation in the space of representations (§13).

If a holonomy of $\mathbb{CP}^1$-structure around a puncture is trivial, as stated above, the correspondence between $\mathbb{CP}^1$-structures and holonomy representations are loose. A non-elementary subgroup of PSL(2, $\mathbb{C}$) has a non-trivial stabilizer, a similar difficulty occurs when the limit holonomy of a component of $S \setminus m$ elementary. The subtlety of the main theorems is to due to such flexibility.

1.3. Outline of this paper. In §2 we recall $\mathbb{CP}^1$-structures, and Schwarzian parameters, Thurston parameters, and Epstein surfaces for $\mathbb{CP}^1$-structures. In §3, we show a lifting property of paths in the character variety to paths in the representation variety. In §4, we give some estimates of Epstein surfaces based on Dumas’ work [Dum17]. In §5, we prove a holonomy theorem for the space of developing pairs of $\mathbb{CP}^1$-structures on surfaces with punctures, where punctures are at most poles of order two. This holonomy theorem is crucial for the convergence on $C_t$ in every thick part.

In §6, we show that there is an upper bound for the upper injectivity radius of $E_t$ for all $t \geq 0$. 

5
In §7, we show that $C_t$ converges every thick part as $t \to \infty$, so that $C_t$ converges to a \( \mathbb{C}P^1 \)-structure on a surface with two punctures homeomorphic to $S \setminus m$. In §8 we state our main theorems, and prove some properties of developing maps of surface with punctures. The limit holonomy around $m$ can only be parabolic or the identity. This will be shown, in §10, by supposing that the limit holonomy is parabolic or elliptic and reducing a contradiction against the convergence of the holonomy. In §9, we determine the asymptotic behavior of $C_t$ when $\rho_\infty(m)$ is parabolic. In §12, we give the asymptotic behavior of $C_t$ when $\rho_\infty(m) = I$.

In §13, we give new examples realizing (ii) in Theorem A, Theorem B, Theorem C.

2. Preliminaries

2.1. \( \mathbb{C}P^1 \)-structures. (General references of \( \mathbb{C}P^1 \)-structures are fund in [Dum09, Kap01].) A \( \mathbb{C}P^1 \)-structure $C$ on $S$ is a \( (\mathbb{C}P^1, \text{PSL}(2, \mathbb{C})) \)-structure, i.e. an atlas of charts embedding into $\mathbb{C}P^1$ with transition maps given by PSL(2, \mathbb{C}) (also called a complex projective structure).

Let $\tilde{S}$ be the universal cover of $S$. Then a \( \mathbb{C}P^1 \)-structure is, equivalently, a pair $(f, \rho)$ of a local homeomorphism $f: \tilde{S} \to \mathbb{C}P^1$ and a homomorphism $\pi_1(S) \to \text{PSL}(2, \mathbb{C})$ such that $f$ is $\rho$-equivariant. The map $f$ is called the developing map and $\rho$ is called the holonomy representation of $C$.

The pair is defined up to PSL(2, \mathbb{C})-equivalence, i.e. $(f, \rho) \sim (\alpha f, \alpha \rho \alpha^{-1})$ for all $\alpha \in \text{PSL}(2, \mathbb{C})$. Thus the holonomy is in the character variety.

2.1.1. Schwarzian parametrization. Each \( \mathbb{C}P^1 \)-structure corresponds to a holomorphic quadratic differential $q$ on a marked Riemann surface $X$. Thus the deformation space $\mathcal{P}$ of \( \mathbb{C}P^1 \)-structures is an (affine) vector bundle over the Teichmüller space $\mathcal{T}$, such that a fiber over a Riemann surface $X$ is the vector space $Q(X)$ of holomorphic quadratic differentials on $X$. In this paper, considering the uniformization map $\Pi: \mathcal{P} \to \mathcal{T}$, we regard the space of marked hyperbolic structures on $S$ as our (smooth) zero section.

Although $\text{Hol}: \mathcal{P} \to \chi$ is a highly non-proper map, for each $X \in \mathcal{T}$, the restriction of $\text{Hol}$ to the space $Q(X)$ is a proper embedding onto a complex analytic subvariety of $\chi$ ([GKM00]). Moreover

**Theorem 2.1** ([Kap95, Tan99]). For every compact subset $K$ of $\mathcal{T}$, the restriction of $\text{Hol}$ to $\Pi^{-1}(K)$ is a proper map.

**Corollary 2.2.** Suppose that $C_t \in \mathcal{P}$ leaves every compact subset in $\mathcal{P}$ and its holonomy $\rho_t$ converges in $\chi$. Then the complex structure $X_t$ of $C_t$ also leaves every compact subset in $\mathcal{T}$ as $t \to \infty$.

2.1.2. Thurston’s parametrization of \( \mathbb{C}P^1 \)-structures. ([KP94, KT92], see also [Bab].) Thurston gave a homeomorphism

$$\mathcal{P} \cong \mathcal{T} \times \text{ML},$$

where $\mathcal{T}$ is the space of marked hyperbolic structures on $S$ and $\text{ML}$ is the space of measured laminations on $S$. 

A pair \((\tau, L) \in \mathbb{P} \times \text{ML}\) yields a pleated surface \(\mathbb{H}^2 \to \mathbb{H}^3\) equivariant under the holonomy \(\pi_1(S) \to \text{PSL}(2, \mathbb{C})\) of its corresponding \(\mathbb{CP}^1\)-structure on \(S\). A collapsing map \(\kappa : C \to \tau\) is a marking preserving continuous map, and there is a measured lamination \(L\) on \(C\) which descends \(L\) by \(\kappa\), preserving strata. Moreover, \(\kappa\) which relates the developing map \(f : \tilde{S} \to \mathbb{CP}^1\) and the pleated surface \(\beta : \mathbb{H}^2 \to \mathbb{H}^3\) in an equivariant manner: For each \(z \in \tilde{S}\), let \(B_z\) be the maximal ball in \(\tilde{C}\) whose core contains \(z\), and let \(\Psi_z : B_z \to \text{Conv}\partial_{\infty}B_z \subset \mathbb{H}^3\) denote the orthogonal projection, where \(\text{Conv}\partial_{\infty}B_z\) is the hyperbolic plane bounded by the boundary circle. Namely,
\[
\beta \circ \tilde{k}(z) = \Psi_z f(z),
\]
where \(\tilde{k} : \tilde{C} \cong \mathbb{H}^2 \to \tilde{\tau}\) be the lift of \(\kappa\) to a map between universal covers.

### 2.2. Epstein maps.
Let \(C = (X, q)\) be a \(\mathbb{CP}^1\)-structure on \(S\), where \(X\) is the complex structure of \(X\), and \(q\) is a holomorphic quadratic differential on \(X\). Then, the integration of \(\sqrt{q}\) along paths yields a singular Euclidean metric \(E\) on \(X\) in the same conformal class (see for example [FM12]). In the complex plane, the directions parallel to the imaginary axis are called \textit{vertical}, and the directions parallel to the real axis are called \textit{horizontal}. Then, by pulling back the vertical and the horizontal lines of \(\mathbb{C}\), we obtain a vertical singular foliation \(V\) and a horizontal singular foliation \(H\) on \(E\) which are orthogonal.

Given a point \(x \in \mathbb{H}^3\), we can normalize the disk model of \(\mathbb{H}^3\) so that \(x\) is the center of the disk; then the ideal boundary of \(\mathbb{H}^3\) has the spherical metric uniquely determined by \(x \in \mathbb{H}^3\).

**Theorem 2.3 (Epstein [Ep])**. Given a \(\mathbb{CP}^1\)-structure \(C = (f, \rho)\) on \(S\), there is a unique continuous \(\rho\)-equivariant map \(\text{Ep} : \tilde{X} \to \mathbb{H}^3\), such that, for every point \(z \in \tilde{X}\), the Euclidean metric of \(\tilde{E}\) at \(z\) agrees with the spherical metric at \(f(z) \in \mathbb{CP}^1\) when \(\mathbb{CP}^1\) is identified with \(S^2\) so that \(\text{Ep}(z) \in \mathbb{H}^3\) is at the center of the disk model of \(\mathbb{H}^3\).

Moreover \(\text{Ep} : \tilde{X} \to \mathbb{H}^3\) is smooth away from the singular points of \(\tilde{E}\) (see Equation (3.1) in [Dum17]).

Let \(U\mathbb{H}^3\) denote the unite tangent bundle of \(\mathbb{H}^3\). Moreover \(\text{Ep}\) lifts to a (Legendrian) immersion \(\text{Ep}_* : T\tilde{E} \to U(\mathbb{H}^3)\) ([Dum17] Lemma 3.2) which is a unit normal to \(\text{Ep} : \tilde{X} \to \mathbb{H}^3\) in the complement of the singular points of \(E\). For \(z \in \tilde{X}\), let \(d(z)\) denote the Euclidean distance from \(z\) to the set \(Z\) of the zeros of the differential \(q\).

**Lemma 2.4 (Lemma 2.6, Lemma 3.4 in [Dum17])**. Let \(h'(z)\) and \(v'(z)\) be the horizontal and vertical unite tangent vectors at \(z \in \tilde{X} \setminus \tilde{Z}\). If \(\frac{6}{d(z)^2} < \frac{3}{2}\), then

1. \(\| \text{Ep}_* h'(z) \| < \frac{6}{d(z)^2}\),
2. \(\sqrt{2} < \| \text{Ep}_* v' \| < \sqrt{2} + \frac{6}{d(z)^2}\),
3. \(h'(z), v'(z)\) are the principal directions of \(\text{Ep}\) at \(z\), and
4. \(|k_v| < \frac{6}{d(z)^2}\), where \(k_v\) is the curvature of \(\text{Ep}\) in the \(v\)-direction.

### 3. A path lifting property of the GIT-quotient

**Definition 3.1.** A representation \(\rho : \pi_1(S) \to \text{PSL}(2, \mathbb{C})\) is elementary if \(\text{Im} \rho\) fixes a point in \(\mathbb{H}^3 \cup \mathbb{CP}^1\) or preserves two points on \(\mathbb{CP}^1\). Equivalently, \(\rho\) is elementary if \(\text{Im} \rho\) is strongly irreducible and \(\text{Im} \rho\) is unbounded in \(\text{PSL}(2, \mathbb{C})\). Otherwise \(\rho\) is called non-elementary.
Let $\mathcal{R}$ denote the $\text{PSL}(2, \mathbb{C})$-representation variety of $S$, the space of representations $\pi_1(S) \to \text{PSL}(2, \mathbb{C})$. By fixing a generating set $\gamma_1, \ldots, \gamma_n$, the topology of $\mathcal{R}$ is the restriction of $\text{PSL}(2, \mathbb{C})^n$ (which is independent on the choice of $\gamma_1, \ldots, \gamma_n$). The Lie group $\text{PSL}(2, \mathbb{C})$ acts on $\mathcal{R}$ by conjugation, and its GIT-quotient
\[ \Psi: \mathcal{R} \to \chi = \{ \pi_1(S) \to \text{PSL}(2, \mathbb{C}) \} / \text{PSL}(2, \mathbb{C}) \]
is called the $\text{PSL}(2, \mathbb{C})$-character variety of $S$.

Each fiber of the GIT-quotient is the set of representations in the same extended orbit equivalence class: Namely, for $\rho_1, \rho_2: \pi_1(S) \to \text{PSL}(2, \mathbb{C})$, $\rho_1 \sim \rho_2$ if and only if the closure of the $\text{PSL}(2, \mathbb{C})$-orbit of $\rho_1$ intersects that of $\rho_2$ in $\mathcal{R}$. For a non-elementary representation $\pi_1(S) \to \text{PSL}(2, \mathbb{C})$, its $\text{PSL}(2, \mathbb{C})$-orbit is a closed subset of $\text{PSL}(2, \mathbb{C})$ and form a single equivalence class \([\text{New}]\). Equivalently, $\rho_1 \sim \rho_2$ if and only if $\text{tr}^2 \rho_1(\gamma) = \text{tr}^2 \rho_2(\gamma)$ for all $\gamma \in \pi_1(S)$ \([\text{HP04}]\). For $\rho \in \mathcal{R}$, let $[\rho]$ denote it equivalent class $\Psi(\rho)$ in $\chi$.

**Proposition 3.2.** Suppose that $C_t$ ($t \geq 0$) is a one-parameter family of $\mathbb{C}P^1$-structures on $S$, such that its holonomy $\eta_t \in \chi$ converges to $\eta_\infty \in \chi$. Then $\eta_t$ lifts a path $\rho_t \in \mathcal{R}$ which converges to $\rho_\infty \in \mathcal{R}$ as $t \to \infty$, so that $[\rho_\infty] = \eta_\infty$.

**Remark 3.3.** The limit $\eta_\infty$ can be a non-elementary representation \([\S13]\), which makes this proposition nontrivial. In addition, there is $\eta \in \mathcal{R}$ with $[\eta] = \rho_\infty$ such that there is no lift $\eta_t$ of $\rho_t$ ending at $\eta$.

**Proof of Proposition 3.2.** Fix a generating set $\gamma_1, \ldots, \gamma_n$ of $\pi_1(S)$. We divide the proof into the three cases:

1. $\eta_\infty$ is non-elementary.
2. $\eta_\infty$ is elementary and there is $\gamma \in \text{PSL}(2, \mathbb{C})$ such that $\eta_\infty(\gamma)$ is hyperbolic, i.e. $\text{tr}^2(\gamma) \in \mathbb{C} \setminus [0, 4]$.
3. $\eta_\infty$ is elementary and elliptic, i.e. $\text{tr}^2 \eta_\infty(\gamma) \in [0, 4]$ for all $\gamma \in \pi_1(S)$, and there is $\gamma \in \pi_1$ with $\eta_\infty^2(\gamma) \in (0, 4)$.

**Case 1.**

**Lemma 3.4.** Suppose that $\eta_\infty$ is non-elementary. For every lift $\rho_\infty \in \text{PSL}(2, \mathbb{C})$ of $\Psi^{-1}(\eta_\infty)$, there is a lift $\rho_t \in \mathcal{R}$ of the path $\eta_t$ such that $\rho_t \to \rho_\infty$ as $t \to \infty$.

**Proof.** Over non-elementary representations, $\Psi$ is a fiber bungle with fibers $\text{PSL}(2, \mathbb{C})$. This implies the lemma. \hfill \Box

**Case 2.** Suppose that $\eta_\infty$ is elementary and there is $\gamma \in \pi_1(S)$ such that $\eta_\infty(\gamma)$ is hyperbolic. Then we have two cases:

(i) $\Psi^{-1}(\eta_\infty)$ consist of (reducible) representations $\rho: \pi_1(S) \to \text{PSL}(2, \mathbb{C})$ such that $\text{Im} \rho$ preserves $\ell$ and contains an elliptic element which reverses the orientation of $\ell$.

(ii) $\Psi^{-1}(\eta_\infty)$ consists of representations $\rho: \pi_1(S) \to \text{PSL}(2, \mathbb{C})$ such that $\text{Im} \rho$ fixes an endpoint of $\ell$ on $\mathbb{C}P^1$.

**Case 3.** Pick arbitrary $\rho \in \Psi^{-1}(\eta_\infty)$ and let $\ell = \text{Axis}(\rho(\gamma))$.

**Claim 3.5.** There are generators $\gamma_1, \gamma_2, \ldots, \gamma_n$ of $\pi_1(S)$, such that, for each $i = 1, \ldots, n$,

- $\rho(\gamma_i)$ is a hyperbolic element for $i = 1, \ldots, n - 1$, and
- $\rho(\gamma_n)$ is an elliptic element of order two about a geodesic orthogonal to $\ell$. 

Proof. By the hypothesis, one can pick generators $\gamma_1, \gamma_2, \ldots, \gamma_n$ of $\pi_1(S)$, such that $\rho(\gamma_i)$ is a (nontrivial) hyperbolic element. Then we can, in addition, assume that $\rho(\gamma_1), \ldots, \rho(\gamma_n)$ are not $I$ (by composing $\gamma_i$ with $\gamma_1$ if necessary). If $\rho(\gamma_i)$ is an elliptic element preserving the orientation of $\ell$, then $\rho(\gamma_1 \gamma_i)$ is hyperbolic—thus without loss of generality, we can assume that if $\rho(\gamma_i)$ is an elliptic element, it must reverse the orientation of $\ell$. Suppose that $\rho(\gamma_i)$ and $\rho(\gamma_j)$ are both elliptic elements reversing the orientation of $\ell$; then $\rho(\gamma_i \gamma_j)$ preserves the orientation of $\ell$. Thus, replacing $\gamma_j$ with $\gamma_i \gamma_j$, we can reduce the number of the generators which maps to elliptic elements reversing the orientation of $\ell$. We can repeat such replacements of generators, we obtain a desired generating set. \hfill \Box

Let $\gamma_1, \gamma_2, \ldots, \gamma_n$ be the generating set of $\pi_1(S)$ as in Claim 3.5. We show that there is indeed a lift $\rho_t$ in $R$ of $\eta_t$ converging to $\rho$ as $t \to \infty$. One can easily find a lift $\rho_t$ ($t \geq 0$) so that $\rho_t(\gamma_1)$ converges to $\rho(\gamma_1)$. Then $\text{Axis}(\rho_t(\gamma_1))$ must converge to $\ell$. For all $1 \leq i \leq n - 1$, $\text{Axis}(\rho_t(\gamma_i))$ and $\text{Axis}(\rho_t(\gamma_n))$ are asymptotically orthogonal (otherwise $\eta_\infty$ is non-elementary). In particular, we can in addition assume that $\rho_t(\gamma_n)$ converges to $\rho(\gamma_n)$, so that $\text{Axis}(\rho_t(\gamma_n))$ converges to a geodesic $m$ orthogonal to $\ell$. Then, for $1 < i < n$, $\text{Axis}(\rho_t(\gamma_i))$ converges $\ell$, as it is asymptotically orthogonal to $m$. Thus $\rho_t$ converges to $\rho$ as $t \to \infty$.

Case (i). Next suppose that $\Psi^{-1}(\eta_\infty)$ consists of elementary representations $\rho$ such that $\text{Im}(\rho)$ fixes a point in $\mathbb{C}P^1$. Then, similarly to Claim 3.5, we can find a generating set $\gamma_1, \ldots, \gamma_n$ such that their $\eta_\infty(\gamma_i), \ldots, \eta_\infty(\gamma_n)$ are all hyperbolic elements (i.e. $\text{tr}^2 \eta_\infty(\gamma_i) \in \mathbb{C} \setminus [0, 4]$).

Pick any lift $\rho_t$ of $\eta_t$ for $t \geq 0$ (which may not converge as $t \to \infty$). Then, similarly, for all $0 < i, j < n$, the distance between $\text{Axis}(\rho_t(\gamma_i))$ and $\text{Axis}(\rho_t(\gamma_j))$ goes to zero in $\text{UT}(\mathbb{H}^3)$ as $t \to \infty$, as $\eta_\infty$ is elementary. Thus we can continuously conjugate $\rho_t$ by elements of $\text{PSL}(2, \mathbb{C})$ so that the axes converge to geodesics sharing an endpoint. By this conjugation, $\rho_t$ converges as $t \to \infty$.

Case (iii). Suppose that $\text{Im} \eta_\infty$ contains no hyperbolic elements. Given an elliptic element and a parabolic element in $\text{PSL}(2, \mathbb{C})$ sharing a fixed point on $\mathbb{C}P^1$ then their product is an elliptic element. Therefore we can pick generators $\gamma_1, \ldots, \gamma_n$ of $\pi_1(S)$, such that $\eta_\infty(\gamma_i)$ are either all elliptic or all parabolic. Pick any lift $\rho_t \in R$ of the path $\eta_t \in \chi$ for $t > 0$, which may not converge as $t \to \infty$.

Definition 3.6. For $\gamma \in \text{PSL}(2, \mathbb{C})$, the axis $\text{Axis}(\gamma)$ of $\gamma$ is the convex hull of the fixed points in $\mathbb{H}^3 \cup \mathbb{C}P^1$ of $\gamma$—we denote it by $\text{Axis}(\gamma) \subset \mathbb{H}^3 \cup \mathbb{C}P^1$.

In particular, if $\gamma$ is hyperbolic or elliptic, $\text{Axis}(\gamma)$ is a geodesic plus its endpoints, and if $\gamma$ is parabolic, $\text{Axis}(\gamma)$ is a single point on $\mathbb{C}P^1$. Note that an ideal point of $\text{Axis}(\gamma)$ is a fixed point of $\gamma$ on $\mathbb{C}P^1$.

Fix a $\text{PSL}(2, \mathbb{C})$-invariant metric on the projective unite tangent space of $\mathbb{H}^3$. Suppose that $\gamma, \omega \in \text{PSL}(2, \mathbb{C})$ be hyperbolic or elliptic elements with axes $\ell_\gamma, \ell_\omega$. We measure the distance between $\ell_\gamma, \ell_\omega$ by embedding them into the projective unite tangent bundle of $\mathbb{H}^3$.

Lemma 3.7. (1) Suppose that $\eta_\infty(\gamma_i)$ and $\eta_\infty(\gamma_j)$ are both elliptic for distinct $1 \leq i, j \leq n$. Then the distance between $\text{Axis}(\rho_t(\gamma_i))$ and $\text{Axis}(\rho_t(\gamma_j))$ in $\text{UT}(\mathbb{H}^3)$ limits to zero as $t \to \infty$.

(2) Suppose that $\eta_\infty(\gamma_i), \eta_\infty(\gamma_j), \eta_\infty(\gamma_k)$ are all elliptic for distinct $1 \leq i, j, k \leq n$. Then there is a lift $\rho_t \in R$ of $\eta_t$ for $t \geq 0$, such that $\text{Axis}(\rho_t(\gamma_i)), \text{Axis}(\rho_t(\gamma_j))$, and $\text{Axis}(\rho_t(\gamma_k))$ converge to geodesics sharing an endpoint on $\mathbb{C}P^1$. 

If there is a diverging sequence $0 < t_1 < t_2 < \ldots$ such that the distance between $\text{Axis}(\rho_t(\gamma_i))$ and $\text{Axis}(\rho_t(\gamma_j))$ in $\text{UT}(\mathbb{H}^3)$ is bounded from below by a positive number, then $\eta_\infty$ is non-elementary. This is a contradiction.

By (1), if the assertion of (2) fails, there is a lift $\rho_t$ such that $\text{Axis}(\rho_t(\gamma_i))$, $\text{Axis}(\rho_t(\gamma_j))$, and $\text{Axis}(\rho_t(\gamma_k))$ converge to the distinct edges of an ideal triangle in $\mathbb{H}^3$. Then, $\eta_\infty$ is non-elementary against the hypothesis. □

Corollary 3.8. Suppose that there is a generating set $\{\gamma_1, \ldots, \gamma_n\}$ of $\pi_1(S)$, such that $\eta_\infty(\gamma_1), \ldots, \eta_\infty(\gamma_n)$ are all elliptic. Then there is a lift $\rho_t \in \mathcal{R}$ of $\eta_t$ such that $\rho_t(\gamma_1), \ldots, \rho_t(\gamma_n)$ converge to elliptic elements whose axes share an endpoint on $\mathbb{C}P^1$.

Last we suppose that $\eta_\infty(\gamma_1), \ldots, \eta_\infty(\gamma_n)$ are all parabolic, and we show that there is a lift of $\rho_t$ of $\eta_t$ to $\mathcal{R}$ such that $\rho_t$ converges to the trivial representation.

Pick a base point $O \in \mathbb{H}^3$. For each $t \geq 0$, let $d_{t,i} = d_{\mathbb{H}^3}(O, \rho_t(\gamma_i)O)$, and let $i_t$ be such that $d_{t,i_t} = \max_i d_{t,i}$.

