Abstract

We present a robust decision support framework with computational algorithms for decision makers in non-cooperative sequential setups. Existing simulation based approaches can be inefficient when there is a large number of feasible decisions and uncertain outcomes. Hence, we provide a novel alternative to solve non-cooperative sequential games based on augmented probability simulation. We propose approaches to approximate subgame perfect equilibria under complete information, assess the robustness of such solutions and, finally, approximate adversarial risk analysis solutions when lacking complete information. This framework could be especially beneficial in application domains such as cybersecurity and counter-terrorism.

Keywords: Sequential decision analysis, Noncooperative games, Augmented probability simulation.
1 Introduction

Non-cooperative game theory refers to conflict situations in which two or more agents make decisions whose payoffs depend on the actions implemented by all of them and, possibly, on some random outcomes. Under complete information about the agents’ preferences and beliefs, the analysis is usually done through Nash equilibria and related methods, which provide a prediction of the agents’ decisions. Heap and Varoufakis (2004) present an in-depth critical assessment. On the other hand, games with incomplete information correspond to cases where the agents do not possess full information about their opponents and are traditionally dealt with Bayes Nash equilibria (BNE) concepts (Harsanyi 1967). Adversarial risk analysis (ARA) is an alternative decision analytic approach (Banks et al. 2015) relaxing the standard common prior hypothesis in BNE (Antos and Pfeffer 2010). It provides prescriptive support to one of the agents based on a subjective expected utility model treating the adversaries’ decisions as uncertainties.

In this paper, our realm will be within algorithmic decision (Rossi and Tsoukias 2009) and game (Nisan et al. 2007) theories, proposing methods to approximate solutions for non-cooperative games with high dimensional decision sets. Simulation based approaches can be utilized for cases where analytical solutions are not available or are computationally expensive. Among those, Monte Carlo (MC) methods are straightforward and widely implemented. However, they can be inefficient when there is a large number of alternatives, as in counter-terrorism and cybersecurity problems which may involve thousands of possible decisions and large uncertainties about the goals and resources of attackers (Zhuang and Bier 2007).
Procedures such as importance sampling that focus on high-probability high-impact events could improve the estimation by decreasing its variance. However, an optimization problem still needs to be solved. As an alternative, Bielza et al. (1999) introduced augmented probability simulation (APS) to approximate optimal solutions in decision analytic problems. APS transforms the problem into a grand simulation in the joint space of both decision and random variables. It constructs an auxiliary augmented distribution (from now on, the augmented distribution) proportional to the product of the utility function and the original distribution, such that the mode of the marginal over the decisions of the augmented distribution coincides with the optimal decision alternative. Thus, simulation from the augmented probability model, allows to perform the estimation and optimization tasks simultaneously.

This paper presents a robust decision support framework with novel APS based computational algorithms for decision makers in non-cooperative sequential games. Sections 2 and 3 provide approaches to approximate sub-game perfect equilibria under complete information, assessing their robustness and, finally, approximate ARA solutions under incomplete information. A computational assessment and the solution of a cybersecurity case study are presented in Sections 4 and 5. The paper concludes with a discussion in Section 6. The code to reproduce the results is available in a GitHub repository (Torres-Barrán and Naveiro 2019). Proofs of propositions, additional results and algorithms relevant in particular settings, as well as details of the cybersecurity case study, are presented in the appendices.
2 Sequential non-cooperative games with complete information

This section focuses on computational methods for finding equilibria in sequential non-cooperative games with complete information. These games have received various names including sequential defend-attack (Brown et al. 2006) and Stackelberg games (Gibbons 1992). As an example, consider a company that must determine the cybersecurity controls to deploy given that a hacker could observe them and launch a distributed denial-of-service (DDoS) attack.

Thus, we assume a Defender \((D, \text{she})\) who chooses her defense \(d \in D\). Then, an Attacker \((A, \text{he})\) chooses his attack \(a \in A\), after having observed \(d\). Both \(D\) and \(A\) are assumed finite, unless noted. Figure 1 shows the corresponding bi-agent influence diagram (Banks et al. 2015). Arc \(D-A\) reflects that the Attacker observes the Defender’s decision. The consequences for both agents depend on the outcome \(\theta \in \Theta\) of the attack. The agents have their own assessment on the outcome probability, respectively \(p_D(\theta | d, a)\) and \(p_A(\theta | d, a)\), dependent on \(d\) and \(a\). The Defender’s utility function \(u_D(d, \theta)\) depends on her chosen defense and the attack result. Similarly, the Attacker’s utility function is \(u_A(a, \theta)\).

If the game is under complete information, the basic game-theoretic solution does not require the Attacker to know the Defender’s probabilities and utilities, as he observes her actions. However, the Defender must know \((u_A, p_A)\), the common knowledge assumption in this case. Then both agents’ expected utilities are computed at node \(\Theta\), \(\psi_A(d, a) = \int u_A(a, \theta) p_A(\theta | d, a) \, d\theta\) and \(\psi_D(d, a) = \int u_D(d, \theta) p_D(\theta | d, a) \, d\theta\). Next, the Attacker’s best re-
response to $D$’s This is used to find the Defender’s optimal action $d^*_{GT} = \arg \max_{d \in D} \psi_D(d, a^*(d))$. The pair $(d^*_{GT}, a^*(d^*_{GT}))$ is a Nash equilibrium and, indeed, a sub-game perfect equilibrium (Heap and Varoufakis 2004).

The solution of such games requires solving a bilevel optimization problem (Bard 1991). These can rarely be solved analytically other than the explicit enumeration applied to simple models. Indeed, even extremely simple instances of bilevel problems have been shown to be NP-hard (Jeroslow 1985). Thus, numerical techniques are required. A variety of methods are available see e.g. Nisan et al. (2007). In particular, several classical and evolutionary approaches have been proposed, as reviewed by Sinha et al. (2018). When the inner problem adheres to certain regularity conditions, it is possible to reduce the bilevel optimization problem to a single level one replacing the inner problem with its Karush-Kuhn-Tucker (KKT) conditions (Gordon and Tibshirani 2012). Then, evolutionary techniques could be used to solve this single-level problem, thus making possible to relax the upper level requirements. As this single-level reduction is not generally feasible, several other
approaches have been proposed, such as nested evolutionary algorithms or metamodeling-based methods. Most of these approaches lack scalability: increasing the number of upper level variables produces an exponential increase on the number of lower level tasks required. However, problems in emerging areas such as cybersecurity and adversarial machine learning (Ríos Insua et al. 2019) may require dealing with high dimensional and/or continuous decision spaces, and, consequently, can hardly be solved using standard methods. Some scalable gradient based solution approaches have been recently introduced (Naveiro and Insua 2019). However, they are restricted to games in which expected utilities can be computed analytically. When this is not the case, MC simulation methods, see e.g. Ponsen et al. (2011) and Johanson et al. (2012) for pointers, could be used as briefly described next.

2.1 Monte Carlo simulation for games

Simulation based methods for sequential games typically approximate expected utilities using MC and, then, optimize with respect to decision alternatives, first to approximate Attacker’s best responses, then to approximate the optimal defense. Algorithm 1 reflects a generic MC based approach to solve non-cooperative games where $Q$ and $P$ are the sample sizes required to respectively approximate the expected utilities $\psi_A(d,a)$ and $\psi_D(d,a)$ to the desired precision, as discussed in B.1. Convergence of the Algorithm 1, detailed in B.1, follows under mild conditions and is based on two applications (for the inner and outer loops within Algorithm 1) of a uniform version of the strong law of large numbers (SLLN) (Jennrich 1969). It shows uniform convergence to the expected utilities as well as to the attacker’s best responses and defender’s optimal decision.
input: $P$, $Q$

for $d \in D$ do

for $a \in A$ do

Generate samples $\theta_1, \ldots, \theta_Q \sim p_A(\theta \mid d, a)$

Compute $\hat{\psi}_A(d, a) = \frac{1}{Q} \sum_i u_A(a, \theta_i)$

Find $a^*(d) = \arg \max_a \hat{\psi}_A(d, a)$

Generate samples $\theta_1, \ldots, \theta_P \sim p_D(\theta \mid d, a^*(d))$

Compute $\hat{\psi}_D(d) = \frac{1}{P} \sum_i u_D(d, \theta_i)$

\[
\hat{d}_{GT} = \arg \max_d \hat{\psi}_D(d)
\]

Algorithm 1: MC approach for non-cooperative sequential games with complete information

From a computational perspective, the algorithm requires generating $|D| \times (|A| \times Q + P)$ samples, where $|\cdot|$ designates the cardinality of the corresponding set, in addition to the cost of the final optimization and $|D|$ inner loop optimizations. When the decision sets are continuous, they need to be discretized to solve the problem to the desired precision, as exemplified in Section 4.2. In the end, MC approaches could turn out to be computationally expensive when dealing with decision dependent uncertainties, as is the case in the games in this study: they require sampling from $p_D(\theta \mid d, a)$ and $p_A(\theta \mid d, a)$ for each possible pair of $d$ and $a$, entailing loops over the decision spaces $D$ and $A$. When these are high dimensional, considering the whole decision space as in MC will typically be inefficient. APS mitigates this issue.

2.2 Augmented probability simulation for games

APS solves for maximization of expected utility by converting the tasks of sequential estimation and optimization into simulation from an augmented distribution in the joint space of decisions and outcomes, not requiring a sep-
arate optimization step. Bielza et al. (1999) introduced it to solve decision analysis problems and Ekin et al. (2014) extended it to solve constrained stochastic optimization models. It can be advantageous in problems with expected utility surfaces that are expensive to estimate rendering the optimization step inefficient. This paper first uses APS to solve sequential games dealing with the Attacker’s and Defender’s decision problems sequentially.

For the Attacker, we introduce an augmented distribution $\pi_A(a, \theta | d)$ over $(a, \theta)$ for a given defender action $d$, defined as proportional to the product of the utility function and the original distribution, $u_A(a, \theta) p_A(\theta | d, a)$. If $u_A(a, \theta)$ is positive and $u_A(a, \theta) p_A(\theta | d, a)$ is integrable, then $\pi_A(a, \theta | d)$ is a well-defined distribution. Simulating from it solves simultaneously for the expectation of the objective function and its optimization since its marginal over actions $a$, given by $\pi_A(a | d) = \int \pi_A(a, \theta | d) d\theta$, is proportional to the Attacker’s expected utility $\psi_A(d, a) = \int u_A(a, \theta) p_A(\theta | d, a) d\theta$. Consequently, the Attacker’s best response given $d$ can be computed as $a^*(d) = \text{mode}[\pi_A(a | d)]$. Using backward induction, and assuming that $u_D(d, \theta)$ is positive and $u_D(d, \theta) p_D(\theta | d, a)$ is integrable, the Defender’s problem is solved sampling from the augmented distribution $\pi_D(d, \theta | a^*(d)) \propto u_D(d, \theta) p_D(\theta | d, a^*(d))$: its marginal $\pi_D(d | a^*(d))$ in $d$ is proportional to the Defender’s expected utility $\psi_D(d, a^*(d))$ and, consequently, $d_{GT}^* = \text{mode}[\pi_D(d | a^*(d))]$. This leads to a solution approach for non-cooperative games that includes the steps of sampling from the augmented distributions, marginalising to the corresponding decision variables and estimating the mode of the marginal sample.

It is generally impossible to sample directly from the augmented distributions. However, Markov chain Monte Carlo (MCMC) methods, e.g. Gamer-
man and Lopes (2006), serve for such purpose. They construct a Markov chain in the space of the target distribution, the augmented distributions in our case, guaranteed to converge in distribution to the target under mild conditions. After convergence is detected, samples from the chain can be used as approximate samples from the target. Various approaches are available to construct the chains. For instance, C.1 discusses Gibbs based algorithms. Here we adopt more versatile Metropolis-Hastings (MH) variants (Chib and Greenberg 1995) as in Algorithm 2. This facilitates sampling approximately from $\pi_D(d, \theta \mid a^*(d))$ (outer APS) to solve the Defender’s problem. Within that, the Attacker’s best response $a^*(d)$ is estimated for any given $d$ using another APS (inner APS) on $\pi_A(a, \theta \mid d)$. Details of the acceptance/rejection step follow. Let $d$ and $\theta$ be the current samples in the MH scheme of the outer APS. Within each iteration, a candidate $\tilde{d}$ for the Defender’s decision is sampled from a proposal generating distribution $g_D(\tilde{d} \mid d)$. We choose this to be symmetric in the sense that it satisfies $g_D(\tilde{d} \mid d) = g_D(d \mid \tilde{d})$. Then, the Attacker’s problem is solved using an inner APS to estimate $a^*(\tilde{d})$. The state $\theta$ is next sampled using $p_D(\theta \mid \tilde{d}, a^*(\tilde{d}))$. The candidate samples are accepted with probability $\pi_D(\tilde{d}, \tilde{\theta} \mid a^*(\tilde{d}))/\pi_D(d, \theta \mid a^*(d))$, which, after simplification, adopts the form $u_D(\tilde{d}, \tilde{\theta})/u_D(d, \theta)$. Algorithm 2 thus defines a Markov chain in $(d, \theta)$ such that $(d^{(N)}, \theta^{(N)}) \xrightarrow{d} \pi_D(d, \theta \mid a^*(d))$ where $\xrightarrow{d}$ represents convergence in distribution. Proposition 1 provides necessary conditions for the convergence of its output to the decision $d^*_{GT}$. Its proof is in Appendix A.