Lemma 3.9. Let $t_1 < t_2 < \ldots$ be a diverging sequence such that $i_{t_k}, k = 1, 2, \ldots$ are a constant $h$ in $\{1, \ldots, n\}$ and suppose that there is a sequence $\omega_{t_k} \in \text{PSL}(2, \mathbb{C})$ such that $\omega_{t_k} \cdot \rho_{t_k}(\gamma_h) =: \omega_{t_k} \rho_{t_k}(\gamma_h) \omega_{t_k}^{-1}$ converges, as $k \to \infty$, to a parabolic element $\begin{pmatrix} 1 & u \\ 0 & 1 \end{pmatrix}$ in $\text{PSL}(2, \mathbb{C})$ with $u \neq 0$. Then, for every $j = 1, \ldots, n$, $\omega_{t_k} \rho_{t_k}(\gamma_j)$ accumulates to a bounded subset of $\begin{pmatrix} 1 & \mathbb{C} \\ 0 & 1 \end{pmatrix}$ whose image in $\mathbb{C}$ has a diameter less than $|u|$. □

Proof. Let $\omega_{t_k} \rho_{t_k}(\gamma_j) = \begin{pmatrix} a_{j,k} & b_{j,k} \\ c_{j,k} & d_{j,k} \end{pmatrix}$. Then, unless $\omega_{t_k} \rho_{t_k}(\gamma_j) \to I$, the limit of the fixed point set of $\omega_{t_k} \rho_{t_k}(\gamma_j) \subset \mathbb{C}P^1$ must converge to $\{\infty\}$ as otherwise, for sufficiently large integer $p$, $\omega_{t_k} \rho_{t_k}(\gamma_h \gamma_i^p)$ are, up to a subsequence, hyperbolic elements of translation length bounded from below by a positive number. Thus $c_{j,k} \to 0$ and $a_{j,k}, d_{j,k} \to 1$ as $k \to \infty$. Then, as $d_{t_k,j} = \max_i d_{t_k,i}$, we have the upper bound on the image in $\mathbb{C}$. □

As the index $h$ realizes the maximal displacement, we have

Corollary 3.10. Suppose that there is a diverging sequence $t_1 < t_2 < \ldots$ such that $d_{t_k,i} = d_{t_k,j} = d_{t_k}$ for some $i \neq j$. Then, if $\omega_{t_k} \rho_{t_k}(\gamma_i)$ converges to a nontrivial parabolic element, then $\omega_{t_k} \rho_{t_k}(\gamma_j)$ also converges to a non-trivial parabolic element with the same translation length in $\mathbb{C}$.

Therefore we have

Corollary 3.11. There is a continuous path $\omega_t \in \text{PSL}(2, \mathbb{C})$ such that $\omega_t \cdot \rho_t(\gamma_i)$ accumulates to a bounded subset of parabolic elements in $\begin{pmatrix} 1 & \mathbb{C} \\ 0 & 1 \end{pmatrix}$ for each $i$. Therefore there is a continuous path $\omega_t \in \text{PSL}(2, \mathbb{C})$ such that $\omega_t \cdot \rho_t$ converges to the trivial representation in $\mathcal{R}$.

4. Holonomy estimates away from zeros

In this section, based on Dumas’ work on Epstein surfaces [Dum17] and we give some further analysis of the Epstein surfaces in the horizontal direction. (We follow Dumas’
notations.) Let \( g_1 = e^{\alpha_1|dz|}, g_2 = e^{\alpha_2|dz|}\) be two conformal metrics on a Riemann surface; then the Schwarzian derivative of \( g_2 \) relative to \( g_1 \) is the following quadratic differential

\[
B(g_1, g_2) = [(\alpha_1)_{zz} - \alpha_2^2 - (\alpha_1)_{zz} + (\alpha_1)_z^2]dz^2.
\]

Let \( C = (X, q) \) be a \( \mathbb{C}P^1 \)-structure on \( S \).

- Let \( \tau \) be the hyperbolic metric on \( X \) by the uniformization.
- Let \( |\sqrt{q}| \) denote the singular Euclidean metric on \( X \) obtain by integrating \( \sqrt{q} \) along paths.
- Let \( g_{\mathbb{C}P^1} \) be the spherical metric on \( \mathbb{C}P^1 \) given by some conformal identification \( \mathbb{C}P^1 \cong \mathbb{S}^2 \).

Let \( f: \tilde{X} \to \mathbb{C}P^1 \) be the developing map of \( C \), and \( f^*(g_{\mathbb{C}P^1}) \) be the pull back of the conformal matrix \( g_{\mathbb{C}P^1} \) to the universal cover \( \tilde{X} \). Then let

\[
\omega = 2B(\tau, f^*(g_{\mathbb{C}P^1})),
\]
\[
\hat{\omega} = 2B(|\sqrt{q}|, f^*(g_{\mathbb{C}P^1})),
\]
\[
\nu = 2B(\sigma, \sqrt{q}),
\]

which are holomorphic quadratic differentials on \( \tilde{X} \).

### 4.1. Curvature of Epstein surfaces in the horizontal direction.

Let \( k_h \) and \( k_v \) be the principle curvatures of \( Ep: \tilde{X} \to \mathbb{H}^3 \) in the horizontal and the vertical directions, respectively. First by Equation 3.7 in [Dum17]

\[
k_v = |\hat{\omega}| - |\omega| \over |\hat{\omega}| + |\omega|.
\]

As the Gaussian curvature \( \kappa_h \kappa_v = 1 \) ([Dum17, p448]), we have

\[
k_h = |\hat{\omega}| + |\omega| \over |\hat{\omega}| - |\omega|.
\]

In addition,

\[
\| Ep_*(h') \|^2 = \frac{(|\hat{\omega}| - |\omega|)^2}{2|\omega\hat{\omega}|}
\]

(Equation 3.6 in [Dum17, p448]). Therefore

\[
(\| k_h \| \text{Ep}_*(h'))^2 = \frac{|\hat{\omega}| + |\omega|}{|\hat{\omega}| - |\omega|} \cdot \frac{(|\hat{\omega}| - |\omega|)^2}{2|\omega\hat{\omega}|} = 1 + \frac{(|\hat{\omega}|^2 + |\omega|^2)}{2|\omega\hat{\omega}|}
\]
\[
= 1 + \frac{1}{2} (\frac{|\hat{\omega}|}{|\omega|} + \frac{|\omega|}{|\omega|})
\]

Since \( \hat{\omega} = \omega - \nu \) ([Dum17, p447]), we have

\[
\left| \frac{\hat{\omega}}{\omega} \right| = \left| 1 - \frac{\nu}{\omega} \right| \quad ([Dum17, p449]).
\]

By [Dum17, Lemma 2.6], we have

\[
\left| \frac{\nu(z)}{\omega(z)} \right| \leq \frac{6}{d(z)^2}.
\]
Thus, recalling that $d(z)$ is the distance from the singular points, we have

$$\frac{|\omega(z)|}{|\omega(z)|} = 1 + O(d(z)^{-2}), \text{ and}$$

$$(k_h(z)\| Ep_\alpha(h'(z))\|)^2 = 2 + O(d(z)^{-2}).$$

Therefore, we have

**Lemma 4.1.** For all nonzero $z \in \tilde{X}$ of the differential $\tilde{q}$,

$$k_h(z)\| Ep_\alpha(h'(z))\| = \sqrt{2} + O(d(z))^{-1}.$$

### 4.2. Holonomy estimates of long flat cylinders

Let $E$ be a singular Euclidean surface. A flat cylinder in $E$ is a cylinder foliated by closed geodesics. A cylinder $A$ in $E$ is expanding if there is a geodesic loop $\ell$ on $E$ such that $A$ is foliated by one-parameter family of circles equidistant from $\ell$ whose length strictly increases as the distance to $\ell$ increases.

Let $\text{Ep}: \tilde{X} \to \mathbb{H}^3$ be the Epstein surface of a projective structure $C = (X, q)$ on $S$. Let $\alpha: [0, 1] \to \tilde{C} \cong \tilde{X}$ be an arc such that $\alpha(0)$ and $\alpha(1)$ are in $\tilde{X} \setminus \tilde{Z}$ and $\alpha$ differentiable at both endpoints. Then the curve $\text{Ep}\alpha: [0, 1] \to \mathbb{H}^3$ is differentiable at both endpoints. Let $\zeta(\alpha) \in \text{PSL}(2, \mathbb{C})$ be such that $\zeta(\alpha)$ takes the unite tangent vector $\alpha'(0)$ to $\alpha'(1)$ on $\text{Ep}$ and the unite normal $\text{Ep}_\alpha \alpha(0)$ to the unite normal $\text{Ep}_\alpha \alpha(1)$. We call $\zeta(\alpha) \in \text{PSL}(2, \mathbb{C})$ the holonomy (of $\text{Ep}$) along $\alpha$.

**Definition 4.2.** For $\alpha \in \text{PSL}(2, \mathbb{C})$, the rotation angle in $[0, \pi]$ is the (unsigned) rotation angle of the tangent plane of $\mathbb{CP}^1$ at a fixed point of $\alpha$.

Let $(E, V)$ be the singular Euclidean surface given by $C = (X, q)$.

**Definition 4.3.** Let $\alpha: [0, 1] \to \mathbb{H}^3$ be a $C^1$-smooth arc on the Epstein surface $\tilde{E} \to \mathbb{H}^3$. Let $v(t)$ and $h(t)$ denote the (unite) vector fields along $\alpha$ tangent to the vertical and horizontal foliations of $E$, respectively.

Let $\ell$ be a geodesic in $\mathbb{H}^3$. Let $\mathcal{H}$ be the foliation of $\mathbb{H}^3$ by the totally geodesic hyperbolic planes $H$ orthogonal to $\ell$. Note that the hyperbolic planes are identified by parallel transports along $\ell$, and thus their ideal boundary circles are identified as well.

Suppose that $v(t)$ is transversal to the foliation $\mathcal{H}$. Let $H_\ell$ be the leaf of $\mathcal{H}$ containing $\alpha(t)$. The translation length of $\alpha$ along $\ell$ is the distance between $H_0$ and $H_1$ (i.e. the length of the segment of $\ell$ between $H_0$ and $H_1$).

As $v(t)$ is transversal to $\mathcal{H}$, then $h(t)$ projects to a non-zero vector at the tangent space $T_{\alpha(t)}H_\ell$. Let $\theta(t) \in \partial_\infty H_\ell$ be the endpoint of the geodesic ray in $H_\ell$ given by the tangent vector. As all $\partial_\infty H_\ell$ are identified, $\theta(t) \in S^3$ lifts to $\tilde{\theta}(t) \in \mathbb{R}$. The rotation angle of $\alpha$ about $\ell$ is the total increase of $\tilde{\theta}(t)$, which takes a value in $\mathbb{R}$.

**Proposition 4.4.** Let $C_i = (f_i; \rho_i)$ be a sequence of $\mathbb{CP}^1$-structures on $S$, and let $(E_i, V_i)$ be the pair of a singular Euclidean structure $E_i$ and a vertical foliation $V_i$ on $E_i$ given by the Schwarzian parameters of $C_i$. Suppose that there are a loop $m$ on $S$, a geodesic representative $m_i$ of $m$ on $E_i$, for each $i$, and a flat cylinder $A_i$ in $E_i$ contains $m_i$, such that

- $m_i$ is in the middle of $A_i$, so that $A_i \setminus m_i$ is a union of two isometric flat cylinders,
- $\text{Mod}(A_i) \to \infty$ as $i \to \infty$, and
- the height $a_i$ of $A_i$ diverges to $\infty$ as $i \to \infty$. 12
Let $\tilde{m}_i$ be a segment on the universal cover $\tilde{E}_i$ obtained by lifting the simple close curve $m_i$. Then, by parametrizing $\tilde{m}_i$ by arc length $s \in [0, \text{length}(m_i)]$, for every $\epsilon > 0$, if $i > 0$ is sufficiently, then

1. the translation length of $\text{Ep}_i \tilde{m}_i(s)$ along $\ell_i$ is $(1 + \epsilon)$-bi-Lipschitz to $\sqrt{2} \left( \text{Re} \int_{m_i} \sqrt{q_t} \right)$,

2. the total rotation angle of $\text{Ep}_i \tilde{m}_i$ about $\ell_i$ is $(1 + \epsilon, \epsilon)$-bi-Lipschitz to $\sqrt{2} \left( \text{Im} \int_{m_i} \sqrt{q_t} \right)$,

3. for all $s \in [0, \text{length} m_i]$, $\text{Ep}_i \tilde{m}_i^*(v_s) \in U\mathbb{H}^3$ is contained in the $\epsilon$-neighborhood of a single oriented geodesic $\ell_i$ in $\mathbb{H}^3$ by embedding $\ell_i$ into $\text{UT}(\mathbb{H}^3)$.

**Proof.** Isotope $m_i$, in $A_i$ fixing a point on $m_i$ so that $m_i$ is a union of a vertical segment $u_i$ and a horizontal segment $w_i$ (Figure 1). Then $m_i$ remains close to the middle of $A_i$.

![Figure 1. Isotope $m_i$ to a union of a vertical and horizontal segment.](image)

We first analyze the vertical segment $\text{Ep}_i | u_i$. In the principal direction, the normal vector is preserved by parallel transports. Therefore the parallel transport along the curve $\Sigma_i | u_i$ yields the holonomy $\zeta_i(u_i(s)) \in \text{PSL}(2, \mathbb{C})$. By the hypotheses, the distance from the loop $u_i \cup w_i$ and the set $Z_i$ of zeros of the differential $q_i$ diverges to $\infty$. Therefore, by Lemma 2.4, the curvature along $\text{Ep}_i | u_i$ limits to zero, and it asymptotically has a constant speed $\sqrt{2}$, so that its length is $\sqrt{2}$ times the Euclidean length of $u_i$, which yields (1). Moreover

**Lemma 4.5.** The total (principal) curvature of the vertical segment $\text{Ep}_i | u_i$ limits to zero as $i \to \infty$.

**Proof.** Notice that $\text{length}_{E_i} u_i \leq \text{length}_{E_i} m_i$, as $u_i$ and $w_i$ are orthogonal. Then, the distance from $u_i$ to the singular set $Z_i$ of $E_i$ is at least $\frac{a_i}{3}$ for sufficiently large $i$.

Since $\text{Mod} A_i \to \infty$, thus $\frac{\text{length}_{E_i} m_i}{a_i} \to 0$. Then, by Lemma 2.4, the curvature of along the curve $\text{Ep}_i | u_i$ is less than

$$\frac{6}{(\frac{a_i}{3})^2} = \frac{54}{a_i^2}.$$ 

Therefore, the total curvature is bounded from above by

$$\left( \text{length}_{E_i} m_i \right) \frac{54}{a_i^2} = \frac{54}{a_i \text{ Mod} A_i},$$

and this upper bound goes to zero as $i \to \infty$ since $a_i \to \infty$ and $\text{Mod} A_i \to \infty$. \qed
The total curvature along the vertical segment $u_i$ goes to zero as $i \to \infty$ (Lemma 4.5). The amount of the total rotation is bounded from above by the total curvature, and the rotational part of the holonomy is at most $\epsilon$ for large $i$. Therefore, the holonomy along $u_i$ is $\epsilon$-close to the translation by $\sqrt{2} \text{length}_{E_i} u_i$ with $\epsilon$-small rotation.

The holonomy along $E_{p_i} u_i$ are asymptotically a hyperbolic element of $PSL(2, \mathbb{C})$ whose translation length by the Euclidean length of $u_i$ times $\sqrt{2}$.

By Lemma 2.4 (1),

$$\text{length}_{E_{p_i}} E_{p_i} w_i < \frac{6 \text{length}_{E_i} m_i}{(a_i/3)^2} \to 0,$$

as $i \to \infty$, we thus have

**Lemma 4.6.** $\text{length}_{E_{p_i}} E_{p_i} w_i \to 0$ as $i \to \infty$.

**Proposition 4.7.** Let $v_i(t)$ denote the tangent vector of $E_{p_i}$ at $E_{p_i} w_i(t)$ in the direction of $V_i$. For every $\epsilon > 0$, if $i$ is large enough, then along $w_i$, $E_{p_i}^* w_i(t)$ is contain in an $\epsilon$-ball in $U\text{Th}_3$.

**Proof.** Let $\tilde{E}_{i}$ be the universal cover of $E_{i}$. Pick a lift $\tilde{u}_i$ of the vertical segment $u_i$ in $E_i$ to $\tilde{E}_i$. Let $R_i$ be a Euclidean rectangle, in $\tilde{E}_i$, bounded by vertical and horizontal edges, such that $w_i$ divides $R_i$ into two isometric rectangles of half height (Figure 2, above). We may assume that the height of $R_i$ divided by the width of $R_i$ goes to zero as $i \to \infty$.

The vertical foliation $V_i$ and the horizontal foliation $H_i$ of $E_i$ induce a vertical and horizontal foliations of $R_i$. By Lemma 2.4 (2), for every $\epsilon > 0$, if $i$ is large enough, the restrictions of $E_{p_i}$ to vertical leaves in $R_i$ are $(\sqrt{2} - \epsilon, \sqrt{2} + \epsilon)$-bi-Lipschitz. By Lemma 2.4 (1), the $E_{p_i}$-images of the horizontal leaves in $R_i$ have diameters less than $\epsilon$. Therefore, for sufficiently large $i$, the images of vertical leaves of $R_i$ are pairwise $\epsilon$-close in the Hausdorff metric (Figure 2 below). As $v_i$ is tangent to the image of such a vertical leaf, we have the lemma.

![Figure 2](image)

Proposition 4.7 and Lemma 4.1 yield (2), and (3) follows from (1) and (2).
5. Holonomy maps for surfaces with punctures

5.1. Classification of cusps of \( \mathbb{CP}^1 \)-structures.

**Definition 5.1.** Let \( F \) be a surface with punctures. A \( \mathbb{CP}^1 \)-structure on \( F \) is a pair \( (X,q) \) of a Riemann surface structure \( X \) on \( F \) and a holomorphic quadratic differential \( q \) such that at each puncture of \( X \), \( q \) is at most a pole of order two.

This class is a natural class to consider, especially in our setting due to the upper injectivity radius bound (see Theorem 6.1). (In general, it is possible to consider higher order poles; see [GM, AB].)

**Proposition 5.2.** Let \( F \) be a surface with at least one puncture \( c \), and \( C = (f, \rho) \) a \( \mathbb{CP}^1 \)-structure on \( F \). Denote by \( \ell_c \) the peripheral loop around \( c \). Let \( C \sim = (\tau, L) \) be Thurston parameters, and \( (E, V) \) be the singular Euclidean structure \( E \) with the vertical foliation \( V \) given by the Schwarzian parameters of \( C \).

1. Suppose that a cusp neighborhood of \( c \) in \( E \) is an expanding cylinder of infinite modulus shrinking towards \( c \). Then
   - \( \rho(\ell_c) \) is parabolic,
   - \( c \) has a horoball quotient neighborhood, and
   - in Thurston parameters, \( c \) also has a horoball quotient neighborhood where the lamination \( L \) is the empty lamination.

2. Suppose that a cusp neighborhood of \( c \) in \( E \) is a (half-infinite) flat cylinder \( F \) of infinite modulus. Then exactly one of the following holds.
   a. The circumferences of \( F \) are not orthogonal to \( V \), \( \rho(\ell_c) \) is hyperbolic, and \( \sqrt{2} \int_{\ell_c} \sqrt{q} \) is its complex translation length.
      In Thurston parameters, the cusp \( c \) corresponds to boundary component \( b \) of \( \tau \) whose length is the real part of the translation length (in \( \mathbb{C}/2\pi i \mathbb{Z} \)).
   b. The circumferences of \( F \) are orthogonal to \( V \).
      - If \( \sqrt{2} V(\ell_c) \) is not a \( 2\pi \)-multiple, then \( \rho(\ell_c) \) is an elliptic element of angle \( \sqrt{2} \int_{\ell_c} \sqrt{q} \) (\( \in \mathbb{R} \)). In Thurston parameters, \( c \) is a cusp of \( \tau \) and the total weight of leaves of \( L \) around \( c \) (counted with multiplicity) is, modulo \( 2\pi \), equal to the rotation angle of \( \rho(\ell_c) \).
      - If \( \sqrt{2} V(\ell_c) \) is a \( 2\pi \)-multiple, then \( \rho(\ell_c) \) is either \( I \) or a parabolic element.
      In Thurston parameters, \( c \) is a cusp of \( \tau \) and the total weight of \( L \) around \( c \) is the \( 2\pi \)-multiple.

In (2b), by “counted with multiplicity”, we mean that, if a single leaf of \( L \) has both endpoints at \( c \), the weight of the leaf is counted twice.

**Proof.** (1) As the Euclidean distance to the cusp is finite in \( E \), in the hyperbolic metric on \( X \), the quadratic differential \( q \) vanishes asymptotically towards the cusp \( c \). The solution of the Schwarzian equation depends continuously in \( q \). As a Riemann surface with the zero differential (in our convention) corresponds to a hyperbolic structure, therefore \( c \) has a horoball quotient neighborhood in \( C \).

In Thurston parameters, \( c \) is a cusp of \( \tau \), and \( L \) is the empty lamination in a sufficiently small neighborhood of \( c \).

(2) By Proposition 4.4, the developing map of the half-infinite flat cylinder becomes closer and closer to the exponential map \( \exp : \mathbb{C} \to \mathbb{C}^* \) as a point in the domain approaches
to the cusp, where, in the domain $\mathbb{C}$, the vertical direction corresponds to the real direction and the horizontal direction corresponds to the imaginal direction (to be precise, the exp is composed with the calling to the domain $\mathbb{C}$ by $\sqrt{2}$). Thus the assertions about the holonomy along $\ell_c$ hold.

It remains only to show the description in Thurston parameters.

(2a) By Proposition 4.4, outside of a large compact set of $F$, all circumferences of $F$ are admissible loops. Therefore an appropriate neighborhood of $c$ corresponds to an infinite grafting cylinder. By [Bab17, Proposition 8.3], the hyperbolic surface $\tau$ has a (possibly open) boundary component corresponding to $c$, and its boundary length is indeed the translation length of the hyperbolic element $\rho(\ell_c)$.

(2b) The developing map in an appropriate cusp neighborhood is the exponential map $\exp: \mathbb{C} \to \mathbb{C}^*$ so that the deck transformation corresponds to the translation in the imaginary direction in the domain.

Therefore, $c$ is a cusp of $\tau$ and the total weight of leaves of $L$ near $c$ must be the length of the circumference times $\sqrt{2}$ (Proposition 4.4 (2)).

5.2. PSL(2, $\mathbb{C}$) and fixed points on CP$^1$. In order to construct an appropriate holonomy map for a surface with punctures, we will make PSL(2, $\mathbb{C}$) slightly bigger as a topological space, by carefully pairing with some fixed points on CP$^1$. Let $(\mathbb{C}P^1)^2/\mathbb{Z}_2$ denote the set of unordered pairs of points on CP$^1$. Let PSL(2, $\mathbb{C}$) be the set of all pairs $(\gamma, \Lambda) \in$ PSL(2, $\mathbb{C}$) $\times ((\mathbb{C}P^1)^2/\mathbb{Z}_2)$ such that

- if $\gamma$ is a hyperbolic element with zero rotation (i.e. $\text{tr} \gamma \in \mathbb{R} \setminus [-2, 2]$ when $\gamma$ is lifted to SL(2, $\mathbb{C}$)), then $\Lambda$ is a pair of (not necessarily distinct) fixed points of $\gamma$, and
- otherwise, $\Lambda$ is $(a, a)$ for a fixed point $a \in \mathbb{C}P^1$ of $\gamma$.

In particular, if $\gamma = I$, then $\Lambda$ can be $(a, a)$ for any $a \in \mathbb{C}P^1$. (By abuse of notation, if $\Lambda$ is a pair $(a, a)$ of identical points on $\mathbb{C}P^1$, for simplicity, we may regard $\Lambda$ as a single point $a$.)

We define a (non-Hausdorff) topology on PSL(2, $\mathbb{C}$) by the following open base at each $(\gamma, \Lambda) \in$ PSL(2, $\mathbb{C}$).

- If $\gamma$ is hyperbolic, for every (small) connected neighborhood $U$ of $\gamma$ in PSL(2, $\mathbb{C}$) consisting of hyperbolic elements, the subset of all pairs $(\gamma', \Lambda')$ such that $\gamma' \in U$ and $\Lambda'$ is a pairs of points in $\Lambda$, where the fixed points of $\gamma$ are naturally identified with those of $\gamma'$.
- If $\gamma$ is not hyperbolic, then the topology near $(\gamma, \Lambda)$ is given by the product topology of PSL(2, $\mathbb{C}$) $\times ((\mathbb{C}P^1)^2/\mathbb{Z}_2)$ equipped with the Hausdorff topology on $(\mathbb{C}P^1)^2/\mathbb{Z}_2$.

Remark 5.3. Let $C = (f, \rho)$ be a CP$^1$-structure on a surface with punctures. Let $\gamma \in \pi_1(S)$ be such that its free homotopy class is the peripheral loop around a cusp $c$ of $C$. Then $\gamma$ corresponds to a unique element in $(\mathbb{C}P^1)^2/\mathbb{Z}_2$ as follows: Let $\bar{c}$ be the point on the ideal boundary of $\hat{C}$ ($\cong \mathbb{H}^2$) fixed by $\gamma \in \pi_1(S)$. Let $(\tau, L) \in T \times ML$ be the Thurston parametrization of $C$, and let $\mathcal{L}$ be the canonical measured lamination on $C$ which descends to $L$. For each leaf $\ell$ of $\hat{L}$ ending at $\bar{c}$, the corresponding endpoint of the circular arc $f(\ell)$ on CP$^1$ is a fixed point of $\rho(\gamma)$. Thus $\gamma$ corresponds to a unique element $(\rho(\gamma), \Lambda)$ in PSL(2, $\mathbb{C}$), where $\Lambda$ is the set of such endpoints of the half leaves of $\hat{L}$ ending at $c$, if $\mathcal{L}$ is non-empty in a
small neighborhood of the cusp. If $L$ is empty near the cusp, an appropriate cusp neighborhood of $c$ is a horoball quotient, and $\gamma$ corresponds to $(\rho(\gamma), \Lambda)$, where $\Lambda$ is the parabolic fixed point of $\rho(\gamma)$.

5.3. Cusp neighborhoods in Thurston parameters. The following lemma determines the isomorphism classes of cusp neighborhoods of $\mathbb{CP}^1$-structures in Thurston coordinates.

**Lemma 5.4.** Let $C = (f, \rho)$ be a $\mathbb{CP}^1$-structure on a surface $F$ with cusps. Let $C \cong (\tau, L)$ be Thurston parameters of $C$. Then, for each cusp $c$ of $C$, its small neighborhood (i.e. its germ) in $C$ is determined by

- the holonomy $h \in \text{PSL}(2, \mathbb{C})$ around $c$,
- the transversal measure of a peripheral loop around $c$ given $L$, and
- if $h$ is hyperbolic, the direction in which the leaves of $L$ spirals towards the boundary component.

(See Figure [3])

![Hyperbolic, elliptic, parabolic, identity](image)

**Figure 3.** Cusp neighborhoods in Thurston parameters

**Proof.** Let $(E, V)$ be the pair of a singular Euclidean structure $E$ on $F$, and $V$ be a vertical foliation on $E$ given by $C$.

**Hyperbolic Case.** Suppose that $h \in \text{PSL}(2, \mathbb{C})$ is hyperbolic. Then, by Proposition 5.2, its cusp neighborhood, in $(E, V)$, corresponds to a half-infinite cylinder $A$, and the complex translation length is $\sqrt{2} \int_{\ell_c} \sqrt{q}$, where $\ell_c$ is a peripheral loop of $c$.

The developing map $f$ of a small neighborhood of $c$ is a restriction of the exponential map $\mathbb{C} \to \mathbb{C}^*$. Thus the complex translation length determines the deck transformation on the domain $\mathbb{C}$ by $\mathbb{Z} \cong \langle \ell_c \rangle$, which determines the $\mathbb{CP}^1$-structure of a small cusp neighborhood.

The cusp $c$ corresponds to the geodesic boundary circle $b$ of $\tau$ whose length equal to the translation length of $h$. By the properties of bending maps, one can show that the total weight of $L$ along $\ell_c$ times $\sqrt{2}$ is the rotational angle of $\ell_c$ and the direction in which leaves of $L$ spiral towards $b$ determines the orientation of the angle (Figure [4]).

**Parabolic Case.** Suppose that $\eta(\ell_c)$ is parabolic.

If a neighborhood of a cusp $c$ in $E$ is an expanding cylinder shrinking towards $c$, then a neighborhood of $c$ in $(\tau, L)$ is a hyperbolic cusp with the empty lamination (Proposition 5.2 (II)).

Next suppose that the cusp neighborhood of $c$ in $(E, V)$ is a half-infinite flat cylinder $A$ in $E$. Then the circumferences of $A$ are orthogonal to $V$, and $\sqrt{2}V(\ell_c)$ is a positive $2\pi$-multiple.
we construct a deformation of $K$ as in Proposition 5.5. Then there are isomorphic subsurfaces

**Proof of Proposition 5.5.**

Moreover, from the proof, we may assume that $\Sigma_\gamma'$ is unique near the cusp.

**Corollary 5.6.** Let $\tilde{D}^*$ be a subsurface of $D^*$ obtained by removing a regular neighborhood of the boundary circle of $D^*$. Suppose, in Proposition 5.5, that there are two projective structures $\Sigma_1$ and $\Sigma_2$ realizing $(\gamma', \Lambda')$ such that their developing maps are $\epsilon$-close to $f$ in $K$ as in Proposition 5.5. Then there are isomorphic subsurfaces $\tilde{\Sigma}_1(\gamma', \Lambda')$ and $\tilde{\Sigma}_2(\gamma', \Lambda')$ of $\Sigma_1(\gamma', \Lambda')$ and $\Sigma_2(\gamma', \Lambda')$ containing $\tilde{D}^*$.

**Proof of Proposition 5.5.** We divide the proof by the isometry type of $\eta(m)$. In each case, we construct a deformation of $\Sigma$ in a small neighborhood in $\text{PSL}(2, \mathbb{C})$ by specifying the deformation of a fundamental membrane.

\[ \text{Figure 4. The opposite spiral directions give the holonomy the opposite rotational directions.} \]

Let $\text{Ep}: \tilde{X} \to \mathbb{H}^3$ be the Epstein map associated with $C = (X, q)$. Let $\tilde{V}$ be the pull-back of $V$ to the universal cover of $E$, and let $\tilde{c}$ be the lift of $c$ to the ideal boundary of $\tilde{X} \cong \mathbb{H}^2$. Let $\gamma \in \pi_1(F)$ be the element which fixes $\tilde{c}$ such that its free homotopy class is $\ell_c$. Then, for every leaf $\ell$ of $\tilde{V}$ ending at $\tilde{c}$, its image $\text{Ep}(\ell)$ is indeed a quasi-geodesic limiting to the parabolic fixed point of $\rho(\gamma)$ on $\mathbb{C}P^1$, and its curvature of $\text{Ep}(\ell)$ converges to zero as it approaches the fixed point by Lemma 2.4. Therefore $c$ corresponds to a cusp of $\tau$. By Proposition 4.4, the total weight of the leaves must be $\sqrt{2V(\ell_c)}$.

**Elliptic Case.** The proof when $h$ is elliptic is similar to the parabolic case.
Elliptic Case. Suppose that $\gamma = I$ or $\gamma$ is an elliptic element. Then the puncture $O$ corresponds to a unique point $f(O)$ on $\mathbb{CP}^1$ by continuously extending $f$. Then pick a cusp neighborhood $\Sigma$ biholomorphic to a punctured disk, such that the development of the boundary circle is a round circle $r$ on $\mathbb{CP}^1$ and there is a Lie subgroup of $\text{PSL}(2, \mathbb{C})$ isomorphic to $SO(2)$ which preserves $r$ and $f(O)$.

Pick a “fan-shaped fundamental domain” in $\hat{D}^*$ bounded by three circular arcs $e_1, e_2, e_3$ such that

- $f|e_1$ and $f|e_2$ are circular arcs on $\mathbb{CP}^1$ connecting $f(O)$ and points on $r$, so that $f|e_1$ and $f|e_2$ are orthogonal to $r$, and
- $f|e_3$ immerses into $r$, and it connects the endpoints of $e_1$ and $e_2$

(Figure 5 left). Let $q$ be the end point of the arc $e_1$ contained in $r$.

If the neighborhood $U$ of $(\gamma, f(O))$ is sufficiently small, then given $(\gamma', \Lambda') \in U$, one can easily construct a $\mathbb{CP}^1$-structure close to $\Sigma$ on $D^*$ realizing $(\gamma', \Lambda')$. Indeed, we pick $z \in \Lambda'$, we can construct a fundamental membrane bounded by $e_1', e_2', e_3'$ such that,

- $e_1'$ is a circular on $S^2$ connecting $z$ and $q$,
- $e_2'$ is $\gamma(e_1')$ (which is a circular arc connecting $z$ and $\gamma(q)$), and
- $e_3'$ is an arc connecting $q$ to $\gamma(q)$ so that $e_3'$ is a segment of a trajectory under a one-dimensional Lie subgroup of $\text{PSL}(2, \mathbb{C})$

(see Figure 5 right). Note that the choice of $z$ may not be unique if $r$ is identity and $\text{tr}r' \in \mathbb{R} \setminus [-2, 2]$ (i.e. hyperbolic without screw motion); but the resulting structure is independent on the choice of $z$.

Generic hyperbolic case. Let $\ell$ be the peripheral loop around $O$. Suppose that $\gamma$ is hyperbolic and $L(\ell) \neq 0$, so that $\Lambda$ is a single point. Let $(\tau, L)$ be the Thurston parametrization of $C$, and let $\mathcal{L}$ be the Thurston lamination on $C$. Then $\tau$ has a geodesic boundary loop $b$ corresponding to the cusp $c$ and, as $L(\ell) > 0$, leaves of $L$ spiral towards $b$. Let $\tilde{b}$ be a lift of $b$ to the universal cover $\tilde{\tau}$ of $\tau$, so that $\tilde{b}$ is a boundary geodesic of $\tilde{\tau}$. Then those spiraling leaves lift to geodesics in $\tilde{\tau}$ having a common endpoint at an endpoint of $\tilde{b}$; by the bending map $\beta: \tilde{\tau} \to \mathbb{H}^3$, the endpoint maps to the point $\Lambda$. Accordingly the leaves of $\mathcal{L}$ near the cusp $O$ develop to circular arcs ending at $\Lambda$.

Normalize $\mathbb{CP}^1 = \mathbb{C} \cup \{\infty\}$ by an element of $\text{PSL}(2, \mathbb{C})$, so that $0$ is at $\Lambda$ and the other fixed point of $\gamma$ is at $\infty$. Let $(E, V)$ be the foliated singular Euclidean structure given by $C$. Then there is a half infinite flat cylinder $A$ in $E$ which corresponds to a cusp neighborhood of $c$; then each circumference has a positive transversal measure given by the horizontal foliation. Therefore, one can take a cusp neighborhood $\Sigma$ bounded by a loop $m$ such that $m$ develops onto a spiral on $\mathbb{CP}^1$, i.e. a curve invariant under a one-parameter subgroup in $\text{PSL}(2, \mathbb{C})$ which contains $\gamma$.

Take, similarly, a “fan-shaped” fundamental domain $F$ in the universal cover $\tilde{\Sigma}$ which is bounded by three smooth segments $e_1, e_2, e_3$ such that

- $e_1$ and $e_2$ are half-leaves of $\tilde{\mathcal{L}}$ such that $f(e_1)$ and $f(e_2)$ end at $0 \in \mathbb{C}$, and $\gamma(f(e_1)) = f(e_2)$, and
- $e_3$ is in a segment of the spiral which connects the other endpoints of $e_1$ and $e_2$

(Figure 6 left). As the set of hyperbolic elements is open in $\text{PSL}(2, \mathbb{C})$, one can take a neighborhood $U$ of $(\gamma, \Lambda)$ sufficiently small so that, for all $(\gamma', \Lambda') \in U$, $\gamma'$ is hyperbolic and $\Lambda'$ corresponds to $\Lambda$. Then, similarly to the elliptic case, one can easily find a $\mathbb{CP}^1$-structure on $D^*$ close to $\Sigma$ which realizes $(\gamma', \Lambda')$, by constructing a fundamental membrane close to $F$ (Figure 6).
Special hyperbolic case (${\sharp}{\Lambda}' = 2$). Suppose that $\gamma$ is hyperbolic and $L(\ell) = 0$ (in particular $\text{tr} \, \gamma \in \mathbb{R}$). Then the boundary component $b$ of $\tau$ is a leaf of $L$ with weight infinity ([Bab17, Proposition 8.3]).

Let $\kappa: C \to \tau$ be the collapsing map; let $F = \kappa^{-1}(b)$, which is a half-infinite cylinder. Then the developing map of $\tilde{F}$ is the restriction of $\exp: \mathbb{C} \to \mathbb{C}^*$ to a half space bounded by a horizontal line in $\mathbb{C}$; we identify the universal cover $\tilde{F}$ of $F$ with the half-space, so that $\gamma$ acts as a horizontal translation. Take a fundamental domain $Q$ in $\tilde{F}$ such that $Q$ is
a vertical half-infinite strip in $\mathbb{C}$ bounded by two vertical rays and one horizontal segment. Then $\ell \in \pi_1(S)$ acts as the translation of $\mathbb{C}$ by a real number.

Note that the deformation of a half infinite strip in the domain of $\exp: \mathbb{C} \to \mathbb{C}^*$ yields the deformation of the cusp neighborhood. In this way, if $U$ is a sufficiently small neighborhood of $(\gamma, \Lambda)$, then, for $(\gamma', \Lambda') \in U$, we can construct a deformation $\Sigma_{\gamma'} \in \mathcal{P}(D^*)$ of $\Sigma$ realizing $(\gamma', \Lambda')$.

Parabolic case. Suppose that $\gamma$ is parabolic. Then in Thurston parameters, it is a hyperbolic cusp and the total weight of $L$ along the peripheral loop $m$ is a non-negative $2\pi$-multiple. Then, similarly to the case that $\gamma = I$, we can show the claim by finding a cusp neighborhood and a fundamental domain in its universal cover which is bounded by circular arcs.

### 5.3.1. Holonomy maps of $\mathbb{CP}^1$-structures with cusps

Let $F$ be a closed surface minus finitely many points $p_1, \ldots, p_n$. Recall that $\mathcal{P}(F)$ denotes the all developing pairs $(f, \rho)$ for $\mathbb{CP}^1$-structures on $F$. Let $(f, \rho) \in \mathcal{P}(F)$, and let $X$ be the complex structure on $F$ given by the induced $\mathbb{CP}$-structure. Identify the universal cover $\tilde{X}$ of $X$ with $\mathbb{H}^2$; then for each $i = 1, \ldots, n$, pick a lift $\tilde{p}_i$ of $p_i$ to a point on the ideal boundary of $\tilde{X}$. Then, by Remark 5.3 for each $(f, \rho) \in \mathcal{P}(F)$ and a puncture $p_i$, we have a corresponding element in $(\gamma_i, \Lambda_i) \in \text{PSL}(2, \mathbb{C})$. Thus we have a map from $\text{hol}: \mathcal{P}(F) \to (\text{PSL}(2, \mathbb{C}))^n \times \mathcal{R}(F)$ taking $(f, \rho) \in \mathcal{P}(F)$ to $\{(\gamma_i, \Lambda_i)_{i=1}^n, \rho\}$.

**Theorem 5.7.** Every $(f, \rho) \in \mathcal{P}(F)$ has a neighborhood $W$ such that

$$\text{hol}|W$$

is a local homeomorphism. Moreover, for any $(f, \rho) \in \mathcal{P}(F)$, if there is a path $\rho_t$ converging to $\rho$ (in $\mathcal{R}(F)$) as $t \to \infty$, then there is a lift of $\rho_t$ to a path in $\mathcal{P}(F)$ for $t \gg 0$ converging to $(f, \rho)$.

Note that as $\text{PSL}(2, \mathbb{C})$ is a non-Hausdorff space, a general path-lifting property fails.

**Proof.** Applying Proposition 5.5 to a small $\epsilon > 0$, we obtain, for each $i = 1, \ldots, n$, a (small) cusp neighborhood $D_i$ of the puncture $p_i$ of $C$, and a neighborhood $U_i$ of $(\gamma_i, \Lambda_i)$ in $\text{PSL}(2, \mathbb{C})$. Without loss of generality, we can assume $D_1, \ldots, D_n$ are disjoint in $C$. Let $N_i$ be the underlying topological cusp neighborhood of $F$.

Let $D'_i$ be a smaller open cusp neighborhood of $p_i$, so that the closure of $D'_i$ is contained in the interior of $D_i$. Let $C$ be the $\mathbb{CP}^1$-structure on $F$ given by $(f, \rho)$. Let $\tilde{C}$ be $C - \bigcup_i D'_i$; and let $\tilde{F}$ be $F \setminus \bigcup_i N_i$, the subsurface of $F$ supporting $\tilde{C}$. For every $(\gamma'_i, \Lambda'_i) \in U_i$, let $D_{\gamma'_i, \Lambda'_i}$ denote the (essentially unique) $\mathbb{CP}^1$-structure on $D^*$ with holonomy $\gamma'_i$ given by Proposition 5.5; then $D_{\gamma'_i, \Lambda'_i}$ realizes $(\gamma'_i, \Lambda'_i)$, and $D_{\gamma'_i, \Lambda'_i}$ is sufficiently close to $D_i$.

We shall regard $(f, \rho)$ as a smooth section $\Sigma$ of a $\mathbb{CP}^1$-bundle $B$ over $F$ such that $\Sigma$ is transversal to the horizontal foliation $H_\rho$ associated with $\rho$. Let $\tilde{\Sigma}$ be the restriction of $\Sigma$ to the bundle over the subsurface $\tilde{F}$. Then there is a neighborhood $W$ of $\rho$ in the representation variety $\mathcal{R}(F)$ such that, for each $\xi \in W$, letting $H_\xi$ be the horizontal foliation of $B$ associated with $\xi$, $\tilde{\Sigma}$ is still transversal to $H_\xi$; then $\tilde{\Sigma}$ yields a projective structure $\tilde{C}$ on $\tilde{F}$ with holonomy $\xi$.

Then we can easily combine $\tilde{C}$ and $D_1, \ldots, D_n$ and obtain a desired developing pair for a $\mathbb{CP}^1$-structure on $F$. In this way, given a sufficiently small neighborhood of $\text{hol}((f, \rho))$, for every element in this neighborhood, we construct a developing pair realizing it.
This new structure is unique in a large compact subset of $K$ and also unique in the cusp neighborhoods. Thus the resulting section is unique up to the transversal isotopy, which implies the injectivity of the map, and thus it is a local homeomorphism.

The path lifting along a path in $\mathcal{R}$ easily follows from the construction.

6. Bound on the upper injectivity radius

Recall that $C_t = (f_t, \rho_t)$ is a path of $\mathbb{CP}^1$ structures on $S$ such that $C_t$ diverges to $\infty$ and the equivalence class $[\rho_t] =: \eta_t$ converges in the character variety, and recall that $C_t = (X_t, q_t)$ is the expression in the Schwarzian parameters.

Let $E_t$ be the singular Euclidean structure on $X_t$ given by $|q_t^\frac{1}{2}|$. Let $R(E_t) \geq 0$ denote that the upper injectivity radius of $E_t$, i.e. the supremum of the injectivity radii over all points in $E_t$ (as $E_t$ is compact it is indeed maximum). In this section we show

**Theorem 6.1.** Suppose that $X_t$ is pinched along a multiloop $M$. Then the upper injectivity radius $R(E_t)$ of $E_t$ is bounded from above for all $t \geq 0$.

Immediately we have the following.

**Corollary 6.2.** There is an upper bound for the area of the expanding cylinders in $E_t$ for all $t \geq 0$.

In order to prove Theorem 6.1 we assume, to the contrary, that $\limsup R(E_t) = \infty$ and show that $\rho_t$ can not converge. Let $M_t$ be a geodesic representative of $M$ on $E_t$ (in the Euclidean metric) such that, for every $\epsilon > 0$ if $t > 0$ is sufficiently large, then $M_t$ is contained in the $\epsilon$-thin part of $X_t$. We will find a conformally thick part which is, in the Euclidean metric, bigger than its adjacent thick parts:

**Proposition 6.3.** Suppose that $X_t$ is pinched along a multiloop $M$ and $\limsup_{t \to \infty} R(E_t) \to \infty$. Then, there are a component $F$ of $S \setminus M$ and a sequence $(0 \leq) t_1 < t_2 < \ldots$ diverging to $\infty$, such that, letting $F_i$ be the component of $E_t \setminus M_t$ isotopic to $F$, for each boundary component $\ell$ of $F_i$, there is an expanding cylinder $B_{\ell,t_i}$ in $F_i$ homotopic to $\ell$ so that

- $\text{Mod } B_{\ell,t_i} \to \infty$ as $t \to \infty$, and
- $B_{\ell,t_i}$ shrinks towards the component of $S \setminus M$ adjacent to $F$ across $\ell$.

**Claim 6.4.** Suppose that there is a diverging sequence $(0 <) t_1 < t_2 < \ldots$ such that $E_{t_i}$ contains a flat cylinder $A_{t_i}$ homotopy equivalent to a fixed loop $m$ of $M$ such that

- (1) $\text{Mod } A_{t_i} \to \infty$ as $i \to \infty$, and
- (2) the circumference of $A_{t_i}$ limits to $\infty$ (equivalently Area $A_{t_i} \to \infty$) as $i \to \infty$.

Then, the restriction of the vertical foliation $V_{t_i}$ to $A_{t_i}$ must be asymptotically orthogonal to the circumferences of $A_{t_i}$.

**Proof.** Suppose, to the contrary, that $V_{t_i}$ does not asymptotically orthogonal to circumferences. Then, up to a subsequence, we may assume that there is a limit $\theta_\infty \in [0, \pi/2)$ between the angle between $V_{t_i}$ and the circumferences. Let $m_{t_i}$ be a geodesic representative of $m$ which sits in the middle of $A_{t_i}$. Then, by Hypotheses (1) and (2), the transversal measure of the horizontal foliation $H_{t_i}$ along $m_{t_i}$ diverges to infinity as $i \to \infty$. By Proposition 4.4 (2), the translation length of $\rho_i(m_{t_i})$ is asymptotically $\sqrt{2}$ times the transversal measure. Therefore the translation length of $\rho_i(m_{t_i})$ must diverge to infinity, which contradicts to the convergence of $[\rho_i]$ as $t \to \infty$. \qed

**Proposition 6.5.** Suppose that there are a component $F$ of $S \setminus M$ and a diverging sequence $(0 <) t_1 < t_2 < \ldots$ such that, letting $F_{t_i}$ be the component of $E_{t_i} \setminus M_{t_i}$ homotopic to $F$,
Proposition 6.7. \[\text{Area}_{E_{t,i}} F_{t,i} \rightarrow \infty \text{ as } i \rightarrow \infty, \text{ and.}\]

- for each boundary component $\ell$ of $F$, there is an expanding cylinder $B_{\ell,t,i}$ in $F_{t,i}$ homotopic to $\ell$ such that
  - $B_{\ell,t,i}$ shrinks toward the adjacent component across $\ell$, and
  - $\text{Mod} B_{\ell,t,i} \rightarrow \infty$ as $i \rightarrow \infty$.

Then $[\rho_i]\pi_1 F$ diverges to $\infty$ in $\chi$ as $i \rightarrow \infty$.

Proof. Let $k_i > 0$ be such that $k_i \text{Area}(F_{t,i}) = 1$ for each $i = 1, 2, \ldots$. Then, as $\text{Area} F_{t,i} \rightarrow \infty$, thus $k_i \rightarrow 0$ as $i \rightarrow \infty$. All ends of $F_{t,i}$ have conformally long expanding cylinders shrinking towards adjacent components. Take a base point in the thick part of $F_{t,i}$. Then, by compactness, up to a subsequence

- $k_i E_{t,i}$ converges, in the Gromov-Hausdorff topology, to a compact singular Euclidean surface minus finitely many points, $E_\infty$, which is homeomorphic to $F^\delta$, and
- $k_i V_{t,i} | k_i E_{t,i}$ converges to a measured foliation $V_\infty$ on $E_\infty$.

Take an (almost geodesic) loop $\ell$ on $E_\infty$ such that $\ell$ does not cross any singular point of $E_\infty$ and $\ell$ is almost parallel to $V_\infty$ at each point on $\ell$ (i.e. the intersection angles are quite close to zero). Then, by Lemma 6.6, there is $\epsilon > 0$, such that the translation length of $\rho_{t,i}(\ell)$ is $(1 + \epsilon)$-bi-Lipschitz to $\sqrt{2} \text{length}_{E_\infty}(\ell)/k_i$. Since $k_i \rightarrow 0$, $\text{Im} \int_{\ell} \sqrt{\nu_i} \rightarrow \infty$, and therefore $\text{tr} \rho_{t,i}(\ell)$ must diverge to infinity. \qed

Let $m_1, \ldots, m_p$ be the loops of the multiloop $M$.