**Proposition 1** If the Attacker’s and Defender’s utility functions are positive; $p_A(\theta \mid d, a), p_D(\theta \mid d, a) > 0 \forall a, \theta; u_A(a, \theta)p_A(\theta \mid d, a)$ and $u_D(d, \theta)p_D(\theta \mid d, a)$ are integrable; $A, D, \Theta$ are either discrete sets or intervals in $\mathbb{R}^n$; and the proposal generating distributions $g_A$ and $g_D$ are symmetric, Algorithm 2 defines
function solve_attacker(M, d, g_A):
    initialize: a^{(0)}
    Draw \( \theta^{(0)} \sim p_A(\theta \mid d, a^{(0)}) \)
    for \( i = 1 \) to \( M \) do  \>
        Propose new attack \( \tilde{a} \sim g_A(\tilde{a} \mid a^{(i-1)}) \).
        Draw \( \hat{\theta} \sim p_A(\theta \mid d, \tilde{a}) \)
        Evaluate acceptance probability \( \alpha = \min \left\{ 1, \frac{u_A(\tilde{a}, \hat{\theta})}{u_A(a^{(i-1)}, \theta^{(i-1)})} \right\} \)
        With probability \( \alpha \) set \( a^{(i)} = \tilde{a}, \theta^{(i)} = \hat{\theta} \). Otherwise, set \( a^{(i)} = a^{(i-1)}, \theta^{(i)} = \theta^{(i-1)} \).
    Discard the first \( K \) samples and estimate mode of rest of draws \( \{a^{(i)}\} \). Record it as \( a^*\).
    return \( a^*\)

input: \( d, M, K, N, R, g_D \) and \( g_A \) symmetric proposal distributions
initialize: \( d^{(0)}, a^*(d^{(0)}) = \text{solve_attacker}(M, d^{(0)}, g_A) \)
    Draw \( \theta^{(0)} \sim p_D(\theta \mid d^{(0)}, a^*(d^{(0))) \)
    for \( i = 1 \) to \( N \) do  \>
        Propose new defense \( \tilde{d} \sim g_D(\tilde{d} \mid d^{(i-1)}) \)
        \( a^*(\tilde{d}) = \text{solve_attacker}(M, \tilde{d}, g_A) \) if not previously computed
        Draw \( \hat{\theta} \sim p_D(\theta \mid \tilde{d}, a^*(\tilde{d})) \).
        Evaluate acceptance probability \( \alpha = \min \left\{ 1, \frac{u_D(\tilde{d}, \hat{\theta})}{u_D(d^{(i-1)}, \theta^{(i-1)})} \right\} \)
        With probability \( \alpha \) set \( d^{(i)} = \tilde{d}, a^*(d^{(i)}) = a^*(\tilde{d}) \) and \( \theta^{(i)} = \hat{\theta} \). Otherwise, set \( d^{(i)} = d^{(i-1)}, \theta^{(i)} = \theta^{(i-1)} \).
    Discard first \( R \) samples and estimate mode of rest of draws \( \{d^{(i)}\} \).
    Record it as \( \hat{d}^*_{GT} \).

Algorithm 2: MH APS for non-cooperative sequential games with complete information.
a Markov Chain with stationary distribution $\pi_D(d, \theta | a^*(d))$, and a consistent mode estimator based on its marginal samples in $d$ converges to $d^*_{GT}$ almost surely.

In practice, as continuous candidate proposal generation $g_D$ and $g_A$ distributions, this paper uses heavy tailed $t$ distributions, centered at the current solutions (Gamerman and Lopes 2006). When facing discrete or ordinal decisions, we display those in a circular list and generate from neighbouring states with equal probability. Practical convergence (for discarding the first $K$ or $R$ samples) may be assessed with various statistics like Brooks-Gelman-Rubin’s (BGR) (Brooks and Roberts 1998). Convergence of the Markov chain is at a geometric rate as a function of the minimum and maximum utility values, as described in D.1. Once the chain is judged to have converged, the initial samples are discarded as burn-in and the remaining simulated values are used as an approximate sample from the distribution of interest. In particular, the marginal draws $d^{(R+1)}, ..., d^{(N)}$ would correspond to an approximate sample from the marginal $\pi_D(d | a^*(d))$. The sample mode must be estimated with a consistent estimator in the sense of Romano (1988), see also the classical work in Parzen (1962) and Grenander (1965).

Computationally, Algorithm 2 removes the loops over both $D$ and $A$. Thus, its complexity does not depend on the dimensions of those decision spaces providing an intrinsic advantage over MC approaches in problems with large or continuous spaces. In particular, Algorithm 2 requires $N \times (2 \times M + 3) + 2M + 2$ samples plus the cost of convergence checks and (at most) $N + 1$ mode approximations.
Example.

We demonstrate the framework with a simple cybersecurity problem. An organization (Defender) has to choose among ten security protocols: $d = 0$ (no extra defensive action); $d = i$ (level $i$ protection protocol with increasing protection), $i = 1, \ldots, 8$; $d = 9$ (a safe but cumbersome protocol). The Attacker has two alternatives: attack ($a = 1$) or not ($a = 0$). Successful (unsuccessful) attacks are denoted with $\theta = 1$ ($\theta = 0$). Clearly, when there is no attack, $\theta = 0$.