Lemma 6.6. If $t > 0$ is sufficiently large, for each $i = 1, \ldots, p$, there are, at most, one maximal flat cylinder $A_i$ and two maximal cylinders $B_i, B'_i$ expanding in the opposite directions such that all $A_{t,i}, B_{t,i}, B'_{t,i}$ are homotopic to $m_i$, and

\[
1 - \epsilon \leq \frac{\text{Mod}_{E_t} m_i}{\text{Mod}_{E_t} A_{t,i} + \text{Mod}_{E_t} B_{t,i} + \text{Mod}_{E_t} B'_{t,i}} \leq 1.
\]

Proof. As $X_{t,i}$ is pinched along $M$, $\text{Mod}_{X_t} m_i \rightarrow \infty$ as $t \rightarrow \infty$. Let $W_{i,t}$ be the union $A_{t,i} \cup B_{t,i} \cup B'_{t,i}$, which is a cylinder in $E_t$ homotopic to $m_i$ since $A_{t,i} \cup B_{t,i} \cup B'_{t,i}$ are maximal. Then, there is $\epsilon > 0$ such that the $\epsilon$-thin part homotopic to $m_i$ is contained in $W_{i,t}$ for all large enough $i$. In addition

\[
\frac{\text{Mod}_{W_{i,t}}}{\text{Mod}_{X_t}} m_i \rightarrow 1
\]
as $t \rightarrow \infty$. The inequality $\text{Mod} m_i \geq \text{Mod} A_{t,i} + \text{Mod} B_{t,i} + \text{Mod} B'_{t,i}$ is well-known (see for example [Hub06, Theorem 3.2.6]). By the analytic definition of moduli,

\[
\text{Mod} W_{i,t} = \inf_{\nu} \frac{\text{Area}_\nu W_{i,t}}{\text{length}_\nu m_i},
\]

where the infimum is takes over all conformal metrics $\nu$ on $W_{i,t}$. Note that the most of parts of $W_{i,t}$ is covered by finitely many round cylinders and a flat cylinder, which contains no singular points. Therefore one can easily construct an appropriated conformal metric on $W_{i,t}$ to show that, for every $\epsilon > 0$, if $t > 0$ is large enough $(1 - \epsilon)\text{Mod}_{X_t} m_i < \text{Mod} A_{t,i} + \text{Mod} B_{t,i} + \text{Mod} B'_{t,i}$ for sufficiently large $t$. \qed

Proposition 6.7. For every (large) $T > 0$, there are $t > T$ and $k \in \{1, \ldots, p\}$ such that

\[
\frac{1}{2} < \frac{\text{length}_{E_t}(m_k)}{\max_{i = 1, \ldots, p} \text{length}_{E_t}(m_i)} \leq 2,
\]

and $\text{Mod}_{X_t}(m_k)$ is $\frac{1}{3}$-dominated by an expanding cylinder $B_{k,t}$ homotopic to $m_k$, i.e.
\[
\frac{\text{Mod } B_{k,t}}{\text{Mod}_X m_k} > \frac{1}{3}.
\]

Proof. For \( u > T \), let \( m_{k_u} \) be the loop realizing \( \max_{i=1, \ldots, p} \text{length}_{E_u}(m_t) \). We may assume that 
\( \max_{i=1, \ldots, p} \text{length}_{E_t}(m_t) \to \infty \) as \( t \to \infty \), as otherwise, the assertion is clear by Proposition 6.5.

We first show that if a long flat cylinder persists, then its circumference must stay almost the same. Namely

**Claim 6.8.** For every \( \epsilon > 0 \), there is \( K > 0 \) such that, if

- a loop \( m \) of \( M \) satisfies \( \text{length}_{E_u} m > K \) for some \( u > K \) and
- there are \( w > u \) and a flat cylinder in \( E_t \) homotopic to \( m \) which \( \frac{1}{4} \)-dominates the modulus of \( m \) for every \( t \in [u, w] \),

then

\[
1 - \epsilon < \frac{\text{length}_{E_t} m}{\text{length}_{E_u} m} < 1 + \epsilon
\]

for all \( t \in [u, w] \).

Proof. By Claim 6.4, for every \( \epsilon > 0 \), if \( K > 0 \) is sufficiently large, then the vertical foliation \( V_t \) is \( \epsilon \)-almost orthogonal to circumferences of the flat cylinder homotopic to \( m \). Then, by Proposition 4.4, for every \( \epsilon > 0 \), if \( K > 0 \) is sufficiently large, then the total rotation angle along \( m \) is \((1 + \epsilon)\)-bi-Lipschitz to \( \sqrt{2} \text{length}_{E_t} m \) for \( t \in [u, w] \). As the holonomy of \( \rho_t(m) \) converges as \( t \to \infty \), the total rotation angle \( m \) must converge. Thus, if \( K \) is sufficiently large, then the ratio of \( \text{length}_{E_t} m \) and \( \text{length}_{E_u} m \) is \( \epsilon \)-close to 1.

As in Claim 6.8, we suppose that a flat cylinder \( \frac{1}{4} \)-dominates \( \text{Mod } m_{k_u} \) for all \( t \in [u, v] \); then \( 1 - \epsilon < \frac{\text{length}_{E_t} m_{k_u}}{\text{length}_{E_u} m_{k_u}} < 1 + \epsilon \) for all \( t \in [u, w] \). Suppose, in addition, that there is a loop \( m_k \) of \( M \) which is not \( m_{k_u} \) such that \( m_k \) on \( E_t \) becomes exactly twice as long as \( m_{k_u} \) on \( E_u \) for the first time at \( t = w \) after \( t = u \). Then, by applying Claim 6.8 to \( m_k \), we can show that there is \( t \in [u, v] \) such that \( \text{Mod } m_k \) is \( 1/3 \)-dominated by an expanding cylinder: Indeed, otherwise, \( \max_{i=1, \ldots, p} \text{length}_{E_t}(m_t) \) must bounded from above by \( \frac{3}{2} \text{length}_{E_t}(m_{k_u}) \) for all \( t \in [u, w] \).

**Corollary 6.9.** There are a component \( F \) of \( S \setminus M \) and a diverging sequence \( 0 < t_1 < t_2 < \ldots \) such that the corresponding component \( F_{t_i} \) of \( E_{t_i} \setminus M \) satisfies the assumptions of Proposition 6.5.

Proof. By Proposition 6.7, there is a loop \( m \) of \( M \) and a diverging sequence \( t_1 < t_2 < \ldots \) such that

- \( \text{length}_{E_{t_i}} m \to \infty \) as \( i \to \infty \),
- 

\[
\frac{1}{2} < \frac{\text{length}_{E_{t_i}} m}{\max\{\text{length}_{E_{t_i}} m_1, \ldots, \text{length}_{E_{t_i}} m_p\}} < 2
\]

for all \( i = 1, 2, \ldots, \) and
- there is an expanding cylinder \( B_{t_i} \) homotopic \( m \) which \( \frac{1}{3} \)-dominates \( \text{Mod } E_{t_i} m \).

Then, up to a subsequence, we may in addition assume that \( B_{t_i} \) is expanding in the same direction. Then, let \( F \) be the connected component of \( S \setminus M \) such that \( m \) is a boundary component of \( F \) and \( B_{t_i} \) expands towards \( F \).
By this corollary, we obtained the desired contradiction, which implies Theorem 6.1.

7. CONVERGENCE OF CP^{1}\text{-STRUCTURES AWAY FROM PINCHED LOOPS}

As in the previous section, we suppose that \( X_t \) is pinched along a multiloop. We will first see that the holonomy \( \rho_\infty(m) \) determines the type of a conformally long Euclidean cylinder in \( E_t \) which is homotopic to \( m \) for \( t \gg 0 \).

**Lemma 7.1.**
- Suppose that there are a sequence \( t_1 < t_2 < \ldots \) diverging to \( \infty \) and a sequence of expanding cylinders \( B_{t_i} \) in \( E_{t_i} \) homotopic to \( m \) at time \( t_i \), such that \( \text{Mod}_{E_{t_i}} B_{t_i} \to \infty \) as \( t_i \to \infty \), then \( \rho_\infty(m) \) is parabolic.
- Let \( m \) be a loop of \( M \) such that \( \rho_\infty(m) \) is not parabolic.
  1. Suppose that \( \rho_\infty(m) = 1 \). Then, for \( t \gg 0 \), \( E_t \) contains a flat cylinder \( A_t \) homotopic to \( m \), such that \( \text{Mod} A_t \to \infty \) and \( \sqrt{2} \int_{m} |\sqrt{q_{t_i}}| \) converges to \( 2\pi n i \) for some positive integer \( n \).
  2. Suppose that \( \rho_\infty(m) \) is an elliptic element of rotation angle \( \theta \). Then, for \( t \gg 0 \), \( E_t \) contains a flat cylinder \( A_t \) homotopic to \( m \), such that \( \text{Mod} A_t \to \infty \) and \( \sqrt{2} \int_{m} |\sqrt{q_{t_i}}| \) converges to \( (2\pi n + \theta)i \) for some non-negative integer \( n \).
  3. Suppose that \( \rho_\infty(m) \) is hyperbolic. Let \( z \in \mathbb{C} \) be such that the Möbius transformation \( \omega \mapsto \omega \exp[\frac{z}{\sqrt{t_i}}] \) conjugates to \( \rho_\infty(m) \). Then, for \( t \gg 0 \), \( E_t \) contains a flat cylinder \( A_t \) homotopic to \( m \) such that \( \text{Mod} A_t \to \infty \) and \( \sqrt{2} \int_{m} |\sqrt{q_{t_i}}| \) converges to \( z + 2\pi n i \) for some integer \( n \);

**Proof.** For every \( \epsilon > 0 \), if \( t > 0 \) is large enough, for each loop \( m \) of \( M \), there is a flat cylinder or an expanding cylinder homotopic to \( m \).

If a puncture of a \( \mathbb{C}P^1 \)-structure corresponds to a regular point of its holomorphic quadratic differential, its peripheral holonomy is parabolic. Thus, if there are a sequence \( t_1 < t_2 < \ldots \) and, for each \( i \), an expanding cylinder \( B_{t_i} \) in \( E_{t_i} \) homotopic to \( m \) such that \( \text{Mod} B_{t_i} \to \infty \) as \( t_i \to \infty \), then, by Corollary 6.2, its shorter boundary component of \( B_{t_i} \) asymptotically corresponds to, at most, a pole of order one of a differential. Therefore \( \rho_\infty(m) \) is parabolic, against the hypothesis.

Therefore, for \( t \gg 0 \), there is a flat cylinder \( A_t \) homotopic to \( m \) such that \( \text{Mod}(A_t) \to \infty \). Therefore Proposition 4.4 implies the lemma. \( \square \)

Given a compact surface \( F \) with boundary, let \( \hat{F} \) denote the surface with punctures obtained by pinching each boundary component of \( F \) to a (puncture) point.

**Proposition 7.2.** Let \( \epsilon > 0 \) be a number less than the Bers constant. Let \( F \) be a component of \( S \setminus M \), and let \( F_t^{> \epsilon} \) be the component of the conformally \( \epsilon \)-thick part of \( E_t \) isotopic to \( F \) for \( t \gg 0 \). Then, if

\[
\liminf_{t \to \infty} \text{Area}_{E_t}(F_t^{> \epsilon}) > 0,
\]

there is a path of \( \mathbb{C}P^1 \)-structures \( \hat{F}_t \) on the punctured surface \( \hat{F} \) such that

1. for every \( \epsilon > 0 \), if \( t > 0 \) is sufficiently large, then such that \( F_t^{> \epsilon} \) isomorphically embeds into \( \hat{F}_t \),
2. for each boundary component \( \ell \) of \( F \), there is a cylinder \( A_{\ell,t} \) in \( E_t \) homotopic to \( \ell \) such that
   - \( \text{Mod} A_{\ell,t} \to \infty \) as \( t \to \infty \),
   - \( A_{\ell,t} \) is either a flat cylinder for all \( t \gg 0 \) or an expanding cylinder shrinking towards the adjacent component of \( S \setminus M \) across \( m \) for all \( t \gg 0 \), and
3. \( \hat{F}_t \) contains \( A_{\ell,t} \) for every boundary component \( \ell \) of \( F \).
Proof. We first show that, for each boundary component $\ell$ of $F$, there is a cylinder $A_\ell$ homotopic to $\ell$, such that

(i) $\text{Mod } A_{\ell,t} \to \infty$ as $t \to \infty$, and

(ii) $A_{\ell,t}$ remains either a flat cylinder or an expanding cylinder shrinking forwards $\ell$ for all $t \gg 0$.

Let $Y_t$, $Z_t$, $W_t$ be disjoint cylinders homotopic to $\ell$, such that $Z_t$ is a maximal flat cylinder, $Y_t$ is the maximal expanding cylinder expanding towards the thicker part of $F_t$ and $W_t$ is the maximal expanding cylinder expanding towards the adjacent component across the geodesic representative $\ell_t$ of $\ell$.

As $X_t$ is pinched along $M$, by Lemma 6.6, $\max\{\text{Mod } Y_t, \text{Mod } Z_t, \text{Mod } W_t\} \to \infty$ as $t \to \infty$. Let $\text{diam } W_t$ and $\text{diam } Y_t$ denote the diameter of $W_t$ and $Y_t$, respectively, in the Euclidean metric $E_t$. Then, by (1) and the upper injectivity radius bound (Theorem 6.1), the ratio $\frac{\text{diam } W_t}{\text{diam } Y_t + 1}$ is bounded from above for all $t > 0$. Thus $\frac{\text{Mod } W_t}{\text{Mod } Y_t + 1}$ is bounded from above for all $t > 0$. Therefore $\text{Mod } Y_t + \text{Mod } Z_t$ diverges to $\infty$ as $t \to \infty$. We claim, moreover, that either $\lim \text{Mod } Y_t = \infty$ or $\lim \text{Mod } Z_t = \infty$.

Suppose that $\limsup_{t \to \infty} \text{Mod } Y_t = \infty$. Let $t_1 < t_2 < \ldots$ be a sequence with $\lim_{t \to \infty} \text{Mod } Y_{t_i} = \infty$. Then the circumference of $Z_{t_i}$ limits to zero, and by Lemma 7.1, $\rho_\infty(\ell)$ is parabolic. Therefore, by, again, Lemma 7.1 and the convergence of the holonomy, genuinely $\text{Mod } Y_{t} \to \infty$ as $t \to \infty$. Then, $Y_t$ satisfies (i) and (ii).

Next suppose that $\limsup_{t \to \infty} \text{Mod } Y_t < \infty$. Then $\text{Mod } Z_t$ diverges to $\infty$ as $t \to \infty$, and the circumference of $Z_t$ converges to a positive number. Then $Z_t$ satisfies (i) and (ii).

We shall construct $\hat{F}_t$ satisfying (3) as follows. Suppose that, for a boundary component $\ell$ of $F$, $\lim_{t \to \infty} \text{Mod } Y_t = \infty$. Let $\hat{Y}_t$ be an expanding cylinder of infinite modulus, obtained by extending the expanding cylinder $Y_t$ only in the shrinking direction, so that $\hat{Y}_t$ is conformally a punctured disk. Then replace $Y_t$ by $\hat{Y}_t$ in $E_t$, so that the boundary component $\ell$ of $F$ corresponds to the puncture of $\hat{Y}_t$. Suppose that $\limsup_{t \to \infty} \text{Mod } Y_t < \infty$. Then, since $\text{Mod } Z_t \to \infty$ and the circumference $\text{Circ}(Z_t)$ converges to a positive number as $t \to \infty$, we extend the flat cylinder $Z_t$, in the direction of $W_t$, to the half-infinite flat cylinder $\hat{Z}_t$; then $\hat{Z}_t$ is conformally a punctured disk. Then replace $Z_t$ in $E_t$ with $\hat{Z}_t$ so that it has a puncture corresponding to $\ell$.

By applying, such a replacement for all boundary component $\ell$ of $F$, we obtains a desired complete singular Euclidean surface $\hat{F}_t$ satisfying (1), (2), (3), since (2) follows from (1) and (3).

**Theorem 7.3.** Let $F$ be a component of $S \setminus M$. Let $\epsilon > 0$ be a number less than the Bers constant for $S$. Then, for $t > 0$ large enough, there is a component $\hat{F}_t^\epsilon$ of the $\epsilon$-thick part of $C_t$ isotopic to $F$.

(1) Suppose that

$$\liminf_{t \to \infty} \text{Area}_{E_t}(\hat{F}_t^\epsilon) = 0.$$  

Then there is a continuous function $\epsilon_t > 0$ with $\lim_{t \to \infty} \epsilon_t = 0$, such that $\hat{F}_t^\epsilon$ converges (in the Gromov-Hausdorff topology) to a complete hyperbolic structure on a closed surface with finitely many punctures, denoted by $\hat{F}$, which is homeomorphic to $F$.

(2) Suppose that

$$\liminf_{t \to \infty} \text{Area}_{E_t}(\hat{F}_t^\epsilon) > 0.$$  

Then $\hat{F}_t^\epsilon$ accumulates to a bounded subset on the space of $\mathbb{CP}^1$-structures on $\hat{F}$. Moreover, if $\rho_\infty(m) \neq 1$ for each boundary component $m$ of $F$, then $\hat{F}_t$ indeed converges to a $\mathbb{CP}^1$-structure on $\hat{F}$.  

---

26
Proof. Let \( t_1 < t_2 < \ldots \) be a diverging sequence such that \( \text{Area}(F_t) \to 0 \) as \( t \to \infty \). Then the holomorphic quadratic differential on \( F_t \) asymptotically vanishes. Thus, for every small \( \epsilon > 0 \), \( F_t^\epsilon \) and \( X_t | F_t^\epsilon \) asymptotically identical, where \( X_t \) is regarded as a hyperbolic surface by the uniformization theorem for each \( i \). Hence there is a sequence \( \epsilon_i > 0 \) converging to 0 as \( i \to \infty \), such that \( F_t^\epsilon_i \) converges to a complete hyperbolic surface \( \hat{F} \) homeomorphic to \( F \). Since the all peripheral loops of \( \hat{F} \) have parabolic holonomy (in particular non-trivial), by Theorem 8.2, \( F_t^\epsilon_t \) must genuinely converges to \( \sigma_\infty \) (without taking a subsequence). In particular \( \text{Area}_{\hat{F}} F_t^\epsilon_t \to 0 \) as \( t \to \infty \).

(2) Suppose that \( \liminf_{t \to \infty} \text{Area} F_t^\epsilon > 0 \) for sufficiently small \( \epsilon > 0 \). Then let \( \hat{F}_t \) denote the singular Euclidean structure obtained from \( F_t \) by Proposition 7.2. Then \( \hat{F}_t \) yields a \( \mathbb{CP}^1 \)-structure on \( \hat{F} \). Let \( (Z_t, w_t) \) be the Schwarzian parameterization of \( \hat{F}_t \). Then, indeed, every puncture of \( Z_t \) is, at most, a pole of order two.

As \( X_t \) is pinched along a multiloop \( M \), \( Z_t \) is bounded in the Teichmüller space \( T(\hat{F}) \). By the upper bound of the upper injectivity radius (Theorem 6.1), the upper injectivity radius of \( \hat{F}_t \) is also bounded from above, and \( (Z_t, w_t) \) is also bounded. Therefore \( \hat{F}_t \) is accumulated to a bounded subset in the deformation space of \( \mathbb{CP}^1 \)-structures on \( \hat{F} \).

Moreover, if each peripheral loop has non-trivial holonomy at \( t = \infty \), the convergence of the holonomy of \( \hat{F}_t \) implies the convergence in \( (\text{PSL}(2, \mathbb{C}))^n \times \mathcal{R}(F) \). Therefore \( \hat{F}_t \) has a unique limit in \( \mathcal{P}(\hat{F}) \). \( \square \)

Theorem 7.3 immediately implies

**Corollary 7.4.** Suppose that \( X_t \) is pinched along a multiloop \( M \). Then, for every sequence \( t_1 < t_2 < \ldots \) diverging to \( \infty \), up to a subsequence, \( X_t \), convergence to a nodal Riemann surface \( X_\infty \) and \( q_t \), converges to a regular quadratic differential on \( X_\infty \).

8. Degeneration for neck-pinning

Let \( C_t = (f_t, \rho_t) \) be a path of \( \mathbb{CP}^1 \)-structures which diverges to \( \infty \) such that its holonomy \( [\rho_t] : = \eta_t \) converges in the character variety \( \chi \). By Proposition 3.2, we can assume that the holonomy \( \rho_t \in \mathcal{R} \) also converges in the representation variety. Let \( X_t \) be the complex structure of \( C_t \).

**Theorem 8.1.** Suppose that \( X_t \) is pinched along a loop \( m \). Then \( \rho_\infty(m) \) is either \( I \) or a parabolic element. Moreover \( \rho_t(m) \neq I \) for large enough \( t > 0 \).

We will show the asymptotic behavior of the developing map \( f_t \), depending on the isometry type of \( \rho_\infty(m) \). Recall that \( \phi : \check{S} \to S \) is the universal covering map. Let \( N_m \) be a regular neighborhood of \( m \), and let \( \check{N}_m \) be a component of \( \phi^{-1}(N_m) \) preserved by \( m \in \pi_1(S) \).

**Theorem 8.2** (Convergence of developing maps). Suppose that \( X_t \) is pinched along a loop \( m \). Let \( N_m \) be a regular neighborhood of \( m \) in \( \check{S} \). Then, exactly one of the following holds.

- \( \rho_\infty(m) \) is parabolic, and, by taking an appropriate path of markings \( S \to C_t \), the developing map \( f_\infty : \check{S} \setminus \phi^{-1}(N_m) \to \mathbb{CP}^1 \) converges to a \( \rho_\infty \)-equivariant continuous \( f_\infty : \check{S} \setminus \phi^{-1}(N_m) \to \mathbb{CP}^1 \) uniformly on compacts. Moreover, if the cusp neighborhoods of \( C_\infty \) are a horoball quotients, then there are \( \rho_\infty \)-equivariant continuous map \( f_\infty : \check{S} \to \mathbb{CP}^1 \) to which \( f_\infty : \check{S} \to \mathbb{CP}^1 \) converges and a multiloop \( M \) on \( S \) consisting of finitely many parallel copies of \( m \), such that \( f_\infty \) is a local homeomorphism on \( \check{S} \setminus \phi^{-1}(M) \) and it takes each component of \( \phi^{-1}(M) \) to its corresponding parabolic fixed point.
- \( \rho_\infty(m) = I \), and, for every sequence \( t_1 < t_2 < \ldots \) diverging to \( \infty \), up to a subsequence, there is a path of markings \( S \to C_t \) such that, as \( i \to \infty \),
For each \( t \geq 0 \), let \((\tau_t, L_t) \in T \times \text{ML} \) be the Thurston parameterization of \( C_t \), and let \( \beta_t : \mathbb{H}^2 \to \mathbb{H}^3 \) be its pleated surface. Then \( \beta_t \) converges a continuous map to \( \mathbb{H}^3 \cup \mathbb{C}^1 \).

Theorem 8.3. Suppose that \( X_t \) is pinched along a loop \( m \) on \( S \). Let \( N_m \) be a regular neighborhood of \( m \) on \( S \). Then, by taking an appropriate path of markings \( \iota_t : S \to \tau_t \), exactly one of the following two holds:

1. \( \rho_\infty(m) \in \text{PSL}(2, \mathbb{C}) \) is parabolic, and \( \beta_t : S \to \mathbb{H}^3 \) converges to a \( \rho_\infty \)-equivariant continuos map \( \beta_\infty : S \to \mathbb{H}^3 \cup \mathbb{C}^1 \) uniformly on compacts as \( t \to \infty \), such that \( \beta_\infty^{-1}(\mathbb{C}^1) \) descends to \( m \).
2. \( \rho_\infty(m) = I \in \text{PSL}(2, \mathbb{C}) \), and for every diverging sequence \( t_1 < t_2 < \ldots \), up to a subsequence, \( \beta_{t_i} : S \to \mathbb{H}^3 \) converges to a \( \rho_\infty \)-equivariant continuos map \( \beta_\infty : S \to \mathbb{H}^3 \cup \mathbb{C}^1 \) as \( i \to \infty \) and the axis \( a_i \) of \( \rho_{t_i}(m) \) converges to a point \( \mathbb{C}^1 \) or a geodesic of \( \mathbb{H}^3 \) such that
   - if \( \lim_{i \to \infty} a_i \) is a point on \( \mathbb{C}^1 \), then \( \beta_\infty^{-1}(\mathbb{C}^1) = \phi^{-1}(m) \), and
   - if \( \lim_{i \to \infty} a_i \) is a geodesic \( a_\infty \) in \( \mathbb{H}^3 \), then \( \beta_\infty \) takes each component of \( \phi^{-1}(N_m) \) to its corresponding limit geodesic \( a_\infty \) and the component of \( S \setminus \phi^{-1}(N_m) \) to either a pleated surface in \( \mathbb{H}^3 \) or a single point on \( \mathbb{C}^1 \).

In order to prove Theorems 8.1 and 8.2 and Theorem 8.3, we carefully observe the behavior of \( C_t \), fixing the isometry type of \( \rho_\infty(m) \). In particular, we will show that, supposing, to the contrary, that \( \rho_\infty(m) \) is hyperbolic (§10) or elliptic (§11), then \( \rho_t \) can not converge. The convergence when \( \rho_\infty(m) = I \) is given in §12, and the convergence when \( \rho_\infty(m) \) is parabolic is given in §9.