Table 1: (a) Def. net costs; (b) Successful attack probs.; (c) Att. net benefits; (d) Beta dist. parameters

**Defender non strategic judgments.** Table 1a presents net costs $c_D$ associated with each decision and outcome, covering a 7M€ business valuation, and 0.05M€ base security cost plus 0.05M€ per each security level increase. When the attack is successful, the defender loses the whole business value.
The probability $p_D(\theta = 1 \mid d, a)$ of successful attack given $d$ and $a$ is in Table 1b (with complementary probabilities for unsuccessful attacks). The Defender is constant risk averse in costs, with utility strategically equivalent to $u_D(c_D) = -\exp(c \times c_D)$ with $c = 0.4$.

**Attacker judgments.** The average attack cost is estimated at 0.03M€. The average benefit (due to market share captured, ransom, etc.) is 2M€. An unsuccessful attack has an extra cost of 0.5M€. Table 1c presents the Attacker’s net benefit $c_A$ associated with each attack and outcome. $D$ thinks that $A$ is constant risk prone over benefits. His utility is strategically equivalent to $u_A(c_A) = \exp(e \times c_A)$, with $e > 0$.

Start with the complete information case. To fix ideas, assume that $p_A(\theta = 1 \mid d, a) = p_D(\theta = 1 \mid d, a)$ (Table 1b) and $e = 1$. MC and APS approximate optimal decisions using Algorithms 1 and 2, respectively. First, Figure 2a represents MC estimates of $A$’s expected utility for each $d$ and $a$. The optimal response $a^*(d)$ for each $d$ is the alternative with maximum expected utility. For example, for $d = 5$, $A$’s optimal decision is to attack;
for $d = 8$, he should not attack. Next, Figure 2b represents the frequencies of marginal samples of $a$ from the augmented distribution $\pi_A(a, \theta | d)$ for each $d$. Its mode coincides with the optimal attack decision. From $d = 0$ (no defense) until 7, the Attacker should attack. With stronger defenses $d = 8$ and $d = 9$, the mode is $a = 0$ and hence an attack is not advised. The Attacker’s best responses $a^*(d)$ for each defense $d$ are thus identical with both approaches.

Armed with $a^*(d)$, the optimal defense is computed again using MC and APS. Figure 3a presents the MC estimation of $\psi_D(d, a^*(d))$ for each $d$. Figure 3b shows sample frequencies from the marginal augmented distribution $\pi_D(d | a^*(d))$. Both methods agree that $d^*_G$ is acquiring level 8 protection, with level 9 a close competitor. It could be argued that finding the exact optimal decision is not that crucial since the expected utilities for protection levels 8 and 9 are very close. Moreover, as the expected utilities of $d = 8$ and $d = 9$ are very close, it is challenging to find the exact optimal decision. APS could be helpful to check that, indeed, $d = 8$ is the optimal decision. To do so, we could sample from a power augmented distribution, see Appendix D.2, more peaked around the mode, as in Appendix E.1. This also
emphasizes another advantage of APS: despite eventual flatness of expected utility, APS provides a method to find the optimal solution with little extra computational cost.

\[ \triangle \]

2.3 Sensitivity analysis for games

The Defender’s judgments, expressed through \((u_D, p_D)\), could be argued to be well assessed, as she is the supported agent in the game. However, as cogently argued in Keeney (2007), our knowledge about \((u_A, p_A)\) may not be that precise as it would require \(A\) to reveal his beliefs and preferences. This is doubtful in domains such as cybersecurity and counter terrorism where information is concealed and hidden to adversaries.

One could conduct a sensitivity analysis to mitigate this issue, considering that \(A\)’s preferences and beliefs are modeled through classes of utilities \(u \in \mathcal{U}_A\) and probabilities \(p \in \mathcal{P}_A\), summarizing the information available to \(D\) possibly obtained from leakage, earlier interactions or informants. The stability of the proposed solution \(d^*_{GT}\) could be assessed by comparing Nash defenses \(d^*_{u,p}\) computed for each pair \((u, p)\). Several criteria have been proposed to assess the stability of solutions in the areas of decision making under uncertainty and sensitivity analysis (Insua 1990) and robust Bayesian analysis (Insua and Ruggeri 2012). Of them, we shall use the regret \(r_{u,p}(d^*_{GT}) = \psi_D(d^*_{GT}, a^*(d^*_{GT})) - \psi_D(d^*_{u,p}, a^*(d^*_{u,p}))\), as it reflects the loss in expected utility for the choice of the proposed \(d^*_{GT}\) instead of \(d^*_{u,p}\) that should have been chosen for the actual judgements; \((u, p) \in \mathcal{U}_A \times \mathcal{P}_A\). Small values of \(r_{u,p}(d^*_{GT})\) would indicate robustness with respect to the Attacker’s utility and probability: any pair \((u, p) \in \mathcal{U}_A \times \mathcal{P}_A\) could be chosen with no significant changes in the attained expected utilities and \(d^*_{GT}\) is thus robust.
Otherwise, the relevance of the proposed Nash defense $d_{GT}^*$ should be criti-
cized and further investigated. Operationally, a threshold on the maximum
acceptable regret would be specified, as sketched in Algorithm 3.

```
input: $d_{GT}^*$, $U_A$, $P_A$, $R$, threshold
for $i = 1$ to $R$ do
    Randomly sample $u$ from $U_A$ and $p$ from $P_A$
    Compute $d_{u,p}^*$ using Algorithm 2
    Compute $r_{u,p}(d_{GT}^*)$
    if $r_{u,p}(d_{GT}^*) > threshold$ then
        Robustness requirements not satisfied
        Stop
    Robustness requirements satisfied.
```

**Algorithm 3:** Robustness assessment of solutions for games with com-
plete information

**Example (cont.)**

We next check the robustness of $d_{GT}^*$ with respect to the utility and probabil-
ity assumptions. The optimal defense is computed for 10,000 perturbations
of $u_A(c_A)$ (sampling $e' \sim \mathcal{U}(0, 2)$ and using $u'_A(c_A) = \exp(e' \times c_A)$) and the
probability $p_A(\theta | d, a = 1)$ of successful attack in case $A$ attacks for each
d (sampling from a Beta distribution with mean equal to the original value
and variance 0.1% of the corresponding mean for each $d$). Figure 4 reflects
the frequency with which each $d$ is found optimal. The proposed $d_{GT}^* = 8$
emerges 25% of the time as optimal. However, it is unstable as inducing
small perturbations in the utilities and probabilities leads to other solutions:
$d = 9$ appears 42% of the time as optimal and $d = 7, 16%$. More importantly,
large variations in optimal expected utilities are observed 33% of the time,
with maximum regret 42.5% of the total optimal expected utility: $d_{GT}^* = 8$
3 Sequential non-cooperative games with incomplete information: ARA

When the game theoretic solution lacks robustness or the complete information assumption does not hold, the problem may be handled as a game with incomplete information. The most common approach in such games is based on the BNE concept. Alternatively, we use a decision analytic approach based on ARA. Rios and Insua (2012) discuss the differences between both concepts in simultaneous games showing that they may lead to different solutions. An interesting feature of ARA is that it mitigates the common prior assumption (Antos and Pfeffer 2010). We describe the relation between both solution concepts in sequential games below.

ARA considers that the Defender actually has uncertainty about $u_A$ and $p_A$. △

This will be addressed next by relaxing the complete information assumption.
Her problem is depicted in Figure 5a as an influence diagram, where $A$’s action appears as an uncertainty. Her expected utility is $\psi_D(d) = \int \psi_D(d, a) p_D(a|d) \, da$ which requires $p_D(a|d)$, her assessment of the probability that the Attacker will choose $a$ after having observed $d$. Then, her optimal decision is $d^*_{ARA} = \arg\max_{d \in D} \psi_D(d)$. Our example will show a solution that does not coincide with a Nash equilibrium.

Figure 5: Influence diagrams for Defender and Attacker problems.

Eliciting $p_D(a|d)$, which has a strategic component, is facilitated by analyzing $A$’s problem from $D$’s perspective, Figure 5b. For that, she would use all information and judgment available about $A$’s utilities and probabilities. However, instead of using point estimates for $u_A$ and $p_A$ to find $A$’s best response $a^*(d)$ given $d$ as in Section 2, her uncertainty about the attacks would derive from her uncertainty about $(u_A, p_A)$ modelled through a distribution $F = (U_A, P_A)$ on the space of utilities and probabilities. Without loss of generality, assume that both $U_A$ and $P_A$ are defined over a common probability space $(\Omega, \mathcal{A}, \mathcal{P})$ with atomic elements $\omega \in \Omega$ (Chung 2001). This induces a distribution over the Attacker’s expected utility $\psi_A(d, a)$, where the ran-
dom expected utility for $A$ would be $\Psi^\omega_{A}(d, a) = \int U^\omega_{A}(a, \theta) P^\omega_{A}(\theta \mid d, a) \, d\theta$. In turn, this induces a random optimal alternative defined through $A^\ast(d)^\omega = \arg \max_{x \in A} \Psi^\omega_{A}(d, x)$. Then, the Defender would find $p_D(a \mid d) = P_F[A^\ast(d) = a] = P(\omega : A^\ast(d)^\omega = a)$ in the discrete case (and, similarly in the continuous one). Observe that $\omega$ and $P$ could be re-interpreted, respectively, as the type and the common prior in Harsanyi’s doctrine. Then, $P^\omega_{A}$ and $U^\omega_{A}$ respectively correspond to $A$’s probability and utility given his type, and $(d^\ast, \{A^\ast(d)^\omega\})$ would constitute a BNE. Thus, in the sequential Defend-Attack game, we can operationally reinterpret the ARA approach in terms of Harsanyi’s, although the underlying principles are different. Computationally, ARA models entail integration and optimization procedures that can be challenging in many cases. Therefore, we explore simulation based methods for ARA.

### 3.1 MC based approach for ARA

MC simulation approximates $p_D(a \mid d)$ for each $d$, drawing $J$ samples $\{(u^i_A, p^i_A)\}_{i=1}^J$ from $F$ and setting $\hat{p}_D(a \mid d) = \frac{\#(A^\ast(d) = a)}{J}$ where $A^\ast(d) = \arg \max_a \int u^i_A(a, \theta) p^i_A(\theta \mid d, a) \, d\theta$. This is then used as an input to the Defender’s expected utility maximization, as reflected in Algorithm 4.

From a computational perspective, it requires generating $|D| \times [J \times (|A| \times Q + 2) + 2P]$ samples where $Q$ and $P$ are the number of samples required to respectively approximate $\int u^i_A(a, \theta) p^i_A(\theta \mid d, a) \, d\theta$ and $\int \int u_D(d, \theta) p_D(\theta \mid d, a) \, d\theta \, da$ to the desired precision. Convergence follows from two applications of a uniform version of the SLLN as reflected in Appendix B.2. In high dimensional cases, and when model uncertainty dominates, methods that automatically focus on high-probability-high impact events could be faster and more robust. Hence, APS to solve ARA is investigated as a
input: \( J, P, Q \)

for \( d \in \mathcal{D} \) do
  for \( i = 1 \) to \( J \) do
    Sample \( u^i_A(a, \theta) \sim U^\omega_A(a, \theta) \), \( p^i_A(\theta | d, a) \sim P^\omega_A(\theta | d, a) \)
    for \( a \in \mathcal{A} \) do
      Generate samples \( \theta_1, \ldots, \theta_Q \sim p^i_A(\theta | d, a) \)
    Approximate \( \hat{\psi}^i_A(d, a) = \frac{1}{Q} \sum_i u^i_A(a, \theta_i) \)
    Find \( a^*_i(d) = \arg \max_a \hat{\psi}^i_A(d, a) \)
    \( \hat{p}_D(a | d) = \frac{1}{J} \sum_{i=1}^J I[a^*_i(d) = a] \)
  for \( d \in \mathcal{D} \) do
  Generate samples \( (\theta_1, a_1), \ldots, (\theta_P, a_P) \sim p_D(\theta | d, a) \hat{p}_D(a | d) \)
  Approximate \( \hat{\psi}_D(d) = \frac{1}{P} \sum u_D(d, \theta_i) \)
  Compute \( \hat{d}^*_\text{ARA} = \arg \max_d \hat{\psi}_D(d) \)

Algorithm 4: MC based approach to solve the ARA problem

3.2 APS for ARA

APS solves the ARA model by constructing augmented distributions for the Attacker’s and Defender’s problems. To solve the Attacker’s decision problem, this study constructs an APS in the state space of the Attacker’s random utilities and probabilities. For a given \( d \), this study builds the random augmented distribution \( \Pi^\omega_A(a, \theta | d) \propto U^\omega_A(a, \theta)P^\omega_A(\theta | d, a) \), whose marginal \( \Pi^\omega_A(a | d) = \int \Pi^\omega_A(a, \theta | d) \, d\theta \) is proportional to the random expected utility \( \Psi^\omega_A(d, a) \). Then, the random optimal attack \( A^*(d)^\omega \) coincides almost surely with the mode of the marginal \( \Pi^\omega_A(a | d) \) of this random augmented distribution. Consequently, by sampling \( u_A(a, \theta) \sim U_A(a, \theta) \) and \( p_A(\theta | d, a) \sim P_A(\theta | d, a) \), one can build \( \pi_A(a, \theta | d) \propto u_A(a, \theta)p_A(\theta | d, a) \), which is a sample from \( \Pi_A(a, \theta | d) \). Then, \( \text{mode}(\pi_A(a | d)) \) is a sample of
$A^*(d)$, whose distribution is $\mathbb{P}_F[A^*(d) = a] = p_D(a \mid d)$. Thus, this study provides a mechanism to sample from $p_D(a \mid d)$.