Pick a positive function \( \epsilon_t > 0 \) in \( t > 0 \) converging to \( 0 \) as \( t \to \infty \). Let \( C_t^\epsilon \) denote the conformally \( \epsilon \)-thick part of \( C_t \). Let \( \mathcal{P}(S \setminus m) \) be the set of the \( \mathbb{C}^1 \)-structures on a surface with two punctures homeomorphic to \( S \setminus m \).

Proposition 8.4. Suppose that \( \rho_\infty(m) \neq I \). Then there exists a \( \mathbb{C}^1 \)-structure \( \hat{C}_\infty \in \mathcal{P}(S \setminus m) \) such that, for every \( \epsilon > 0 \), the \( \epsilon \)-thick part \( C_t^\epsilon \) of \( C_t \) converges to the \( \epsilon \)-thick part of \( \mathbb{C}^1 \)-structure \( \hat{C}_\infty \) uniformly.

Proof. Since \( X_t \) is pinched along \( m \), one can construct a path \( F_t \) of \( \mathcal{P}(S \setminus m) \) such that, for every \( \epsilon > 0 \), the \( \epsilon \)-thick part \( F_t^\epsilon \) of \( F_t \) and \( C_t^\epsilon \) become closer and closer as \( t \to \infty \). Then, by the upper injectivity radius bound (Theorem 6.1), \( F_t \) is contained in a compact subset of \( \mathcal{P}(S \setminus m) \). The holonomy map for \( \mathcal{P}(S \setminus m) \to \mathbb{P}(S \setminus m) \) is a local homeomorphism as long as the puncture is non-trivial. Therefore \( F_t \) converges in \( \mathcal{P}(S \setminus m) \).

8.1. \( \mathbb{C}^1 \)-structures on surface with punctures.

Lemma 8.5. Let \( F \) be a closed surface with finitely many punctures, such that the Euler characteristic of \( F \) is negative. Let \( C = (f, \rho) \) be a \( \mathbb{C}^1 \)-structure on \( F \) such that

- \( \rho \) is an elementary representation, and
- for each puncture of \( C \), its peripheral holonomy is non-hyperbolic (so that its developing image is a single point on \( \mathbb{C}^1 \)).

Then, letting \( \Lambda \) be the subset in \( \mathbb{C}^1 \) of cardinality 0, 1, or 2 which \( \text{Im} \rho \) preserves, there is at least one puncture of \( C \) which maps to the point which maps to \( \mathbb{C}^1 \setminus \Lambda =: \Omega \).
Proposition 8.6. Let $F$ be a closed surface with two punctures $p$ and $q$. Suppose that $C = (f, \rho)$ is a $\mathbb{CP}^1$-structure on $F$ such that

- the holonomy of $C$ is elementary, and the stabilizer of $\text{Im} \rho$ (in $\text{PSL}(2, \mathbb{C})$) is non-discrete,
- the degrees of $f$ around the two punctures are the same.

Then, no puncture of $F$ maps to $\Lambda$.

Proof. By Lemma 8.5, we can assume that $p$ does not develop to $\Lambda$. Let $C \cong (\tau, L)$ be the Thurston parameters of $C$; then by the assumption of the holonomy, $p$ and $q$ correspond to cusps of $\tau$. Then, as the degrees at $p$ and $q$ agree, the total weights of leaves of $L$ around the punctures are the same.

Suppose, to the contrary, that a puncture $q$ develops to a point of $\Lambda$. Then $f$ takes all lifts of $q$ to the same point of $\Lambda$; Otherwise, as $\Lambda$ has cardinality two, $\text{Im} \rho$ contains hyperbolic elements and there must be an elliptic element in $\text{Im} \rho$ exchanging the points of $\Lambda$; then the stabilizer of $\text{Im} \rho$ must be discrete against the hypothesis. Therefore all leaves of $L$ initiating from $q$ must end at $p$. Then, for every complementary region $R$ of $\tau \setminus L$, letting $\tilde{R}$ be the universal cover of $R$ (in $\tilde{\tau} = \mathbb{H}^2$), at most, one ideal point of $\tilde{R}$ maps to $q$ by the pleated surface.

In addition, every leaf of $L$ initiating form $p$ must end at $q$, as the total weights of $L$ around $p$ and $q$ agree. Then $f$ must be a covering map onto $\mathbb{CP}^1$ minus two points corresponding to $p$ and $q$, and therefore $F$ is a cylinder; this is a contradiction.

9. PARABOLIC LIMIT

In this section, we assume that $\rho_\infty(m)$ is parabolic. Then, by Theorem 7.3, for each component $F$ of $S \setminus m$, by taking an appropriate base point $b_i$ in the thick part of $C_i$ homotopic $F$, $(C_i, b_i)$ converges to a $\mathbb{CP}^1$-structure $F_\infty$ on a compact surface with one or two punctures, such that $F_\infty$ is homeomorphic to $F$. Let $C_\infty$ be the disjoint union of all $F_\infty$ for all components of $S \setminus m$, so that $C_\infty$ is a $\mathbb{CP}^1$ on a closed surface with two cusps homeomorphic to $S \setminus m$. ($C_\infty$ is not connected, if $m$ is separating.)

Lemma 9.1. Suppose that $\rho_\infty(m)$ is parabolic. Then, for each component $F$ of $S \setminus m$, $\rho_\infty(F)$ is non-elementary.

Proof. Let $(\sigma, \nu)$ be the Thurston parameterization of $F_\infty$, where $\sigma$ is a complete closed hyperbolic with one or two cusps homeomorphic to $F$ and $\nu$ is a measured lamination on $\sigma$. Clearly, the cusps of $F_\infty$ correspond to the cusps of $\sigma$. Then there is a bi-infinite simple geodesic $\ell$ properly embedded in $\sigma$ such that $\ell$ is a leaf of $\nu$ or disjoint from $\nu$ (note that each endpoint of $\ell$ is at a cusp of $\sigma$).

Let $\beta : \mathbb{H}^2 \to \mathbb{H}^3$ be the pleated surface given by $(\sigma, \nu)$, such that $\beta$ is equivariant by $\rho_\infty|_{\pi_1(F)}$. Then $\beta(\ell)$ is a bi-infinite geodesic in $\mathbb{H}^3$, and its endpoints on $\mathbb{CP}^1$ are the parabolic fixed points of different peripheral elements of $\pi_1(F)$. Then, as they do not commute, those
parabolic elements generate a non-elementary subgroup of $\text{PSL}(2, \mathbb{C})$, which is contained in $\rho_\infty(F)$. \hfill \square

Proposition \ref{prop:thick_part} implies:

**Lemma 9.2.** Let $C = (f, \rho)$ be a $\mathbb{CP}^1$-structure on a closed surface with finitely many punctures, denoted by $F$, such that the holonomy around each puncture is parabolic. Then the developing map $f : \tilde{F} \to \mathbb{CP}^1$ extends continuously to the lift of punctures so that they map to their corresponding parabolic fixed points.

For every $\epsilon > 0$ is the $\epsilon$-thick part of $C_t$ converges to the $\epsilon$-thick part of $C_\infty$. By Theorem \ref{thm:thick_part}

**Theorem 9.3.** Suppose $\rho_\infty(m)$ is parabolic. Then there is a regular neighborhood $N$ of $m$ such that $f_t|\tilde{S}\setminus\phi^{-1}(N)$ converges to a $\rho_\infty$-equivariant continuous map $f_\infty : \tilde{S}\setminus\phi^{-1}(N) \to \mathbb{CP}^1$, such that each boundary component of $\tilde{S}\setminus\phi^{-1}(N)$ maps to its corresponding parabolic fixed point.

**Lemma 9.4.** Suppose that cusps of $C_\infty$ have horodisk quotient neighborhoods. Then, for sufficiently large $t > 0$, $\rho_t(m)$ is hyperbolic.

**Proof.** We show that $\rho_\infty(m)$ can not be neither the identity $I$, a parabolic element or an elliptic element.

First suppose, to the contrary, that there is a diverging sequence $t_1 < t_2 < \ldots$ such that $\rho_t(m) = I$. Then, for $i \gg 0$, there is a round cylinder $A_{t_i}$ in $E_{t_i}$ homotopic to $m$ such that $\text{Mod} A_{t_i} \to \infty$. Therefore, as the holonomy of each component is non-elementary by Lemma \ref{lem:non-elementary}, there is a component $P$ of $S \setminus m$, such that $\rho_{t_i}|P$ diverges to infinity, possibly, up to a subsequence, which contradicts the hypothesis.

Next suppose there is a diverging sequence $t_1 < t_2 < \ldots$ such that $\rho_t(m)$ is parabolic. Then, for each $i \gg 0$, there is a $\mathbb{CP}^1$-surface with punctures, denoted by $C_{t_i}'$, homeomorphic to $S \setminus m$, such that the holonomy of $C_{t_i}'$ is $\rho_{t_i}|S \setminus m$ and, for every $\epsilon > 0$, the $\epsilon$-thick part of $C_{t_i}'$ converges to the $\epsilon$-thick part of $C_\infty$ as $i \to \infty$. Then $C_{t_i}$ is obtained by removing cusp horodisk neighborhoods $N_{t_i}$ of $C_{t_i}'$ and gluing them together around the boundary components. Therefore, for each $i = 1, 2, \ldots$, there is a Euclidean cylinder $A_{t_i}$ in $E_{t_i}$ with geodesic boundary such that $A_{t_i}$ is homotopic to $m$ and $\text{Mod} A_{t_i} \to \infty$ as $i \to \infty$. As the holonomy of each component $C_\infty$ is non-elementary, the holonomy of $C_{t_i}$ must diverge to $\infty$, which contradicts our hypothesis.

Suppose that there is a sequence $t_1 < t_2 < \ldots$ diverging to $\infty$ such that $\rho_{t_i}(m)$ is elliptic. For sufficiently small $\epsilon > 0$, let $N_{t_i}'$ be the component $N_{t_i}$ of the $\epsilon$-thin part of $C_{t_i}$ homotopy equivalent to $m$ on $S$. Note that $N_{t_i}'$ converges to two cusp neighborhoods of $C_\infty$. Then, since each cusp of $C_\infty$ has a horodisk quotient neighborhood and $\rho_{t_i}$ converges in $\chi$, if $\epsilon > 0$ is sufficiently small, then for $i \gg 0$, the developing image of $N_{t_i}'$ contains no fixed point of the elliptic element $\rho_{t_i}(m)$. As the elliptic element $\rho_{t_i}(m)$ converges to $I$, there can not be such a developing map $f_{t_i}$ realizing the conditions. \hfill \square

**Theorem 9.5.** Suppose that $\rho_\infty(m)$ is parabolic. Then, up to an isotopy of $S$ in $t$, $\beta_t \circ \tilde{\kappa}_t : \tilde{S} \to \mathbb{H}^3$ converges to a $\rho_\infty$-equivariant continuous map $\alpha : \tilde{S} \to \mathbb{H}^3 \cup \mathbb{CP}^1$ such that
$\alpha^{-1}(\mathbb{CP}^1)$ covers the loop $m$ by the universal covering map $\phi: \tilde{S} \to S$, and

• for each component $P$ of $\tilde{S} \setminus \phi^{-1}(m)$, $\beta_t \circ \kappa_t|P$ converges to the pleated surface for the component of $C_\infty$ corresponding to $P$.

Proof. The second assertion holds immediately from Theorem 9.3.

The axis $a_t$ of $\rho_t(m)$ converges to the parabolic fixed point of $\rho_\infty(m)$. As in Lemma 9.4, one can show can $\rho_t(m) \neq I$ for sufficiently large $t > 0$. Let $D \subset \mathbb{H}^3$ be a horoball centered at the parabolic fixed point of $\rho_\infty(m)$. Then we pick a continuous path of $\rho_t(m)$-invariant subsets $D_t$ in $\mathbb{H}^3$ converging to $D$ as $t \to \infty$, such that,

• if $\rho_t(m)$ is hyperbolic or elliptic then, $D_t$ is a neighborhood of the axis $a_t$ of $\rho_t(m)$ bounded by the surface equidistant from $a_t$, and

• if $\rho_t(m)$ is parabolic, then $D_t$ is a horoball centered at the parabolic fixed point of $\rho_t(m)$.

Pick a sufficiently small $\delta > 0$. For sufficiently large $t > 0$, let $N_t^\delta$ be the component of the $\delta$-thin part of $\tau_t$ homotopic to $m$, and let $\tilde{N}_t^\delta$ be the lift of $N_t^\delta$ to $\tilde{\tau} \cong \mathbb{H}^2$. If $\delta > 0$ is sufficiently small, by the convergence of $\rho_t$, the $\beta_t,\delta$-image of $\tilde{N}_t,\delta$ is eventually contained in $D_t$. This implies the first assertion. \hfill $\square$

Theorem 9.6. Suppose that $\rho_\infty(m)$ is parabolic, and each cusp of $C_\infty$ has a horodisk quotient neighborhood. Then, by an appropriate isotomy of $S$ in $t$, $f_t: \tilde{S} \to \mathbb{CP}^1$ converges to a $\rho_\infty$-equivariant continuous map $\tilde{S} \to \mathbb{CP}^1$ such that, for some multiloop $M$ on $S$,

• $f_\infty$ is a local homeomorphism on $\tilde{S} \setminus \phi^{-1}(M)$, and

• $f_\infty$ takes each component of $\phi^{-1}(M)$ to its corresponding parabolic fixed point.

Let $\gamma_t \in \text{PSL}(2, \mathbb{C}), t \geq 0$ be a path of hyperbolic elements such that $\gamma_t$ converges to a parabolic element in $\text{PSL}(2, \mathbb{C})$ as $t \to \infty$. Let $G_t$ be the one-parameter subgroup of $\text{PSL}(2, \mathbb{C})$ containing $\gamma_t$ such that the cyclic group generated by $\gamma_t$ is asymptotically dense in $G_t$ with respect to the path metric on $G_t$ induce by the invariant metric on $\text{PSL}(2, \mathbb{C})$. 

Figure 9. Normalisation and the isotope of the fundamental domain
For each \( t \geq 0 \), let \( \tilde{c}_t : \mathbb{R} \to \mathbb{CP}^1 \) be a non-constant trajectory of \( G_t \). Then \( \mathbb{CP}^1 \setminus (\tilde{c}_t \cup \text{Fix} \gamma_t) \) is topologically an open disk invariant under \( \langle \gamma_t \rangle \cong \mathbb{Z} \). Let \( \tilde{A}_t \) be the quotient of \( \mathbb{CP}^1 \setminus (c_t \cup \text{Fix} \gamma_t) =: \tilde{A}_t \) by the infinite cyclic group \( \langle \gamma_t \rangle \), which is a cylinder; let \( \phi_t : \tilde{A}_t \to A_t \) be the covering map.

Then \( \text{Mod } A_t \to \infty \) as \( t \to \infty \). Notice that \( A_t \) is foliated by loops whose lifts are \( G_t \)-orbits.

Pick a cylinder \( A'_t \) in \( A_t \) bounded by two leaves of the foliation such that, for every \( \varepsilon > 0 \), if \( t > 0 \) is large enough, \( A'_t \) is contained in the \( \varepsilon \)-thin part of \( A_t \). Let \( \tilde{A} \) be the underlying topological cylinder, and let \( m \) be a loop in the interior of \( A \) homotopy equivalent to \( A \); let \( \tilde{m} \) be the lift of \( m \) to \( \tilde{A} \).

**Lemma 9.7.** By taking an appropriate isotopy of \( A \), the developing map \( d_t : \tilde{A} \to \mathbb{CP}^1 \setminus \tilde{c}_t \) converges a \( \langle \gamma_\infty \rangle \)-equivariant continuous map \( d_\infty : \tilde{A} \to \mathbb{CP}^1 \) such that

- \( d_\infty \) takes \( \tilde{m} \) to the parabolic fixed point of \( \gamma_\infty \), and
- \( d_\infty \) is a local homeomorphism on \( \tilde{A} \setminus \tilde{m} \), and \( d_\infty \) yields a \( \mathbb{CP}^1 \)-structure on \( A \setminus m \) so that the each component of \( A \setminus m \) has a cusp (corresponding to \( m \)).

**Proof.** Continuously conjugate \( \gamma_t \) to by elements \( \omega_t \) of \( \text{PSL}(2, \mathbb{C}) \), such that the axis of \( \omega_t \cdot \gamma_t \) is the geodesic connecting 0 and \( \infty \) in \( \mathbb{CP}^1 = \mathbb{C} \cup \{ \infty \} \). Conformally identify \( \tilde{A}_t \) with a component \( R_t \) of \( \mathbb{CP}^1 \setminus \exp^{-1}(\omega_t c_t) \). Take a “Z-shaped” fundamental domain of the cylinder \( A_t \) in \( R_t \) (see Figure 10) in the domain \( F_t \) in \( R_t \), such that

- \( F_t \) is the union of two isometric trapezoids \( T_{1,t} \) and \( T_{2,t} \) and a parallelogram \( P_t \),
- \( \exp : \mathbb{C} \to \mathbb{C}^* \) identifies the edge \( e_{1,t} \) of \( T_{1,t} \) contained in \( \exp^{-1}(\omega_t c_t) \) and the edge \( e_{2,t} \) of \( T_{2,t} \) contained in \( \exp^{-1}(\omega_t c_t) \), and
- for every \( \varepsilon > 0 \) if \( t > 0 \) is sufficiently large, then \( \exp(P_t) \) maps into the \( \varepsilon \)-thin part of \( A_t \).

![Figure 10](image-url)

**Figure 10.** Left, \( F_t \subset R_t \subset \mathbb{C} \). Right, the exp-image of \( F_t \).
In addition, by the convergence of $\gamma_t$ to the parabolic element $\gamma_\infty$, we may in addition assume that, for $t \gg 0$, \(\exp e_{1,t}\) and \(\exp e_{2,t}\) are contained in a compact subset of $\mathbb{C}P^1 \setminus \Fix(\gamma_\infty)$, where $\Fix\gamma_\infty$ is the parabolic fixed point of $\gamma_\infty$.

Then $d_t(T_{1,t})$ and $d_t(T_{2,t})$ each converge to a fundamental domain of a hyperbolic cusp neighborhood. Then, since $\exp(P_t)$ is contained in the $\epsilon$-part of $A_t$, for every neighborhood of $\Fix\gamma_\infty$, if $t \geq 0$ is sufficiently large, $d_t(P_t)$ is contained in the neighborhood. \(\square\)

Let $\ell_t$ be the leaf of $A_t$ dividing $A_t$ into two isomorphic (projective) cylinders. Note that $\ell_t$ is an admissible loop on $A_t$. Let $\tilde{B}_t$ be the $2\pi n$-grafting $\Gr^\gamma_t(A_t)$ of $A_t$ along $\ell_t$, which remains to be a projective structure on a cylinder $A$ whose holonomy is the isomorphism onto $\langle \gamma_t \rangle$. Let $\phi: \tilde{A} \to A$ be the universal covering map.

**Proposition 9.8.** There is a multiloop $M$ on the interior of $A$ consisting $n$-parallel copies of $m$, such that, up to an isotopy, $\dev(B_t): \tilde{A}_t \to \mathbb{C}P^1$ converges to a $\langle \gamma_\infty \rangle$-equivariant continuous map $d_\infty: \tilde{A} \to \mathbb{C}P^1$ such that

- $d_\infty$ is a local homeomorphism in the complement of $\phi^{-1}(M)$, and
- $d_\infty$ yields a $\mathbb{C}P^1$-structure $A_\infty$ on $A \setminus M$, and for each component $F$ of $A \setminus M$, if $F$ is bounded by two loops of $M$, $A_\infty|F$ is a biinfinite Euclidean cylinder, and if $F$ is bounded by a single loop of $M$, $A_\infty|F$ has a single hyperbolic cusp neighborhood.

**Proof.** We describe how the fundamental domain $F_t$ of $A_t$ in $\mathbb{C}$ changes by the grafting. Notice that $\phi^{-1}(\ell_t) =: \tilde{\ell}_t$ divides the infinite strip $R_t$ into two isometric infinite stripes. Then $\tilde{\ell}_t$ intersects $F_t$ in a segment $s$ in the parallelogram $P_t$. Then the fundamental domain $F^m_t$ for $\Gr^\gamma_t(A_t)$ is obtained by inserting, along $\tilde{\ell}_t$ a parallelogram $P^m_t$ bounded by vertical translates of $s_t$ and vertical edges of length $2\pi n$ (see Figure 12 for $P^1$).

The exponential map $\exp: \mathbb{C} \to \mathbb{C}\setminus 0$ conformally identifies $R_t$ with $\tilde{A}_t \subset \mathbb{C}P^1$, $\exp^{-1}(\omega_t \ell_t)$ is a set of parallel lines in $\mathbb{C}$ transitive by the vertical translations by $2\pi$-multiples. Then the universal cover of $\tilde{B}_t$ is identified with the domain between two lines, so that the developing map corresponds to $\omega_t^{-1}\exp$. Then let $\tilde{M}_t$ be the multiloop on $B_t$ obtained from the inverse-image of $\ell_t$ by $\dev B_t$. Then, the inverse image of $\ell_t$ decomposes the inserted parallelogram $P^m_t$ into $n$ isometric parallelograms $P^i_1, \ldots, P^i_n$, whose vertical edges have length $2\pi$.

Then, for each $i = 1, \ldots, n$, $P^i_t$ converges to the fundamental domain of the Euclidean cylinder $(\mathbb{C}P^1 \setminus \Fix(\rho_\infty))/\langle \gamma_\infty \rangle$ such that the boundary components of $P_t$ converges to the constant map to the parabolic fixed point of $\gamma_\infty$. \(\square\)
Proof of Theorem 9.6. By Theorem 9.3, we already know the convergence of the developing map in the every thick part. The convergence of the thin part is given by Proposition 9.8 and Lemma 9.7.

9.1. Convergence in holomorphic quadratic differential in the case of parabolic cusps. By Theorem 6.1, Corollary 6.2, Theorem 5.7, we have

Theorem 9.9. Suppose that $\rho_{\infty}(m)$ is parabolic. Then $X_t$ converges to a nodal Riemann surface $X_{\infty}$ such that $X_{\infty}$ minus the node is homeomorphic to $S \setminus m$ and $q_t$ converges a regular quadratic differential $q_{\infty}$ on $X_{\infty}$.

10. $\rho_{\infty}(m)$ can not be hyperbolic

In this section, we show that $\rho_{\infty}(m)$ can not be a hyperbolic element.

Claim 10.1. Suppose that $X_t$ is pinched along a loop $m$ and, to the contrary, $\rho_{\infty}(m)$ is hyperbolic. Then

1. $C_t$ converges to a $\mathbb{CP}^1$-structure $C_{\infty}$ on a compact surface with two punctures, which is homeomorphic to $S \setminus m$, in the sense that, for every $\epsilon > 0$, the $\epsilon$-thick part of $C_t$ converges to the $\epsilon$-thick part of $C_{\infty}$ uniformly, and
2. $\rho_{\infty}(F)$ is non-elementary for each component $F$ of $S \setminus m$.

Proof. (1) is an immediate corollary of Proposition 8.4.

(2) Let $F_{\infty}$ be the component of $C_{\infty}$ corresponding to $F$. Then let $(\sigma, \nu)$ be the Thurston parametrization of $F_{\infty}$. Note that $\sigma$ is a hyperbolic surface with geodesic boundary, such that the lengths of the boundary components are the translation length of $\rho_{\infty}(m)$ (see the proof of Lemma 5.4). Let $(\tilde{\sigma}, \tilde{\nu})$ be the universal cover of $(\sigma, \nu)$ so that $\tilde{\sigma}$ is a convex subset of $\mathbb{H}^2$ bounded by geodesics and that $\tilde{\nu}$ is a $\pi_1(\sigma)$-invariant lamination on $\tilde{\sigma}$. Let $\alpha: \tilde{\sigma} \to \mathbb{H}^3$ be its pleated surface equivariant by the holonomy of $F_{\infty}$.

Let $\ell$ be a boundary geodesic of $\tilde{\sigma}$. Then the endpoints of $\alpha(\ell)$ are in the limit set $\Lambda$ of $\text{Hol} F_{\infty}$, as $\alpha(\ell)$ is the axis of the hyperbolic $\rho_{\infty}(m)$. Every component $R$ of $\tilde{\sigma} \setminus \tilde{\nu}$ has at least three ideal points. Then the ideal points of $\alpha(R)$ are in $\Lambda$ (see [Bab]). Thus $\rho_{\infty}|F$ is non-elementary.