Next, using backward induction, an augmented distribution for the Defender’s problem is introduced as $\pi_D(d,a,\theta) \propto u_D(d,\theta) p_D(\theta \mid d, a) p_D(a \mid d)$. Its marginal $\pi_D(d) = \int \int \pi_D(d,a,\theta) da d\theta$ is proportional to the expected utility $\psi_D(d)$ and, consequently, $d^*_{\text{ARA}} = \text{mode}(\pi_D(d))$. Thus, one just needs to sample $(d,a,\theta) \sim \pi_D(d,a,\theta)$ and estimate its mode in $d$.

Algorithm 5 summarizes a nested MH based procedure for APS. Let $d$, $a$ and $\theta$ be the current state of the Markov Chain. This study samples a candidate defense $\tilde{d}$ from a proposal generating distribution $g_D(\tilde{d} \mid d)$, a candidate $\tilde{a}$ from $p_A(a \mid \tilde{d})$ using the Attacker’s APS as explained before, and $\tilde{\theta} \sim p_D(\theta \mid \tilde{d}, \tilde{a})$. These samples are accepted with probability $\alpha = \min \left\{ 1, \frac{u_D(\tilde{d},\tilde{\theta})}{u_D(d,\theta)} \right\}$. The stationary distribution of this Markov Chain converges to $\pi_D(d,a,\theta)$ as reflected in Proposition 2, which provides conditions for the convergence of the output of Algorithm 5 to the optimal decision $d^*_{\text{ARA}}$. The Appendix A contains the proof.

**Proposition 2** If $u_D$ and almost all the utilities in the support of $U_A$ are positive; $p_D(\theta \mid d, a)$ and almost all distributions in the support of $P_A(\theta \mid d, a)$ are also positive; the products of utilities and probabilities are integrable; $A$, $D$ and $\Theta$ are either discrete or intervals in $\mathbb{R}^n$; and the proposal generating distributions $g_A$ and $g_D$ are symmetric, Algorithm 5 defines a Markov Chain with stationary distribution $\pi_D(d,\theta,a)$. Moreover, the mode of the marginal samples of $d$ from this Markov chain approximates the solution $d^*_{\text{ARA}}$.

Computationally, Algorithm 5 requires generating $N \times (2M + 5) + 2M + 4$ samples from multivariate distributions in addition to the cost of the convergence checks and mode computations. Again, this algorithm removes the
function sample_attack(d, M, K, g_A, U_A, P_A):
    initialize: a^{(0)}
    Draw u_A(a, θ) ∼ U_A(a, θ)
    Draw p_A(θ | a, d) ∼ P_A^d(θ | d, a)
    Draw θ^{(0)} ∼ P_A(θ | a^{(0)}, d)
    for i = 1 to M do
        Propose new attack ˜a ∼ g_A(˜a | a^{(i-1)})
        Draw ˜θ ∼ p_A(θ | d, ˜a)
        Evaluate acceptance probability α = min \{ 1, \frac{u_A(˜a, ˜θ)}{u_A(a^{(i-1)}, θ^{(i-1)})} \}
        With probability α set a^{(i)} = ˜a, θ^{(i)} = ˜θ. Otherwise, set
        a^{(i)} = a^{(i-1)} and θ^{(i)} = θ^{(i-1)}.
        If convergence, discard first K samples and compute mode a^*(d) of rest of draws \{a^{(i)}\}
    return a^*(d)

input: d, U_A, P_A, M, K, N, R, g_D and g_A symmetric distributions
initialize: d^{(0)} = d
    Draw a^{(0)} ∼ p_A(a | d^{(0)}) using sample_attack(d^{(0)}, M, K, g_A, U_A, P_A)
    Draw θ^{(0)} ∼ p_D(θ | d^{(0)}, a^{(0)})
    for i = 1 to N do
        Propose new defense ˜d ∼ g_D(˜d | d^{(i-1)})
        Draw ˜a ∼ p_A(a | ˜d) using sample_attack(˜d, M, K, g_A, U_A, P_A)
        Draw ˜θ ∼ p_D(θ | ˜d, ˜a)
        Evaluate acceptance probability α = min \{ 1, \frac{u_D(˜d, ˜θ)}{u_D(d^{(i-1)}, θ^{(i-1)})} \}
        With probability α set d^{(i)} = ˜d, a^{(i)} = ˜a and θ^{(i)} = ˜θ. Otherwise, set
        d^{(i)} = d^{(i-1)}, a^{(i)} = a^{(i-1)} and θ^{(i)} = θ^{(i-1)}.
        If convergence, discard first R samples and compute mode ˜d^*_{ARA} of rest of draws \{d^{(i)}\}

Algorithm 5: MH APS to approximate ARA solution in the sequential game.
need for loops over $A$ and $D$. This would be an excellent choice when facing a problem where the cardinality of these spaces is large or the decisions are continuous. Note though that, in the discrete case, an alternative could be to combine MC and APS. If the cardinality of the $D$ is low, it could be more convenient to estimate the value of $p_D(a \mid d)$ for each $d$, drawing $J$ samples $a \sim p_D(a \mid d)$ and counting frequencies as in Section 3.1. Then, in the Defender’s APS, instead of invoking the attacker’s one each time we need a sample $a \sim p_D(a \mid d)$, we would directly sample from the estimate $\hat{p}_D(a \mid d)$. Finally, Appendix C.2 provides a Gibbs based algorithm.

**Example (Cont.)**

Complete information is no longer available. $D$’s beliefs over $A$’s judgements are described through $P_A$ and $U_A$. Assume $A$’s random probability of success is modeled as $P_A(\theta = 1 \mid d, a = 1) \sim Beta(\alpha_d, \beta_d)$ with parameters $\alpha_d$ and $\beta_d$ in Table 1d (their expected values are equal to $p_D(\theta = 1 \mid d, a)$ from Table 1b). In addition, $A$’s risk coefficient $e$ is uncertain, with $e \sim U(0, 2)$, inducing the random utility $U_A(c_A)$.

![Figure 6](image_url)

(a) MC estimation of $p_D(a \mid d)$  
(b) APS estimation of $p_D(a \mid d)$

Figure 6: Estimation of $p_D(a \mid d)$ through ARA
In this case, for APS, as the cardinality of $D$ is small, one can estimate the value of $p_D(a \mid d)$ for each $d$. Figure 6 presents the estimates $\hat{p}_D(a \mid d)$, obtained using MC and APS. They coincide up to numerical errors. Next, the ARA solution for the Defender is computed. Figure 7a shows the MC estimation of the Defender’s expected utility; Figure 7b presents the frequency of samples from the marginal $\pi_D(d)$. Its mode coincides with the optimal defense, $d^*_{ARA} = 9$, in agreement with the MC solution. The ARA decision does not correspond to the Nash equilibrium $d^*_{GT}$ since its informational assumptions are different. In this case, it appears to be more conservative, as it suggests a safer but more expensive defense. In Appendix E.2, we repeat the experiment dividing the $\alpha_d$ and $\beta_d$ values by 100 in Table 1d, thus inducing more uncertainty about the attacker’s probabilities. The ARA solution ($d^*_{ARA} = 9$) remains stable despite these changes.

3.3 Sensitivity analysis of the ARA solution

The ARA approach leads to a decision analysis problem with the peculiarity of including a sampling procedure to forecast $A$’s actions. A sensitivity analy-
sis should be conducted with respect to its inputs \((u_D(d, \theta), p_D(\theta|d, a), p_D(a|d))\). However, focus should be on \(p_D(a \mid d)\), the most contentious element as it comes from adversarial calculations based on the random utility \(U_A(a, \theta)\) and probability distribution \(P_A(\theta \mid d, a)\). We would proceed similarly to Section 2.3 evaluating the impact of the imprecision on \(U\) and \(P\) over the attained expected utility \(\psi(d^*_\text{UPA})\) using classes \(\mathcal{U}_A, \mathcal{P}_A\) of random utilities and probabilities, and for each pair \((U, P)\) from such classes, \(p^*_{UP}(a \mid d)\) would be obtained to compute \(d^*_\text{UPA}\), estimating then the maximum regret.

4 Computational assessment

This section discusses computational complexity results of the proposed algorithms.

4.1 Computational complexity

Table 2 summarizes the computational complexity of MC and APS for solving games with complete and incomplete information compiled from earlier sections. Recall that parameters \(P, Q, N\) and \(M\) would typically depend on the desired precision, as outlined in EC.1.1.

<table>

Table 2: Required sample sizes by MC and APS algorithms for games with complete and incomplete information

With continuous decision variables, the decision space is discretized to
approximate the MC solution, as will be done in Section 4.2. This discretization step impacts the precision of the solution and the cardinalities of $D$ and $A$ which, in turn, affect complexity. The main lesson from Table 2 is that the number of MC samples depends on the cardinality of the Defender’s and Attacker’s decision spaces, whereas this dependence is not present in APS. Thus, this approach would be expected to be more efficient than MC for problems with large decision spaces as is illustrated next.

### 4.2 A computational comparison

A simple game with continuous decision spaces is used to compare the scalability of both methods. Each agent makes a decision $d, a \in [0, 1]$ about the proportion of resources respectively invested to defend and attack a server with value $s$. Let $\theta$ designate the proportion of losses for the defender under a successful attack. It is modeled with a Beta distribution with parameters $\alpha(d, a)$ and $\beta(d, a)$, with $\alpha$ ($\beta$) increasing in $a$ ($d$) and decreasing in $d$ ($a$).

$D$’s payoff function is $f(d, \theta) = (1 - \theta) \times s - c \times d$, where $c$ denotes her unit resource cost. She is constant risk averse with utility strategically equivalent to $1 - \exp(-h \times f(d, \theta))$, $h > 0$. $A$’s payoff is $g(a, \theta) = \theta \times s - e \times a$, where $e$ denotes $A$’s unit resource cost. He is constant risk prone with utility strategically equivalent to $\exp(-k \times g(a, \theta))$, $k > 0$.

Figure 8 provides the MC estimates of $D$’s expected utility, which is arguably flat. To increase efficiency of the APS algorithm in finding the mode, we replace the marginal augmented distribution $\pi_D(d \mid a^*(d))$ by its power transformation $\pi_D^H(d \mid a^*(d))$, where $H$ is defined as the augmentation parameter, to make the distribution more peaked around the mode (Müller 2005), see Aktekin and Ekin (2016) and Ekin (2018) for applications. As we shall
see, this provides another advantage of APS over MC, by improving the efficiency of direct MC sampling from flat regions. EC.3.2 present details and sketches a convergence proof for this approach. Sampling from $\pi_H^D(d | a^*(d))$ can be easily done using Algorithm 2 but drawing $H$ copies of $\tilde{\theta}$ instead of just one (Müller et al. 2004). The acceptance probability for $D$’s problem at a given iteration $i$, would be now $\min \left\{ 1, \prod_{t=1}^{H} \frac{u_D(d_t, \tilde{\theta}_t)}{u_D(d_{(i-1)}, \theta_{(i-1)})} \right\}$, as shown in Appendix D.2. A’s problem includes a similar augmentation. The augmentation parameters for A and D are referred to as inner and outer powers, respectively.

![Defender's expected utility surface](image)

**Figure 8: Defender’s expected utility surface**

We therefore investigate the trade-off between precision and required sample size finding a limit precision such that MC (APS) is faster for smaller (bigger) precision. The minimum number of required MC and APS samples for optimality and the time to achieve an optimal decision with a given precision are computed for both A and D problems, respectively designated as inner and outer samples. APS also includes choosing the minimum inner and outer powers for which chains are judged to have converged. For a fair comparison, this study conducts several parallel replications of MC and APS with an increasing number of samples until 90% of the solutions coincide
with the optimal decision (computed with MC for a large number of samples) and the algorithm is declared to have reached the desired precision for such number of iterations.