Lemma 10.2. For each cusp $p$ of $C_{\infty}$, there is a neighborhood of $p$ foliated by isomorphic admissible loops which develop to simple curves on $\mathbb{CP}^1$ invariant under a one-parameter subgroup in $\text{PSL}(2, \mathbb{C})$ containing $\rho_t(m)$.
Proof. The developing map near a cusp neighborhood is the restriction of the exponential map \( \exp : \mathbb{C} \to \mathbb{C}^* \); moreover, by taking an appropriate neighborhood, one can assume that the restriction is to a half plane bounded by a straight line in \( \mathbb{C} \) invariant under the deck transformation corresponding to \( \rho_t(m) \).

The half plane is foliated by straight lines parallel to the boundary, and this foliation descends to a desired foliation of the cusp neighborhoods by admissible loops.

\textbf{Claim 10.3.} If \( \epsilon > 0 \) is sufficiently small, then, for every sufficiently large \( t > 0 \), there is a cylinder \( A_t \) in \( C_t \) homotopy equivalent to \( m \) such that

- \( A_t \) changes continuously in \( t \gg 0 \);
- \( A_t \) is foliated by admissible loops whose developments are invariant under a one-parameter subgroup \( G_t \) in \( \text{PSL}(2, \mathbb{C}) \) containing \( \rho_t(m) \);
- \( A_t \) contains the conformally \( \epsilon \)-thin part of \( C_t \);
- \( C_t \setminus A_t \) converges to a \( \mathbb{CP}^1 \)-structure on \( S \setminus m \) whose boundary components are admissible loops.

\textit{Proof.} Consider the cusp neighborhoods of \( C_\infty \) foliated by admissible loops by Lemma 11.2. By the convergence of Lemma 10.1 and the stability of the admissible loops, for \( t \gg 0 \), there is a cylinder \( A_t \) foliated admissible loops whose developments are invariant under \( G_t \). Then it is easy to realized other desired properties. \( \square \)

By Claim 10.1, the developing map of \( C_t \setminus A_t \) converges uniformly on compacts. The developing map of the cylinder \( A_t \) is the immersion into the region bounded by the developments of the two boundary components of \( C_t \setminus A_t \). Then, because of the convergence of \( C_t \setminus A_t \), \( A_t \) must converge. Thus \( C_t \) converges to a \( \mathbb{CP}^1 \)-structure on \( S \), this contradicts against the divergence of \( C_t \) in the deformation space. Hence \( \rho_\infty(m) \) cannot be hyperbolic.

11. \( \rho_\infty(m) \) Can Not Be Elliptic

In this section, we show that \( \rho_\infty(m) \) cannot be elliptic. To show this, we assume, to the contrary, that \( \rho_\infty(m) \) is elliptic and reduce a contradiction against the convergence of \( \rho_t \) as \( t \to \infty \). By Proposition 8.4, we have

\textbf{Proposition 11.1.} Suppose that \( \rho_\infty(m) \) is elliptic. Then \( C_t \) converges to a \( \mathbb{CP}^1 \)-structure \( C_\infty \) on a compact surface minus two points homeomorphic to \( S \setminus m \), in the sense that, for every \( \epsilon > 0 \), the \( \epsilon \)-thick part of \( C_t \) converges to the \( \epsilon \)-thick part of \( C_\infty \).

\textbf{Lemma 11.2.} For each component \( F_\infty \) of \( C_\infty \), the stabilizer of \( \rho_\infty(F_\infty) \) by conjugation is a discrete subgroup in \( \text{PSL}(2, \mathbb{C}) \).

\textit{Proof.} Let \( F_\infty \) be a component of \( C_\infty \). Then let \((\sigma, \nu)\) be the Thurston parametrization of \( F_\infty \), and let \((\tilde{\sigma}, \tilde{\nu})\) be the universal cover of \((\sigma, \nu)\). Then the rotation angle of the elliptic element \( \rho_\infty(m) \) is, modulo \( 2\pi \), equal to the total weight, give by \( \nu \), of the leaves ending at a puncture (Proposition 5.2). Let \( \beta_\infty : \tilde{\sigma} \to \mathbb{H}^3 \) be the equivariant pleated surface. Pick an isolated leaf \( \ell \) of \( \nu \) whose endpoints are at cusps of \( \nu \). Let \( \tilde{\ell} \) be a leaf of \( \tilde{\nu} \) which is a lift of \( \ell \). Then its image \( \beta_\infty(\tilde{\ell}) \) is a geodesic in \( \mathbb{H}^3 \), and its endpoints are fixed points some elliptic elements in \( \rho_\infty(F_\infty) \).

Moreover, the geodesic \( \ell \) bounds a component \( P \) of \( \tilde{\sigma} \setminus \tilde{\nu} \), and \( P \) has at least three ideal points. Then for each ideal point \( p \) of \( P \), let \( \gamma \in \pi_1(F_\infty) \) be such that \( \gamma \) fixes \( p \). Then \( \beta_\infty(p) \) is fixed by the elliptic element \( \rho_\infty(\gamma) \). Therefore, the stabilizer of \( \rho_\infty(F_\infty) \) is a discrete subgroup of \( \text{PSL}(2, \mathbb{C}) \). \( \square \)

Lemma 11.1 and Lemma 11.2 imply:

\textbf{Proposition 11.3.} If \( \epsilon > 0 \) is sufficiently small, then for every sufficiently large \( t > 0 \), there is a cylinder \( A_t \) in \( C_t \) homotopy equivalent to \( m \) such that
• $A_t$ changes continuously in $t \gg 0$;
• $A_t$ is foliated by loops whose developments are invariant under the one-dimensional subgroup $G_t$ of $\text{PSL}(2, \mathbb{C})$ containing $\rho_t(m)$, and $G_t$ converges to a one-dimensional subgroup $G_\infty$ of $\text{PSL}(2, \mathbb{C})$ containing $\rho_\infty(m)$;
• $A_t$ contains the conformally $\epsilon$-thin part of $C_t$ homotopic to $m$;
• $C_t \setminus A_t$ converges to a $\mathbb{CP}^1$-structure on $S \setminus m$ such that the boundary components cover round circles on $\mathbb{CP}^1$.

**Proposition 11.4.** Suppose that $\rho_\infty(m)$ is parabolic. Then $C_t$ converges to a $\mathbb{CP}^1$-structure on $S$, which is a desired contradiction.

**Proof.** Fix sufficiently small $\epsilon > 0$, and let $A_t$ be a cylinder given by Proposition 11.3. Let $\tilde{\phi}_t : C_t \to C_t$ be the universal covering map. Then the developing map of $C_t \setminus \phi_t^{-1}(A_t)$ converges uniformly on compacts. Let $A_t$ be a component of $\phi_0^{-1}(A_t)$ which changes continuously in $t$. Then $f_t$ converges on the boundary components of $A_t$ and thus $A_t$ must converge (up to isotopy). Therefore $C_t$ converges to a $\mathbb{CP}^1$-structure on $S$, which is a contradiction. \( \square \)

12. Limit when $\rho_\infty(m) = I$.

Let $A$ be a regular neighborhood of $m$ on $S$. Let $(\tau_t, L_t)$ be Thurston parameters of $C_t$. Let $\beta_t : \mathbb{H}^3 \to \mathbb{H}^3$ be its $\rho_t$-equivariant pleated surface. Let $\kappa_t : C \to \tau$ be the collapsing map, and $\tilde{\kappa}_t : \tilde{C} \to \mathbb{H}^2$ denote the lift of $\kappa$ to the map between their universal covers.

**Theorem 12.1.** Suppose that $\rho_\infty(m) = I$. Then the following holds:

1. $\rho_t(m) \neq I$ for sufficiently large $t > 0$.
2. The Fenchel-Nielsen twisting parameter (in $\mathbb{R}$) of $X_t$ along $m$ diverges to either $\infty$ or to $-\infty$.
3. For every diverging sequence $0 < t_1 < t_2 < \ldots$, there is a subsequence such that
   (a) the axis $\alpha_t$ converges to a point on $\mathbb{CP}^1$ or a geodesic in $\mathbb{H}^3$, denoted by $a_\infty$;
   (b) there is a $\mathbb{CP}^1$-structure in $\mathcal{P}(S \setminus m)$ such that, for every $\epsilon > 0$, the $\epsilon$-thick part of $C_t$ converges to the $\epsilon$-thick part of $C_\infty$ uniformly;
   (c) up to an isotopy of $S$ in $t$, the restriction of $f_t$ to $\tilde{S} \setminus \phi_t^{-1}(A_t)$ converges to a $\rho_\infty$-equivariant continuous map $f_\infty : \tilde{S} \setminus \phi_t^{-1}(A_t) \to \mathbb{CP}^1$ as $t_i \to \infty$ such that, for each component $\tilde{A}$ of $\phi_t^{-1}(A_t)$, its boundary components map onto the ideal points of $a_\infty$.
4. The pleated surface $\tilde{\kappa}_t \circ \beta_t : \tilde{S} \to \mathbb{H}^3$ converges to a $\rho_\infty$-equivariant continuous map $\tilde{S} \to \mathbb{H}^3 \cup \mathbb{CP}^1$, up to an isotopy of $S$.

Notice that, in (3c), if $a_\infty$ is a geodesic, then the different boundary components of $\tilde{A}$ map to the different endpoints of $a_\infty$.

We will prove (1) in the next section (§12.0.1). In this section, we will prove the other assertions: (1) will be proved in Lemma 12.7, (2) will be proved in Lemma 12.8, (3c) will be proved in Proposition 12.11. The proof of (3b) is similar to the proof of Proposition 8.4.

Let $C_\infty \cong (\sigma_\infty, \nu_\infty)$ denote the Thurston parameterization, where $\sigma_\infty$ is a hyperbolic structure in the Teichmüller space $\mathcal{T}(S \setminus m)$ and $\nu_\infty$ be a measured lamination on $\sigma_\infty$. Then $\sigma_\infty$ has two cusps, and, at each cusp $c$ of $\sigma_\infty$, there are only finitely many leaves of $\nu_\infty$ ending at $c$, and, since $\rho_\infty(m) = I$, the total weight of those leaves is a positive $2\pi$-multiple.

**Lemma 12.2.** If $\nu_\infty$ contains an irrational sublamination, then the holonomy of $C_\infty$ is non-elementary.

**Proof.** Suppose that $\nu_\infty$ contains an irrational sublamination. Then there is a minimal irrational sublamination $N$ of $L$, so that every leaf of $N$ is dense in $N$. Let $F$ be a (topologically)
smallest subsurface of $S$ containing $N$, such that $F \subset N$ is a $\pi_1$-injective. Let $\ell$ be a geodesic loop in $\sigma_\infty$ which is a good approximation of $N$. Let $\beta_\infty: \mathbb{H}^2 \to \mathbb{H}^3$ be the equivariant pleated surface corresponding to $(\sigma_\infty, \nu_\infty)$. Then, for each component $R$ of $F \setminus \ell$, the restriction of $\beta_\infty$ to $R$ is a quasi-isometric embedding ([Bab10]). Thus $\rho_\infty|_{\pi_1R}$ is non-elementary, which immediately implies the lemma. □

Using the assumption that $C_t$ is pinched along a single loop (not a multiloop), we prove the following:

**Proposition 12.3.** For each component $F$ of $S \setminus m$, the restriction of $\rho_\infty$ to $\pi_1F$ is a non-trivial representation.

**Proof.** If $\nu_\infty$ contains an irrational lamination, by Lemma 12.2 $\rho_\infty$ is non-elementary. Then we can assume, without loss of generality, that $\nu_\infty$ contains only isolated leaves, and $\nu_\infty$ divides $\sigma_\infty$ into ideal polygons.

Since each component of $\sigma_\infty$ has one or two cusps, there is a leaf $\ell$ of $\nu_\infty$ whose endpoints are at a single cusp $c$ of $\sigma_\infty$. Let $D$ be a small horodisk quotient neighborhood of $c$. Then $\ell \setminus D$ is a long geodesic segment, and by connecting its endpoints by a horocyclic arc in $\partial D$, we obtained a simple loop $\gamma$ (which is a good approximation of $\ell$).

Notice that $\beta_\infty(\ell)$ is a (biinfinite) geodesic in $\mathbb{H}^3$. Then the holonomy along $\gamma$ takes one endpoint of $\beta_\infty(\ell)$ to a point close to the other endpoint, and thus $\rho_\infty(\gamma) \neq I$. □

**Lemma 12.4.** Let $G$ be a non-trivial subgroup of $\text{PSL}(2, \mathbb{C})$. Consider the (pointwise) stabilizer of $G$ by conjugation by $\text{PSL}(2, \mathbb{C})$. Suppose that the stabilizer is continuous. Then there is a set $\Lambda$ of one or two points of $\mathbb{CP}^1$ fixed pointwise by the action of $G$.

**Proof.** Suppose that $G$ has a continuous stabilizer. Then, clearly, $G$ is an elementary subgroup of $\text{PSL}(2, \mathbb{C})$. First suppose, in addition, that $G$ contains a hyperbolic element $h$. Then no element in $G$ exchanges the fixed points of $h$, as otherwise the stabilizer can not be continuous. Therefore $\Lambda$ is the fixed point set of $h$, and all elements in $G \setminus \{I\}$ must be hyperbolic or elliptic elements with the same axis.

Next suppose that $G$ contains a parabolic element $p$. Then there is no elliptic element or hyperbolic element in $G$, as otherwise the stabilizer can not be continuous. Then $\Lambda$ must be the single fixed point of $p$, and all $G \setminus \{I\}$ are all parabolic elements with the same fixed point.

Suppose that $G$ contains an elliptic element $e$ and contains no hyperbolic element. Then, similarly, $\Lambda$ must the fixed point set of $e$, and $G$ contains no parabolic element. Moreover $G \setminus \{I\}$ are all elliptic elements with a common axis. Then $\Lambda$ is the set of the two endpoints of the axis. □

Given a $\mathbb{CP}^1$-surface with a puncture such that the holonomy around the puncture is trivial, its developing map continuously extends to the puncture, so that it is a branched covering map near the puncture.

**Lemma 12.5.** Let $F$ be a compact surface with finitely many punctures, such that the Euler characteristic of $F$ is negative. Let $(f, \rho)$ be a developing pair of a $\mathbb{CP}^1$-structure $C$ on $F$ such that

- $\rho: \pi_1(F) \to \text{PSL}(2, \mathbb{C})$ is not the trivial representation,
- the holonomy around each puncture is trivial, and
- the stabilizer of $\text{Im} \rho$ in $\text{PSL}(2, \mathbb{C})$ is continuous; thus let $\Lambda \subset \mathbb{CP}^1$ be the one- or two-point set in Lemma 12.4.

Then, there is a puncture $p$ of $F$ such that $f(p)$ is not a point of $\Lambda$. 37
Then, by Proposition 12.6, Lemma 12.5, and Proposition 12.3, either $\rho$ must diverge to $\infty$ (unique up to scaling). Thus, if $t \to \infty$.

**Proof.** Notice that $\mathbb{CP}^1$ minus $\Lambda$ admits a complete Euclidean metric invariant under $\text{Im} \rho$ (unique up to scaling). Thus, if $f$ takes all punctures of $F$ into $\Lambda$, then $F$ minus finitely many points admits a complete Euclidean metric. This is a contraction as the Euler characteristic of $F$ is negative. □

**Proposition 12.6.** Let $F$ be a compact connected surface with two punctures, such that the Euler characteristic of $F$ is negative. Let $C = (f, \rho)$ be a $\mathbb{CP}^1$-structure on $F$, such that

- $\text{Im} \rho$ has a continuous stabilizer in $\text{PSL}(2, \mathbb{C})$;
- the holonomy around punctures are trivial;
- the degrees around the two punctures are the same.

Then no puncture of $C$ maps to a point of $\Lambda$ by $f$, where $\Lambda$ is as in Lemma 12.4.

**Proof.** By Lemma [12.5](#), at least one puncture $q$ must develop to a point in the complement of $\Lambda$. Suppose, to the contrary, that there is a puncture $p$ of $C$ which develops to a point in $\Lambda$.

Let $(\tau, L)$ be the Thurston parameters of $C$. As $\rho$ is elementary, by Lemma [12.2](#), $L$ consists of isolated leaves. By the third condition, the total weights of leaves of $L$ ending $p$ and $q$ are the same $2\pi$-multiple; let $2\pi d$ denote the total weights, where $d$ is the degree. As $\text{Im} \rho$ has a continuous stabilizer, $f(p)$ must be preserved by $\text{Im} \rho$. Thus every leaf of $L$ starting from $p$ must end at $q$. Thus, as the total weights agree, every leaf of $L$ must connects $p$ and $q$.

Let $R$ be a component of $\tau \setminus L$, and let $\tilde{R}$ be a lift of $R$ to the universal cover $\tilde{\tau} \cong \mathbb{H}^2$. Then $f : \mathbb{H}^2 \to \mathbb{H}^2$ isometrically embeds $\tilde{R}$ into a totally geodesic hyperbolic plane, which has at least three ideal vertices. As all lifts of $p$ to the ideal boundary of $\tilde{\tau}$ map to the single point in $\Lambda$, there is exactly one point of $\tilde{R}$ corresponding to $p$. Then there must be an edge of $\tilde{R}$ connecting different lifts of $q$. This is a contradiction. □

Let $\tilde{m}$ be a lift of $m$ to $\tilde{S}$. Let $Q$ and $R$ be the adjacent components of $\tilde{S} \setminus \phi^{-1}(m)$ along $\tilde{m}$. Let $\text{Stab}_Q$ and $\text{Stab}_R$ denote the stabilizers, in $\pi_1(S)$, of $Q$ and $R$. We first prove (1) in Theorem [12.1](#).

**Lemma 12.7.** For sufficiently large $t > 0$, $\rho_t(m) \neq I$.

**Proof.** Suppose, to the contrary, that there is a diverging sequence $0 \leq t_1 < t_2 < \ldots$ such that $\rho_t(m) = I$ for each $i$. We may, in addition, assume that $C_{t_i}$ converges to $C_\infty$ as $i \to \infty$ uniformly on compacts as $i \to \infty$. Then, as $\rho_t(m) = I$ and $C_t$ is pinched along $m$ for $i \gg 0$, there is a cylinder $A_i$ in $C_{t_i}$ homotopic to $m$ such that

- $A_i$ is bounded by round circles (i.e. the development of each boundary component is a round circle on $\mathbb{CP}^1$),
- $\text{Mod} A_i \to \infty$, and
- $C_i \setminus A_i$ converges to $C_\infty$ minus cusp neighborhoods bounded by round circles.

Then, by Proposition [12.6](#), Lemma [12.5](#), and Proposition [12.3](#), either $\rho_t|\text{Stab}_R$ or $\rho_t|\text{Stab}_Q$ must diverge to $\infty$ in the $\text{PSL}(2, \mathbb{C})$-character variety. This is a contradiction against the convergence of $\rho_t$. □

**Lemma 12.8.** The Fenchel-Nielsen twist coordinate along $m$ must diverge to $\infty$ or $-\infty$ as $t \to \infty$.

**Proof.** The proof is similar to that of Lemma [12.7](#) □

Then, for each $t > 0$, let $i_t$ be some power of the Dehn twist of $S$ along $m$ such that the twist coordinated of $i_tC_t$ along $m$ is bounded from above and below uniformly in $t > 0$. Then, by Lemma [12.8](#) the power must diverge to either $\infty$ or $-\infty$ as $t \to \infty$. 38
There is a sequence \(0 \leq t_1 < t_2 < \ldots\) such that \(C_{t_i} \to C_\infty\) as \(i \to \infty\) uniformly on compact. Let \(F\) be a component of \(S \setminus m\). Let \(\tilde{F}\) be the universal cover of \(F\).

First suppose that \(\rho_\infty|F\) has a discrete stabilizer (in \(\text{PSL}(2, \mathbb{C})\)). Let \(F_\infty\) be a component of \(C_\infty\) which corresponds to \(F\). Then \(\text{dev} F_\infty\) is the limit of \(f_{t_i}|\tilde{F}\), so that \(\lim_{i \to \infty} f_{t_i}\) takes each boundary components of \(\tilde{F}\) to a single point corresponding to a cusp of \(C_\infty\).

Pick a fundamental domain \(D_i\) in \(\tilde{F}\) with an arc \(s_i\) on \(\partial D_i \cap \partial \tilde{F}\) such that \(s_i\) descends to a loop \(m_i\) isotopic to \(m\), it is contained in the \(\epsilon_i\)-thin part of \(C_{t_i}\) with \(\epsilon_i \to 0\) as \(i \to \infty\), and the development of \(m_i\) is invariant under a one-dimensional subgroup \(G_i\) of \(\text{PSL}(2, \mathbb{C})\) containing \(\rho_i(m)\). As \(\rho_i(m) \to I\), the image of \(s_i\) becomes more and more like a round circle \(c_i\) as \(i \to \infty\).

Next suppose that \(\rho_\infty(F)\) has a continuous stabilizer. Then \(\rho_\infty(F)\) is elementary, and the restriction of \(f_{t_i}\) to \(\tilde{F}\) may not converges to a local homeomorphism, even, up to a subsequence. Nonetheless, as \(C_t\) accumulates to a bounded subset of \(\mathcal{P}(S \setminus m)\), we can certainly normalize it in a nice way:

**Lemma 12.9.** Suppose that there is no subsequence of \(t_i\) such that \(f_{t_i}|\tilde{F}\) converges to a developing map of \(F_\infty\). Then there is a sequence \(\gamma_i\) of \(\text{PSL}(2, \mathbb{C})\) such that, up to a subsequence, \(\gamma_i(f_{t_i}|\tilde{F}, \rho_i|F)\) converges to a developing pair \((h_\infty, \zeta_\infty)\) of \(F_\infty\).

**Proposition 12.10.** Suppose that there is no subsequence such that \(f_{t_i}|\tilde{F}\) converges to a developing map of \(F_\infty\). Then \(f_{t_i}|\tilde{F}\) converges to a \(\rho_\infty|F\)-equivariant continuous map \(f_{F, \infty}: \tilde{F} \to \mathbb{CP}^1\) uniformly on compacts, such that each boundary component of \(\tilde{F}\) maps to a single point. Moreover, \(f_{F, \infty}\) is either a constant map to a fixed point of \(\rho_\infty|F\) or a there are open disks \(D_1, \ldots, D_n\) on \(F\) such that \(f_{F, \infty}\) takes \(\tilde{F} \setminus \phi^{-1}(D_1 \cup \cdots \cup D_n)\) to a fixed point \(p\) of \(\rho_\infty(F)\) and each lift \(D_i\) of \(D_i\) to \(\mathbb{CP}^1 \setminus \{p\}\) for all \(i = 1, \ldots, n\).

**Proof.** Let \(\gamma_i \in \text{PSL}(2, \mathbb{C})\) be the sequence obtained by Lemma 12.9.

First suppose that \(\rho_\infty(F)\) is loxodromic or elliptic. Then let \(\ell\) be the axis of \(\rho_\infty(F)\). Then \(\gamma_i\) will be a hyperbolic element for sufficiently large \(i\), and, as \(i \to \infty\), the translation length of \(\gamma_i\) diverges to infinity and \(\text{Axis}(\gamma_i)\) converges to \(\ell\). Let \(p\) be the limit of the repelling fixed point of \(\gamma_i\), and let \(q\) be the limit of the attracting fixed point of \(\gamma_i\), so that \(\{p, q\}\) are the endpoints of \(\ell\).

Take a connected fundamental domain \(Q\) in \(\tilde{F}\) so that the \(h_\infty(\partial Q) \cap \{p, q\} = \emptyset\). Suppose that \(h_\infty(Q)\) is disjoint from \(q\). Then, letting \(f_i = f_{t_i}\), the restriction \(f_i|Q\) converges to the constant map to \(p\) uniformly, as \(i \to \infty\), and thus \(f_i: \tilde{F} \to \mathbb{CP}^1\) converges to the constant map to \(p\) uniformly on compacts. Suppose that \(h_\infty(Q) \cap \{q\} \neq \emptyset\). Then there are finitely many points of \(h_\infty^{-1}(q)\) in the interior of \(Q\). Pick disjoint open disk neighborhood of the points in \(h_\infty^{-1}(q)\) in \(Q\), and let \(D_1, \ldots, D_n\) be their disjoint images on \(F\). Then, up to an isotopy of \(F\), the restriction of \(f_i\) to \(\tilde{F} \setminus \phi^{-1}(D_1 \cup \cdots \cup D_n)\) converges to the constant map to \(p\) uniformly on compacts and for each lift \(D_i\) of \(D_i\) to \(\tilde{F}\), \(f_i|D_i\) converges to a homeomorphism to \(\mathbb{CP}^1 \setminus \{p\}\), as desired. By Lemma 8.5 and Proposition 8.6, the boundary components of \(\tilde{F}\) all map to \(p\).

Next suppose that \(\rho_\infty(F)\) is parabolic. Let \(p\) be the parabolic fixed point of \(\rho_\infty(F)\). Then \(\text{Axis} \gamma_i\) converges to \(p\) as \(i \to \infty\). By normalizing \(\mathbb{CP}^1\) appropriately, we may assume that \(\gamma_i\) is asymptotically in the form of \(\begin{bmatrix} 1 & c_i \\ 0 & 1 \end{bmatrix}\) and \(\|c_i\| \to \infty\). Then up to a subsequence, we may in addition assume that \(\arg c_i\) converges as well. Then, similarly, pick a fundamental domain \(Q\) in \(\tilde{F}\) so that \(h_\infty(\partial Q)\) does not intersect \(p\). Suppose that there is no point of \(Q\) maps to \(p\) by \(h_\infty\). Then \(f_i|\tilde{F}\) converges to the constant map to \(p\) uniformly on compacts.
Otherwise there are finitely many points \( z_1, z_2, \ldots, z_n \) of the interior of \( Q \), which map to \( p \). Normalize \( \mathbb{CP}^1 = \mathbb{C} \cup \{ \infty \} \) so that \( p = \infty \). Then consider a half plane \( H \) of \( \mathbb{C} \) (bounded to by a straight line) such that \( \partial H \) is asymptotically orthogonal to \( c_i \) (regarded as a vector) but not containing \( c_i \) (as a point) for sufficiently large \( i \), so that the translation of \( H \) by \( c_i \) will asymptotically be the entire complex plane \( \mathbb{C} \) as \( i \to \infty \). Then, for each point \( z_j \) in \( Q \) mapping to \( p \), takes a sufficiently small round ball such that it boundary contain \( z_j \) and its \( h_\infty \)-image is the half plane \( H \). Then, take disjoint open balls \( D_1, \ldots, D_n \) on \( F \) which lift to those open balls in \( Q \), we can show the desired convergence.

Last suppose that \( \rho_\infty (F) \) is the trivial representation. Then the normalized holonomy \( \zeta_\infty \) is a parabolic representation. Let \( p \) be the parabolic fixed point of \( \zeta_\infty \). Pick a connected fundamental domain \( Q \) in \( \tilde{F} \) so that \( h^{-1}(p) \) is disjoint from \( \partial Q \). Suppose in addition that no point of \( Q \) maps to \( p \). Then, up to a subsequence, \( f_i|F \) converges to a constant map uniformly on compacts. Suppose there are (finitely many) points of \( Q \) which map to \( p \). Then, similarly to the case of hyperbolic and elliptic element, take disjoint open ball neighborhoods of those points in \( Q \), and let \( D_1, D_2, \ldots, D_n \) be disjoint disks on \( F \) which lift to those open balls. Then the desired convergence follows similarly.

By Proposition 12.10, the restriction of \( f_i \) to \( \tilde{S} \setminus \phi^{-1}(A) \) converges to a \( \rho_\infty \)-equivariant map \( f_\infty : \tilde{S} \setminus \phi^{-1}(A) \to \mathbb{CP}^1 \).

**Proposition 12.11.** For each component \( \tilde{A} \) of \( \phi^{-1}(A) \), let \( \gamma \in \pi_1(S) \) be the representative of \( m \) preserving \( \tilde{A} \). Then, by taking a subsequence so that \( \text{Axis}(\rho_i(\gamma)) =: a_i \) converges to a subset \( a_\infty \in \mathbb{H}^3 \cup \mathbb{CP}^1 \), which is either a point on \( \mathbb{CP}^1 \) or a geodesic in \( \mathbb{H}^3 \), then \( f_\infty \) takes the boundary components of \( \tilde{A} \) onto the ideal points of \( a_\infty \).

**Proof.** By Lemma 12.7 \( \rho_i(m) \neq I \) for sufficiently large \( i \in \mathbb{Z}_{>0} \). Then, by taking a subsequence, we may in addition assume that \( \rho_i(\gamma) \) converges to \( I \) tangentially to a unite tangent vector of \( \text{PSL}(2, \mathbb{C}) \) at \( I \). We let \( G_i \) denote the one-parameter subgroup of \( \text{PSL}(2, \mathbb{C}) \) which contains \( \rho_i(\gamma) \), such that the cyclic group generated by \( \rho_i(\gamma) \) is asymptotically dense in \( G_i \) with respect to the intrinsic metric on \( G_i \). Then the trajectories of \( G_i \) yields a unique foliation of \( \mathbb{H}^3 \) except that, if \( \rho_i(\gamma) \) is elliptic, only of \( \mathbb{H}^3 \setminus a_i \) (Figure 14). We have chosen a subsequence \( t_i \) so that \( C_{t_i} \to C_\infty \) uniformly on every thick part and the axis \( a_i \) converges to a closed subset \( a_\infty \) of \( \mathbb{H}^3 \). Let \( P, Q \) be the components of \( \tilde{S} \setminus \phi^{-1}(N) \) adjacent across \( \tilde{N} \).

**Claim 12.12.** Let \( \ell \) be the common boundary component of \( P \) and \( \tilde{N} \). Suppose, to the contrary, that \( \lim f_{t_i}(\ell) \) is not a point of the limit axis \( a_\infty \). Then \( \rho_i|Q \) diverges to \( \infty \) in \( \chi \).

**Proof.** Let \( \iota_i \) be some power of the Dehn twist of \( S \) along \( m \) so that the Fenchel-Nielsen twist parameter of \( \iota_i X_{t_i} \) along \( m \) is bounded from above and below uniformly in \( i \).

Let \( r \) be the common boundary component of \( \tilde{N} \) and \( Q \). By Proposition 12.3, there is \( \gamma \in \pi_1(S) \) belonging to \( \text{Stab} Q \) such that \( \rho_\infty(\gamma) \) is not the identity matrix. We may in addition assume the axis of \( \rho_i(\iota_i \gamma) \) converges to the point \( f_{F_\infty}(\ell) \) on \( \mathbb{CP}^1 \) (if \( \rho_\infty(\text{Stab} Q) \) is elementary, use Lemma 12.5 and Proposition 12.6). By the tangential convergence of \( \rho_i(m) \to I \), the \( G_i \)-invariant foliation of \( \mathbb{H}^3 \) by \( \mathcal{F}_i \) converges to a foliation of \( \mathcal{F}_\infty \) of \( \mathbb{H}^3 \). If \( f_{F_\infty}(\ell) \) is not the ideal point of \( a_\infty \), \( \text{Axis}(\rho_i(\gamma)) \) be eventually disjoint from every compact subset in the space of the leaves of \( \mathcal{F}_\infty \). Therefore \( \text{Axis}(\rho_i(\gamma)) \) leaves every compact subset of the leaf space of \( \mathcal{F}_\infty \), and thus \( \rho_i(\gamma) \) must diverge to \( \infty \) in \( \text{PSL}(2, \mathbb{C}) \), which is a contradiction. (Figure 13)

This claim completes the proof.

It remains only to prove the surjectivity in (3c):
Lemma 12.13. Suppose that $a_\infty$ is a geodesic in $\mathbb{H}^3$. Then $f_\infty(\ell)$ and $f_\infty(r)$ are the different endpoints of $a_\infty$.

Proof. By Claim 12.12 $f_i|\ell$ converges to the constant map to an endpoint of $a_\infty$.

Let $n_i \in \mathbb{Z}$ be the power of the Dehn twist along $m$ which gives $x_i \in \pi_1(S)$. Thus $\rho_i(\gamma^{n_i})$ is a hyperbolic element whose axis $a_i$ converges to $a_\infty$ and its translation length diverge to infinity. Then the attracting fixed point of $\rho_i(\gamma^{n_i})$ converges to the endpoint of $a_\infty$ which is not $f_\infty(\ell)$. Thus $f_\infty(q)$ must be at the other endpoint. □

12.0.1. Convergence of pleated surfaces when $\rho_\infty(m) = I$. First we compare developing maps of $\mathbb{CP}^1$-structures and the exponential map $\exp: \mathbb{C} \rightarrow \mathbb{C}^*$. Let $\ell$ be the geodesic in $\mathbb{H}^3$ connecting $0$ to $\infty$. Let $\Psi: \mathbb{C}^* \rightarrow \ell$ be the continuous extension of the nearest point projection $\mathbb{H}^3 \rightarrow \ell$. Then, the composition is $\Psi \circ \exp: \mathbb{C} \rightarrow \mathbb{H}^3$ is the Epstein map of the $\mathbb{CP}^1$-structure on $\mathbb{C}$ given by $\exp$.

Recall that, given a $\mathbb{CP}^1$-structure $C = (X, q)$, for $x \in \mathbb{C}$, $d(x)$ is the Euclidean distance from the zeros of the holomorphic differential $q$. Note that, if $d(x)$ is large, then we can naturally embeds a large neighborhood of $x$ into $\mathbb{C}(\cong \mathbb{E}^2)$ by an isometric map onto its image, so that vertical leaves map into horizontal lines, and horizontal leaves map into vertical lines.

Proposition 12.14. For every $\epsilon > 0$, there is $R > 0$, such that, if $x \in C$ satisfies $d(x) > R$, then the Epstein map $\tilde{\Sigma}: \tilde{C} \cong \tilde{S} \rightarrow \mathbb{H}^3$ is $\epsilon$-close in the $C^1$-topology and the composition of the collapsing map $\tilde{\kappa}: \tilde{S} \rightarrow \mathbb{H}^2$ and the bending map $\beta: \mathbb{H}^2 \rightarrow \mathbb{H}^3$ at every lift $\tilde{x}$ of $x$.

Proof.
Lemma 12.15. For every $\epsilon > 0$, there is $R > 0$ such that, if $z \in \tilde{C}$ satisfies $d(z) > R$, then the restriction of $\Sigma$ to the $\frac{1}{\epsilon}$-neighborhood $N_{1/\epsilon}(z)$ of $z$ is $\epsilon$-close to $w \mapsto \Psi \exp(\frac{w}{\sqrt{2}})$ on the corresponding region in $\mathbb{C}$.

Proof. By Lemma 2.4, the vertical leaves on $\Sigma$ are almost geodesic on $\mathbb{H}^3$, and on the other hand, horizontal leaves on $\Sigma$ is very short in $\mathbb{H}^3$. Moreover the vertical and horizontal direction are orthogonal. The curvature estimate along the horizontal direction is given by Lemma 1.1. Therefore $\Sigma$ is $\epsilon$-close to $\omega \mapsto \Psi \exp(\frac{\omega}{\sqrt{2}})$ in both horizontal and vertical direction, and as they stay orthogonal on $\Sigma$ (Lemma 2.4 (3)), we have the claim. \hfill $\square$

Lemma 12.16. For every $\epsilon > 0$, there is $R > 0$, such that, if $z \in \tilde{C}$ satisfies $d(z) > R$, then the maximal ball centered at $z$ is $\epsilon$-close to the maximal ball of the corresponding exponential map.

Proof. As the Epstein maps of $C$ and $\exp$ are close, their developing maps are also close. This implies the closeness of their maximal balls centered at $z$ and their ideal points. \hfill $\square$

The proposition follows from the above lemmas. \hfill [12.14]

Proposition 12.17. Suppose that $\rho_\infty(m) = I$. Then for every diverging sequence $t_1 < t_2 < \ldots, \hfill [12.17]

up to taking a subsequence, there are a sequence of compatible markings $\iota_i; S \to \tau_i$, and a path of cylinders $A_t$ in $C_t$ homotopy equivalent to $m$, such that in addition to Theorem 12.1 (1), (2), (3), the following holds:

1. $A$ maps to $A_t := A_{t_i}$ by $t_i := t_{i_i}$;
2. $\beta_{t_i} \circ \kappa_{t_i}; \tilde{S} \to \mathbb{H}^3$ converges to a $\rho_\infty$-equivariant continuous map $\tilde{S} \to \mathbb{H}^3 \cup \mathbb{C}P^1$ uniformly on compact subsets;
3. for each connected component $F$ of $\tilde{S} \setminus \phi^{-1}(A)$, the restriction of $\beta_{t_i} \kappa_{t_i}$ to $F$ converges to the pleated surface of the corresponding component of $C_\infty$ or the constant map to a point of $a_\infty$;
4. letting $\tilde{A}_t$ be a connected component of $\phi^{-1}(A)$ in $\tilde{S}$, then $\beta_{t_i} \circ \kappa_{t_i}|\tilde{A}_t$ converges to a map onto $a_\infty$ uniformly on compacts in $\tilde{A}$ with respect to a disk metric on $\mathbb{H}^3 \cup \mathbb{C}P^1$.

Remark 12.18. If $\beta_i \circ \kappa_i|F$ is a constant map, then $\rho_\infty(F)$ must be the trivial representation by the equivariance property.

Proof. For $t \gg 0$, there is a one-parameter family of loops homotopic to $m$ such that their developments are invariant under a unique one-dimensional subgroup $G_t$ of $PSL(2, \mathbb{C})$. Then we can pick a cylinder $A_t$ in $C_t$ homotopy equivalent to $m$, such that

- $A_t$ is foliated by loops whose developments are invariant under $G_t$ for each $t \gg 0$,
- $C_t \setminus A_t$ converges to $C_\infty$ as $t \to \infty$, and
- $\text{Mod } A_t \to \infty$ as $t \to \infty$.

By the second property, $A_t$ is contained in a thinner and thinner part of $C_t$ as $t \to \infty$. Then the developing map of $A_t$ is the restriction of $\exp; \mathbb{C} \to \mathbb{C}^*$ to a bi-infinite strip $T_t$, i.e. a region in $\tilde{C}$ bounded by a pair of parallel lines. Then its deck transformation group ($\cong \mathbb{Z}$) is generated by a translation of $T_t$. Then $A_t$ has a natural Euclidean metric by identifying $\mathbb{C}$ with $\mathbb{E}^2$.

Pick a cylinder $A$ in $S$ homotopic to $m$, and fix a finite volume Euclidean structure on $A$ with geodesic boundary (by picking a homeomorphism $A \to S^1 \times [-1, 1]$).

Pick a marking $\iota_t; S \to C_t$ such that

- $\iota_t$ takes $A$ to $A_t$ (1);
- the restriction of $C_t$ to $\iota_t(S \setminus A)$ converges to $C_\infty$;
• \( \nu_t | A \) is linear with respect to the Euclidean structures on \( A \) and \( A_t \).

Given a component \( F \) of \( \tilde{S} \setminus \phi^{-1}(A) \), suppose that \( f_t | F \) converges to a developing map of the component of \( C_\infty \). Then, accordingly, \( \beta_i \circ \kappa_t | F \) converges to a pleated surfer for the corresponding component of \( C_\infty \). By Proposition 12.10 if \( f_t | F \) does not converge to a developing map, then \( \beta_i \circ \kappa_t | F \) converges to a constant map. Thus we have (3).

We can assume that the most of the twisting of \( C_t \) along \( m \) (given by Theorem 12.1[2]) occurs in \( A_t \).

(Case One) Suppose that \( a_\infty := \lim_{i \to \infty} \text{Axis } \rho_i(m) \) is a biinfinite geodesic. We have already fixed a Euclidean structure on the cylinder \( A \). Pick a connected fundamental domain \( D \) in the universal cover \( \tilde{S} \) so that \( D \cup \phi^{-1}(A) \) is single a single parallelogram \( P \) which is a fundamental domain for \( \tilde{A} \). Let \( e \) and \( h \) be the opposite edges of \( P \) which map onto different boundary circles of \( A \). Then \( f_i(e) \) and \( f_i(h) \) are arcs contained in a \( G_i \)-invariant curve on \( \mathbb{CP}^1 \), and, by Lemma 12.13, they converge to the different endpoints of \( a_\infty \). The four edges of \( P_i \subset \mathbb{C} \) are asymptotically parallel as \( i \to \infty \) as the twisting parameter diverges to infinity (i.e. the angles at the vertices converges to either 0 or \( \pi \)). We may, in addition, assume that \( \sup \{ \text{Im}(z - w) | z, w \in P_i \} \to 0 \) as \( i \to \infty \). The complex length of \( e \) and \( h \) converges to an integer multiple of \( \pi/\sqrt{2} \) as \( i \to \infty \) as \( \rho_i(m) \to I \).

Recall that \( \rho_i(m) \) is hyperbolic if \( i \) is large enough. Then the foliation of \( \mathbb{C} \) by horizontal lines induces a foliation \( \mathcal{F}_i \) of \( P_i \).

**Claim 12.19.** For every \( \epsilon > 0 \) is \( i \in \mathbb{Z}_{>0} \) is sufficiently large, then, for each leaf \( s \) of \( \mathcal{F}_i \), \( \beta_i \circ \kappa_i(s) \) has diameter less than \( \epsilon \) and it is contained in the \( \epsilon \)-neighborhood of the geodesic \( \text{Axis } \rho_i(m) \).

**Proof.** Note the distance of \( A_t \) from zeros of \( q_t \) diverges to \( \infty \) as \( t \to \infty \). By Lemma 2.4 (1), the diameter of each arc is less than \( \epsilon > 0 \).

Recall that, as the convergence \( C_t \to C_\infty \), by Theorem 12.1[3c], \( f_i(e) \) and \( f_i(h) \) converge to the end points of the limit axis \( a_\infty \). Then by Proposition 12.14 \( \beta_i \circ \kappa_i(e) \) and \( \beta_i \circ \kappa_i(h) \) are \( \epsilon \)-close to the axis \( a_i \) of \( \rho_i(m) \), by taking an appropriate \( A_t \). Then, if a leaf \( s \) of the horizontal foliation \( \mathcal{F}_i \) in \( P_i \) has an endpoint at the edge \( e \) or \( h \), then \( \beta_i \circ \kappa_i(s) \) is \( \epsilon \)-close to \( \beta_i \circ \kappa_i(e) \) or \( \beta_i \circ \kappa_i(h) \). Thus, as \( \sup \{ | \text{Im}(z - w) | | z, w \in P_i \} \to 0 \) as \( i \to \infty \), by the equivariant property, all leaves of \( \mathcal{F}_i \) have this property. (Figure 16)  

**Figure 15.**

Then by Claim 12.19 implies (4)
(Case Two) Suppose that $a_\infty$ is a single point on $\mathbb{CP}^1$. Then, by Proposition \ref{prop:12.11}, $f_\infty(\ell) = f_\infty(r)$.

Pick any horoball $B$ in $\mathbb{H}^3$ tangent at $a_\infty$. For each $i$, pick a subset $U_i \subset \mathbb{H}^3$ converging to $B$ uniformly on compacts, such that, if $\rho_i(\gamma)$ is either hyperbolic or elliptic, then $U_i$ is an $r_i$-neighborhood of $a_i$ for some $r_i > 0$, and if $\rho_i(\gamma)$ is parabolic, then $U_i$ is a horoball centered at the parabolic fixed point of $\rho_i(\gamma)$.

For sufficiently large $i$, Let $N_i$ be the $\epsilon$-thin part of $\tau_i$ homotopy equivalent to $m$. Let $\tilde{N}_i$ be a component of $\psi_i^{-1}(N_i)$, where $\psi_i : \mathbb{H}^2 \to \tau_i$ be the universal covering map.

**Lemma 12.20.** If $\epsilon > 0$ is sufficiently small, then $\beta_i(\tilde{N}_i)$ is eventually contained in $U_i$ as $i \to \infty$. Therefore, $\beta_i \circ \kappa_i|\tilde{A}$ converges to the constant map to the point $a_\infty$.

**Proof.** Let $P$ and $R$ be the components of $\tilde{S} \setminus \phi^{-1}(A)$ adjacent across a lift $\tilde{A}$ of $A$ which corresponds to $\tilde{N}_i$. If $\beta_i(\tilde{N}_i)$ is not eventually contained in $U_i$, then, either $\rho_i|\text{Stab } P$ or $\rho_i|\text{Stab } R$ diverges to $\infty$, up to a subsequence, which is a contradiction. \hfill \Box

12.1. Non-discreteness of holonomy.

**Theorem 12.22.** Suppose that $\rho_\infty(m) = I$. Then $\text{Im } \rho_t \subset \text{PSL}(2, \mathbb{C})$ is a non-discrete subgroup for sufficiently large $t \gg 0$.

**Proof.** Recall that $\rho_t(m) \to I$ but $\rho_t(m) \neq I$ (Theorem \ref{thm:12.1}(1)). For each component $F$ of $S \setminus m$, $\rho_t(\pi_1(F))$ is nontrivial for sufficiently large $t \gg 0$ (Proposition \ref{prop:12.3}). Thus the subgroup of $\text{Im } \rho_t$ generated by $\{ \rho_t(m)\gamma \rho_t(m)^{-1} | \gamma \in \rho_t(F) \}$ is non-elementary (Lemma \ref{lem:12.5} and Proposition \ref{prop:12.6}). As $\rho_t(m) \to I$, by the Margulis lemma, $\text{Im } \rho_t$ can not be discrete. \hfill \Box
13. Examples of exotic degeneration

We construct examples of a path $C_t = (f_t, \rho_t)$ of $\mathbb{CP}^1$-structures pinched along a loop $m$ such that $\rho_\infty(m) = I$ and $[\rho_t]$ converges in $\chi$ as $t \to \infty$, as in the second part of Theorem 8.2. Indeed, we construct two examples: one with $\rho_t(m)$ hyperbolic and one with $\rho_t(m)$ elliptic for all $t \gg 0$.

13.1. Hyperbolic $\rho_t(m)$ converging to $I$. Let $E$ be the singular Euclidean surface obtained from an $L$-shaped polygon by identifying the opposite edges (Figure 17). Then $E$ has exactly one cone point, and its cone angle is $6\pi$. Let $F'$ be the underlying topological surface of $E$, which is a closed surface of genus two. Let $E'$ denote $E$ minus the cone point, and let $F''$ denote the underlying topological surface of $E'$.

![Figure 17](image)

Let $\ell_p$ be the (oriented) peripheral loop around the removed cone point. Let $\xi : \pi_1(F') \to \text{PSL}(2, \mathbb{C})$ be the holonomy of $E$ minus the cone point; then, as $F'$ has a Euclidean structure, we can assume that its image consists of upper triangular matrices with 1's on the diagonal. In particular $\xi(\ell_p) = I$ (as before, by abuse of notation, we regard $\ell_p$ also as a fixed element of $\pi_1(S)$). Notice that there is a point in the universal cover $\tilde{E}$ of $E$ corresponding to $\ell_p \in \pi_1(S)$.

**Proposition 13.1.** There is a path of $\mathbb{CP}^1$-structures, $D_t = (h_t, \xi_t)$, on $F'$ converging to $E = (h, \xi)$ as $t \to \infty$, such that $\xi_t(\ell_p)$ is a hyperbolic translation whose axis converging to a geodesic connecting the parabolic fixed point of $\xi_\infty$ and the $h$-image of the corresponding singular point of $E$.

Note that elements of $\text{Im} \xi$ are translations of $\mathbb{C}$. Pick non-separating simple closed curves $a_1, b_1, a_2, b_2$ on $E$ (as in Figure 17) forming a standard generating set of $\pi_1(F)$ so that

- for each $i = 1, 2$, $a_i$ and $b_i$ intersect in a single point, and $[a_1, b_1][a_2, b_2] = I$,
- the translation directions of $a_1$ and $a_2$ are the same and the translation direction of $b_1$ and $b_2$ are the same, and
- the translation directions of $a_i$ and $b_i$ are orthogonal for each $i = 1, 2$.

Let $c$ be a separating loop on $E$ which separates $\{a_1, b_1\}$ and $\{a_2, b_2\}$. Then let $F_1$ and $F_2$ be the components of $F \setminus c$ which are homeomorphic to a torus minus a disk.

**Lemma 13.2.** Let $q_i$ be any geodesic in $\mathbb{H}^3$ starting from the parabolic fixed point $p \in \mathbb{CP}^1$ of $\text{Hol} E$, and let $H_i$ be the hyperbolic plane, in $\mathbb{H}^3$, containing an $\langle a_i \rangle$-orbit of $q_i$. For each $i = 1, 2$, given any path $h_{i,t} (t \geq 0)$ of hyperbolic elements in $\text{PSL}(2, \mathbb{C})$ such that

1. the axis of $h_{i,t}$ is orthogonal to $H_i$ at a point in $q_i$ for all $t \geq 0$, and
2. $h_{t,i} \to I$ as $t \to \infty$. 

45
Then, there is a path \( \zeta_{i,t} : \pi_1(F_i) \to \text{PSL}(2, \mathbb{C}) \) of homomorphisms converging to \( \text{Hol}(E)|\pi_1(F_i) \) such that \( \zeta_{i,t}(c) = h_{i,t} \).

**Proof.** The point \( p \) is contained in the ideal boundary of \( H_i \). Let \( r_i \) be a geodesic in \( H_i \), such that \( R(r_i)R(q_i) = \xi(a_i) \), where \( R(r_i) \) and \( R(q_i) \) are the \( \pi \)-rotations of \( \mathbb{H}^3 \) about \( r_i \) and \( q_i \), respectively (Figure 18).

![Figure 18](image18.png)

Let \( H_i^\perp \) be the hyperbolic plane in \( \mathbb{H}^3 \) orthogonal to \( H_i \) in \( q_i \). As \( \text{Axis}(h_{i,t}) \) is in \( H_i \) and orthogonal to \( q_i \), we let \( q_{i,t}, q'_{i,t} \) be continuous paths of geodesics in \( H_i^\perp \) such that \( R(q_{i,t})R(q'_{i,t}) = h_{i,t} \), the geodesics \( q_{i,t} \) and \( q'_{i,t} \) converge to \( q_i \) as \( t \to \infty \), and the \( \pi \)-rotation \( R(q_i) \) exchanges \( q_{i,t} \) and \( q'_{i,t} \). There is a path of geodesics \( r_{i,t} \) such that, for all \( t \gg 0 \),

- there is a hyperbolic plane intersecting \( r_{i,t}, q_{i,t}, q'_{i,t} \) orthogonally, and
- \( d_{\mathbb{H}^3}(r_{i,t}, q_{i,t}) = d_{\mathbb{H}^3}(r_{i,t}, q'_{i,t}) \).

Thus by the symmetry, \( \text{tr} R(q_{i,t})R(r_i) = \text{tr} R(q'_{i,t})R(r_i) \in \mathbb{R} \setminus [-2, 2] \).

The surface \( F_i \setminus a_i \) is a pair of pants, and two of its boundary components correspond to \( a_i \). Consider the path of homomorphisms \( \zeta_{i,t} : \pi_1(F_i \setminus a_i) \to \text{PSL}(2, \mathbb{C}) \) for \( t > 0 \), such that the two boundary components corresponding to \( a_i \) map to \( R(q_{i,t})R(r_i) \) and \( R(q_{i,t})R(q'_{i,t}) \) — thus the other boundary corresponding to \( \partial F_i \) maps to \( R(q_{i,t})R(q'_{i,t}) = h_{i,t} \) (see [Gol09]). Then, by Theorem 5.7, there is a path of \( \mathbb{CP}^1 \)-structures on \( F_i \setminus a_i \) with holonomy \( \zeta_{i,t} \) which converges to its component of \( E \setminus (c \cup a_i) \) as \( t \to \infty \) corresponding to \( F_i \setminus a_i \). As the holonomy along the two boundary components are conjugate, for large enough \( t > 0 \), there is a path of \( \mathbb{CP}^1 \)-structures \( \Sigma_{i,t} \) on \( F_i \) which converges to the component of \( E \setminus c \), so that \( \text{Hol}(\Sigma_{i,t})|\pi_1F_i = \zeta_{i,t} \). In particular, the holonomy of \( \Sigma_{i,t} \) round the puncture is the hyperbolic element \( R(q_{i,t})R(q'_{i,t}) = h_{i,t} \). \( \square \)

Notice that \( H_1 \) and \( H_2 \) are totally geodesic hyperbolic planes in \( \mathbb{H}^3 \) tangent at \( p \). We in addition assume that \( H_1 \) and \( H_2 \) are different and \( H_1^\perp = H_2^\perp =: H \). Pick a geodesic \( q \) in \( H \) initiating from \( p \) contained in the region bounded by the geodesics \( q_1 = H \cap H_1 \) and \( q_2 = H \cap H_2 \).
**Proposition 13.3.** We can choose, the path of the hyperbolic isometries $h_{1,t}, h_{2,t}$ (given by Lemma 13.2) so that their composition $h_{1,t}h_{2,t}$ is eventually a hyperbolic element whose axis is $q$ as $t \to \infty$.

**Proof.** Pick $h_{1,t}$ and $h_{2,t}$ such that their axes converge to the parabolic fixed point $p$. Since $h_{1,t}$ and $h_{2,t}$ converge to $I$, their product $h_{1,t}h_{2,t}$ also converges to $I$ in $\text{PSL}(2, \mathbb{C})$.

For each $i = 1, 2$, let $u_{i,t}$ be the attracting fixed and $v_{i,t}$ be the repelling fixed point of $h_{i,t}$. We may first assume that the endpoints of $\text{Axis}(h_{1,t})$, $\text{Axis}(h_{2,t})$ lie on $\partial H$ in this cyclic order $u_{2,t}, v_{1,t}, v_{2,t}, u_{1,t}$ (Figure 19). The composition $h_{1,t}h_{2,t}$ fixes a point on the arc in $\partial H$ between $v_{1,t}$ and $v_{2,t}$ for each $t > 0$. Note that the segment contains $p$. Then as $\text{Axis}(h_{1,t}), \text{Axis}(h_{2,t})$ converge to the parabolic fixed point $p$, there is a fixed point of $h_{1,t}h_{2,t}$ converging to $p$. Moreover, as $h_{1,t} \to I$, one can continuously adjust the translation length of $h_{2,t}$ so that $h_{1,t}h_{2,t}$ also fixes the other endpoint of $q$ for sufficiently large $t > 0$.

Therefore $h_{1,t}h_{2,t}$ is a hyperbolic element with the axis $q$ as $t \to \infty$. □

Let $h_{1,t}, h_{2,t} \in \text{PSL}(2, \mathbb{C})$ be the paths given by Proposition 13.3. Then, by Lemma 13.2, for each $i = 1, 2$, we have a path of homomorphisms $\varsigma_{i,t} : \pi_1(F_i) \to \text{PSL}(2, \mathbb{C})$ such that $\varsigma_{i,t}(\ell) = h_{i,t}$ for $t \gg 0$. Then there is a unique path $\varsigma : \pi(\tilde{F}) \to \text{PSL}(2, \mathbb{C})$ so that $\varsigma \circ \pi_1(F_i) = \varsigma_{i,t}$ for $i = 1, 2$; thus $\varsigma(\ell_p) = h_{1,t}h_{2,t}$. Then there is a path $D_t$ of $\mathbb{CP}^1$-structures on $F'$ with holonomy $\varsigma_t$ for $t \geq 0$ such that $D_t$ converges to $E'$ as $t \to \infty$.

13.1.1. Constructing a closed surface from punctures surfaces. In order to make a desired example of exotic degeneration, we take two copies $D_t$ of $\mathbb{CP}^1$-surfaces with a single puncture from the previous section, and glue them together with a lot of twists.

**Theorem 13.4.** There is a path of $\mathbb{CP}^1$-structures $C_t = (f_t, \rho_t)$ on a closed surface $S$ of genus four with following properties:

- The conformal structure $X_t$ is pinched along a separating loop $m$; let $F_1$ and $F_2$ be the connected components of $S \setminus m$.
- $\rho_t : \pi_1(S) \to \text{PSL}(2, \mathbb{C})$ converges in the representation variety as $t \to \infty$.
- Pick an element $\gamma \in \pi_1(S)$ whose free homotopy class is $m$. Then $\rho_\infty(\gamma) = I$, and, for all $t > 0$, the holonomy $\rho_t(\gamma)$ is a hyperbolic element such that its axis $a_t$ converges to a geodesic $a_\infty$ in $\mathbb{H}^3$ as $t \to \infty$.
- Let $\tilde{F}_1, \tilde{F}_2$ be the connected components of $\tilde{S} \setminus \phi^{-1}(m)$ which are adjacent across the lift $\tilde{m}$ of $m$ invariant under $\gamma$. Then $C_t|\tilde{F}_1$ converges to the developing map of a $\mathbb{CP}^1$-structure on a genus two surface minus a point such that the puncture maps to an endpoint of $a_\infty$ as $t \to \infty$.
- $f_t|\tilde{F}_2$ converges to the constant map to the other endpoint of $a_\infty$ uniformly on compacts, and $\rho_\infty|\pi_1(F_2)$ is the trivial representation.

**Proof.** Recall that $\ell_p$ be the peripheral loop around $p$. Recall that the holonomy of $E'$ is parabolic, and the holonomy around the puncture of $D_t$ is a hyperbolic element whose axis $a_t$ is converging to a geodesic starting from the parabolic fixed point of $\text{Hol} E'$ to the image of the puncture of $E$ corresponding to $\ell_p$.

For sufficiently large $t > 0$, there is a cusp neighborhood $N_t$ of $D_t$ such that $N_t$ is foliated by admissible loops whose developments are invariant under a one-dimensional subgroup $G_t$ of $\text{PSL}(2, \mathbb{C})$ containing $\xi_t(\ell_p)$. We can assume that $N_t$ changes continuously in $t$ and asymptotically the empty set on $D$ as $t \to \infty$. As $G_t$ is a one-dimensional subgroup $\rho_t(m)$ of $\text{PSL}(2, \mathbb{C})$, integer powers $\rho_t(m)^n$ for $n \in \mathbb{Z}$ continuously extends to real powers.

Let $E'$ be the universal cover of $E'$. Pick any path of compact subsets $K_t$ of the universal cover $\tilde{D}_t$ converges to a compact subset in $E'$. Then there is a continuous function $r_t \in \mathbb{R}$ diverging to $\infty$ such that
ponents so that the amount of twisting is 

\[ \rho_t(m)^t \text{ dev } D_t|K_t \text{ is asymptotically the constant map to the fixed point of } \rho_t(m) \text{ corresponding to the singular point of } \tilde{E}, \]

\[ \rho_t(m)^t \cdot \text{Hol}(D_t) \text{ is asymptotically the trivial representation, as } t \to \infty. \]

Take two copies \( \Sigma_{1,t}, \Sigma_{2,t} \) of \( D_t \setminus N_t \) and glue them together along their boundary components so that the amount of twisting is \( r_t \). Then we obtain a continuous family of the resulting \( \mathbb{C}P^1 \)-structures \( C_t \) on \( S \). By the properties of \( r_t \), we can normalize the developing pair of \( C_t \) so that

\[ C_t|\Sigma_{t,1} \text{ converges to a developing pair of } E', \]

\[ \text{the developing pair of } C_t|\Sigma_{t,2} \text{ converges to a pair of the constant map (uniformly on compacts) and the trivial representation}. \]

Thus we obtained a desired path of \( \mathbb{C}P^1 \)-structures. \( \square \)

13.2. **Elliptic** \( \rho_t(m) \) **converging to the identity.** In this section, we construct an example of \( C_t = \{f, \rho_t\} \) in Theorem [C] such that \( \rho_t(m) \) is an elliptic element for all sufficiently large \( t \geq 0 \) and it converges to \( I \) as \( t \to \infty \).

Given an elliptic element \( e \in \text{PSL}(2, \mathbb{C}) \), normalize the unite disk model \( \mathbb{D}^3 \subset \mathbb{R}^3 \) of \( \mathbb{H}^3 \) centered at the origin, so that \( \text{Axis}(e) \) is contained in the axis of the third coordinate. Let \( \zeta \in (0, 2\pi) \) be the rotation angle of \( e \). Then define \( b_e : \mathbb{R} \to \partial \mathbb{H}^3 \) by \( x \mapsto (\cos(\zeta x) \sin \zeta, \sin(\zeta x) \sin \zeta, \cos \zeta) \) which is equivariant under \( \mathbb{Z} \to \langle e \rangle \).

**Lemma 13.5.** Let \( r \) be a geodesic in \( \mathbb{H}^3 \). Pick a parallel vector field \( V \subset T\mathbb{H}^3 \) along \( r \) such that \( V \) is orthogonal to \( r \). Then there are a path of (nontrivial) elliptic elements \( e_t \in \text{PSL}(2, \mathbb{C}) \) and a continuous function \( \theta_t \in \mathbb{R}_{\geq 0} \) satisfying the following:

\[ e_t \to I \text{ as } t \to \infty. \]

\[ \text{Axis}(e_t) \text{ orthogonally intersects } r, \text{ and } \text{Axis}(e_t) \text{ converges to an endpoint of } r \text{ on } \mathbb{C}P^1 \text{ as } t \to \infty. \]

\[ \text{Letting } \theta_t \in \mathbb{R} \text{ be a continuous function such that the angle between } \text{Axis } e_t \text{ (oriented) and } V \text{ is } \theta_t \text{ mod } 2\pi. \]

\[ \text{Let } u_t = 2\theta_t. \text{ Then the rotation angle of } e_t^{u_t} \text{ is } \pi \text{ for all } t \geq 0 \text{ (so that } e_t^{u_t} \text{ takes } r \text{ to itself with the opposite orientation).} \]

**Proof.** It is easy to construct an example satisfying the first three conditions. Then adjust the rotation angle of \( e_t \) so that it also satisfies the last condition. \( \square \)

**Lemma 13.6.** Let \( e_t \) be as in Lemma [13.5]. Let \( p \) be the endpoint of \( r \) to which \( \text{Axis}(e_t) \) converges. Pick a round disk \( D \) in \( \mathbb{C}P^1 \) containing \( p \) but not the other endpoint of \( r \), so that \( D \setminus \{p\} \) is a \( \mathbb{C}P^1 \)-structure on a punctured disk. Then there is a path \( A_t \) of \( \mathbb{C}P^1 \)-structures on an annulus \( A \) with smooth boundary for sufficiently large \( t \gg 0 \), such that

\[ A_t \text{ converges to } D \setminus \{p\}, \text{ and} \]

\[ \text{letting } \ell_t \text{ be the boundary component of } A_t \text{ converging to } p, \text{ the development of } \ell_t \text{ is equivalent to } b_{e_t}. \]

**Proof.** For sufficiently large \( t > 0 \), one can easily construct the fundamental membrane for \( A_t \) for sufficiently large \( t > 0 \) (Figure 20).
Lemma 13.7. Let $P$ be a pair of pants, and let $\ell$ be a boundary component of $P$. Let $\tilde{\ell}$ be a lift of $\ell$ to the universal cover of $P$. Consider a (flat) Euclidean cylinder with geodesic boundary, and let $P_\infty$ be the surface obtained by removing an interior point $p$ of $P_\infty$. Then regard $P_\infty$ as a $\mathbb{CP}^1$-structure on $P$, and let $(h, \xi)$ be its developing pair, so that $h$ takes $\tilde{\ell}$ to a single point $v$ on $\mathbb{CP}^1$. Let $r$ be a geodesic in $\mathbb{H}^3$ connecting $v$ and the parabolic fixed point of $h$, and let $e_t \in PSL(2, \mathbb{C})$ be a path of (non-trivial) elliptic elements given by Lemma 13.5.

Then there is a path of $\mathbb{CP}^1$-structures $P_t = (h_t, \xi_t)$ on $P$ satisfying the following:

1. For all $t > 0$, $\xi_t(\ell) = e_t$.
2. $P_t$ converges to $P_\infty$ as $t \to \infty$. Let $\gamma_t \in PSL(2, \mathbb{C})$ be a path of hyperbolic elements with the axis $r$, such that $\gamma_t \text{Axis}(e_t)$ converges to a geodesic $g_\infty$ in $\mathbb{H}^3$ orthogonal to $r$ as $t \to \infty$. Let $H$ be the hyperbolic plane orthogonal to $r$ which contains $g_\infty$. Then the modified developing pair $\gamma_t(h_t, \xi_t)$ converges to a developing pair for a disk minus a point, where the removed point is the attracting fixed point $p$ of $\gamma_t$ and the disk is the component of $\mathbb{CP}^1 \setminus \partial H$ containing $p$.
3. Let $\ell_t$ be the boundary component of $P_t$ corresponding to $\ell$. Then dev $P_t$ along a lift of $\ell_t$ is $b_{\ell_t}$ (up to $PSL(2, \mathbb{C})$).
4. Let $\alpha$ be a boundary component of $P$ not equal to $\ell$. Then $\xi_t(\alpha)$ is hyperbolic element for all $t \gg 0$ (converging to a parabolic element as $t \to \infty$).

Proof. First we construct an appropriate path of representations $\xi_t: \pi_1(P) \to PSL(2, \mathbb{C})$. Let $a_t$ denote Axis($e_t$). Pick a pair of geodesics $q_t, q'_t$ in $\mathbb{H}^3$ for each $t > 0$ such that

- $R(q_t)R(q'_t) = e_t$, where $R(q_t), R(q'_t) \in PSL(2, \mathbb{C})$ are the $\pi$-rotations of $\mathbb{H}^3$ about $q_t, q'_t$, respectively.
- $q_t$ and $q'_t$ change continuously in $t > 0$.
- $q_t$ and $q'_t$ intersect at the intersection $a_t \cap r$.
- $q_t$ and $q'_t$ are symmetric about $r$.
- $q_t$ and $q'_t$ are orthogonal to $a_t$, and
- $q_t$ and $q'_t$ converge to $p$ as $t \to \infty$ (see Figure 21).

There is a path of geodesics $h_t(t \geq 0)$ in $\mathbb{H}^3$ such that

- $h_t$ is disjoint from $q_t$ and $q'_t$ for all $t \geq 0$, and
- $h_t$ converges to a geodesic $h$ in $\mathbb{H}^3$ sharing an endpoint with $r$ as $t \to \infty$, such that the composition $R(r)R(h)$ is the parabolic holonomy along a boundary geodesic of $P_\infty$. 

\[\Box\]
Let \( \xi_t : \pi_1(P) \to \text{PSL}(2, \mathbb{C}) \) be such that the holonomy along boundary components are \( R(h_t)R(q_t), R(q_t)R(q_t'), R(q_t')R(h_t) \). Note that \( R(h_t)R(q_t), R(q_t)R(h_t) \) are hyperbolic elements, as the rotation axes are disjoint, and they converge to the parabolic holonomy along the boundary geodesics of \( P_\infty \).

Pick a round disk \( D \) on \( P_\infty \) containing \( p \) such that \( \partial D \) on \( \mathbb{C}P^1 \) bounds a hyperbolic plane in \( \mathbb{H}^3 \) orthogonal to \( r \). Then, apply Lemma \ref{lem:3.6} to \( D \), let \( D_t \) be a path of \( \mathbb{C}P^1 \)-structures on an annulus converging to \( D \setminus \{ p \} \), so that it gives the desired path only near the punctured \( P_\infty \).

Pick a smaller closed regular neighborhood of the puncture \( p \) of \( P_\infty \), so that its complement \( K \) in \( P_\infty \) and the interior of \( D \setminus \{ p \} \) form an open cover of \( P_\infty \). Then \( K \) is topologically a pair of pants. There is a path of \( \mathbb{C}P^1 \)-structures on a pair of pants \( K_t \) for sufficiently large \( t > 0 \) such that \( K_t \) converges to \( K \) and \( e_t \) is the holonomy of \( K_t \) around the boundary component corresponding to \( \ell \).

Then, by gluing \( K_t \) and \( D_t \), we obtained a desired path of \( \mathbb{C}P^1 \)-structures \( P_t \).

\[
\begin{tikzpicture}
  \draw (0,0) circle (1);
  \draw (0,1) -- (1,1); \node at (0.5,1.2) {\( a_t \)};
  \draw (0,-1) -- (1,-1); \node at (0.5,-1.2) {\( b_t \)};
  \draw (0,0) -- (0,1.5); \node at (0,1.8) {\( q_t \)};
  \draw (0,0) -- (0,-1.5); \node at (0,-1.8) {\( q_t' \)};
  \draw (0,0) -- (1,0); \node at (1.2,0) {\( h_t \)};
  \draw (0,0) -- (-1,0); \node at (-1.2,0) {\( h_t' \)};
\end{tikzpicture}
\]

\[\text{Figure 21. Realize } e_t \text{ as the compositions of the } \pi \text{-rotations about } q_t \text{ and } q_t'.\]

**Proposition 13.8.** Let \( P_t = (h_t, \xi_t) \) be a path of \( \mathbb{C}P^1 \)-structures on a pair of pants from Lemma 13.7. Then there is a path \( \Sigma_t \) of \( \mathbb{C}P^1 \)-structures on a closed surface \( F \) minus a point which satisfies the following:

- There is a subsurface \( A \) of \( F \) whose interior contains \( p \), such that \( A \) is homeomorphic to a pair of pants, and \( \Sigma_t|A = P_t \) for large enough \( t > 0 \).
- \( \Sigma_t \) converges to a \( \mathbb{C}P^1 \)-structure \( F_\infty \) on \( F \) as \( t \to \infty \).

**Proof.** First we construct the limit structure \( F_\infty \). Take any complete hyperbolic surface \( \tau \) with a single cusp, such that \( \tau \) is homeomorphic to a closed surface minus a point, denoted by \( F' \). Pick a cusp neighborhood \( N \) of \( \tau \) which is a horoball quotient. The pair of pants \( P_\infty \) has two boundary components and one puncture. As the two boundary components of \( P_\infty \) lift to horocycles, we can glue a copy of \( \tau \setminus N \) along each boundary component of \( P_\infty \). We thus obtained a \( \mathbb{C}P^1 \)-structure on a closed surface with a single puncture so that \( P_\infty \) is its subsurface.

There are paths \( \zeta_{1,t} \) and \( \zeta_{2,t} \) of representations \( \pi_1(\tau) \to \text{PSL}(2, \mathbb{C}) \) which converge to the holonomy of \( \tau \) as \( t \to \infty \), such that their images of the peripheral loop are \( R(r_t)R(q_t') \) and \( R(q_t)R(r_t) \), respectively, which are hyperbolic elements (c.f. \cite{Gol09}). Let \( \tau_{1,t}, \tau_{2,t} \) be paths of \( \mathbb{C}P^1 \)-structures homeomorphic to \( \tau \setminus N \) for \( t \gg 0 \) such that \( \text{Hol}(\tau_{1,t}) = \zeta_{1,t} \), and \( \text{Hol}(\tau_{2,t}) = \zeta_{2,t} \) and \( \tau_{1,t}, \tau_{2,t} \) converge to \( \tau \setminus N \). We may in addition assume that the boundary components of \( \tau_{1,t}, \tau_{2,t} \) are invariant under one-dimensional subgroups of \( \text{PSL}(2, \mathbb{C}) \) containing \( R(r)R(q_t') \) and \( R(q_t)R(r) \), respectively.
Then by gluing \( \tau_{t,1}, \tau_{t,2}, P_t \) along their boundary, we obtain a desired path \( \Sigma_t \) of \( \mathbb{C}P^1 \)-structures.

Let \( \Sigma_t \) be the path of \( \mathbb{C}P^1 \)-structures, obtained from Proposition 13.8 on a compact surface with one boundary component. Let \( R_t \) be the \( \pi \)-rotation of \( \mathbb{H}^3 \) around the axis \( a_t \) of the elliptic \( e_t \). By Lemma 13.7(2, 3), we can glue two copies of \( \Sigma_t \) by the involution \( R_t \), and we obtain a path of \( \mathbb{C}P^1 \)-structures \( C_t \) on a closed surface, so that two copies of \( \Sigma_t \) are embedded in \( C_t \) disjointly up to an isotopy. Let \( \Sigma_t^1 = (h^1_t, \rho^1_t), \Sigma_t^2 = (h^2_t, \rho^2_t) \) are the subsurfaces of \( C_t \) corresponding to \( \Sigma_t \). Then we have, by Lemma 13.5, we have

**Proposition 13.9.** Let \( C_t = (f_t, \rho_t) \) be the path of \( \mathbb{C}P^1 \)-structures as above, and let \( m \) be the loop on \( C_t \) corresponding to the boundary components of \( \Sigma_t^1 \) and \( \Sigma_t^2 \). Let \( N \) be the regular neighborhood of \( m \). Then

1. \( \rho_t(m) \) converges to \( I \) as \( t \to \infty \), and \( \rho_t(m) \) is an elliptic element for all \( t > 0 \);
2. the axis of \( \rho_t(m) \) converges to the point \( p \) of \( \mathbb{C}P^1 \);
3. \( f_t : \tilde{S} \setminus \phi^{-1}(N) \to \mathbb{C}P^1 \) converges to a \( \rho_\infty \)-equivariant continuous map \( f_\infty : \tilde{S} \setminus \phi^{-1}(N) \to \mathbb{C}P^1 \), such that \( f_\infty \) is a local homeomorphism in the interior;
4. for each connected component \( \tilde{N} \) of \( \phi^{-1}(N) \), the boundary components of \( \tilde{N} \) map to the corresponding limit \( p \) of the axis \( a_t \).

**Figure 22.** The rotation of the axis \( a_t \) yields twist.