Table 3: Computational time, minimum number of required MC and APS samples and augmentation parameters at optimality for different precisions.

Table 3 presents MC and APS performance, in terms of computational times, for precisions 0.1 and 0.01, computed using a server node with 16 cores Intel(R) Xeon(R) CPU E5-2640 v3 @ 2.60GHz. For instance, with precision 0.1, we discretise $\mathcal{D}$ through $d = \{0, 0.1, 0.2, ..., 1\} \in \mathcal{D}$, and the cardinality of the decision spaces is small, $|\mathcal{D}| = |\mathcal{A}| = 11$. Computational runs show the need for only 1,000 and 100 MC samples to reach optimality with the required precision to solve $D$ and $A$ problems, respectively: MC outperforms APS. However, the performance of MC diminishes for higher precision. For instance, for 0.01, $|\mathcal{D}| = |\mathcal{A}| = 101$ and MC becomes more demanding: APS outperforms MC, as we get rid of the dependence on $|\mathcal{D}|$ and $|\mathcal{A}|$. Indeed, for MC, there is a factor of 200 between the time needed to obtain the solutions with precision 0.01 and 0.1. For APS, this factor is just 10, suggesting that it scales much better with precision. For smaller precision, such as 0.001, we could not even get a stable solution using MC even with a large number of samples ($P = 10M, Q = 100k$). Finally, observe that as the expected utility
is flat around the optimal decision, see Figure 8, MC requires a higher number of samples to converge to the optimal solution than the peaked version of APS. To sum up, in problems with large or continuous decision spaces and/or flat expected utilities, APS would be preferred over MC for its scalability.

## 5 A cybersecurity application

We illustrate the proposed framework by solving a real cybersecurity problem. Figure 9 presents the influence diagram, which simplifies the case study in Rios Insua et al. (2019) by retaining only the adversarial cyber threat. An organisation (Defender) faces a competitor (Attacker) that may attempt a DDoS to undermine the Defender site’s availability and compromise her customer services.

![Bi-agent influence diagram of the cybersecurity application.](image)

The Defender has to determine which security controls to implement: she
has to decide about the level of subscription to a monthly cloud-based DDoS protection system, with choices including 0 (not subscribing), 5, 10, 15, \ldots, 190, and 195 gbps. The Attacker must decide on the intensity of his DDoS attack, viewed as the number of days (from 0 to 30) that he will attempt to launch it. The duration of the DDoS may impact the Defender’s market share, due to reputational loss. The Attacker gains all market share lost by \( D \), which determines his earnings. However, he runs the risk of being detected with significant costs. Both agents aim at maximizing expected utility. Details on the required models at various nodes are presented in Appendix F, further explanations can be found at Rios Insúa et al. (2019) and our GitHub site (Torres-Barrán and Naveiro 2019).

This is a problem with incomplete information and large decision spaces. We compute the ARA solution using APS. First, we estimate the probabilities \( p_D(a \mid d) \) for each defense \( d \). As in Section 4.2, we replace \( A \)’s marginal augmented distribution \( \pi_A \) by its power transformation \( \pi_A^H \) to increase APS efficiency in finding the mode. In addition, as in simulated annealing, within each APS iteration we increase \( H \) using an appropriate cooling schedule (Müller et al. 2004), see Appendix D.2 for details. Figure 10a displays \( p_D(a \mid d) \) for four possible defenses (0, 5, 10, 15). When no defensive action is adopted \( (d = 0) \), \( D \) is convinced that \( A \) will launch the worst DDoS attack (30 days). Subscribing to a low protection plan \( (d = 5) \) makes little practical difference. However, when increasing the protection to 10 gbps, the attack forecast (from \( D \)’s perspective) becomes a mixture of high and low intensity values. The reason for this is that, when \( d = 10 \), small perturbations in the Defender’s assumptions about the Attacker’s elements, induce big changes in the optimal attack. Finally, a 15 gbps protection convinces \( D \) that she will
avoid the attack, attaining a deterrence effect. The optimal solution remains
the same for \( d > 15 \), and therefore results are not displayed.

![Figure 10](image.png)

(a) Attack intensity for each decision

(b) APS solution of the Defender problem

Figure 10: ARA solution computed using APS

Figure 10b shows a histogram of the APS samples for the \( D \)’s decision. As expected, the frequency of samples with value 15 is similar to the ones with higher values. As the histogram, and consequently the expected utility surface, is very flat, we cannot resolve the mode. Thus, as we did in \( A \)’s problem, we sample from increasing \( H \) powers of \( D \)’s marginal augmented distribution. As illustrated in Figure 11, increasing \( H \) makes the distribution more peaked around the optimal decision \( d^{*}_{\text{ARA}} = 15 \), the cheapest plan that avoids the attack from \( D \)’s perspective.

One can argue that finding the exact optimal decision may not be that crucial since the expected utilities for different protections are close. That is a valid point. However, the flat expected optimal utility region might be too big. By sampling from a power transformation of the marginal augmented distribution, APS permits finding the optimal solution even when facing such flat expected utilities at little extra computational cost. Moreover, we can
emphasize another advantage of APS: it provides the distribution $\pi_D(d|a^*(d))$ as part of the solution, providing sensitivity analysis at no extra cost. The decision maker may want to take such sensitivity of the optimal decision into account, and could consider a defense which could be practically more robust.

![APS solutions for different augmentation parameter values](image)

Figure 11: APS solutions for different augmentation parameter values

6 Discussion

We have considered the problem of supporting a decision maker against adversaries in an environment with random consequences depending on the actions of all participants. The proposed procedure is summarized as follows. Under complete information, we compute the game-theoretic solution and conduct a sensitivity analysis. If stable, such solution may be used with confidence and no further analysis is required. Otherwise, or if complete information is lacking, we relax the above assumption and use ARA as an alternative decision analytic approach. If the ARA solution is stable, one may use it with confidence and stop the analysis. Otherwise, one must
gather more data and refine relevant probability and utility classes, eventually declaring the robustness of the ARA solution. If not sufficient, one could undertake a minimum regret (or other robust) analysis.

We have provided MC and APS methods to solve for these games. With large decision spaces, APS would be more efficient as its complexity does not depend on decision sets’ cardinality. It should be also noted that MC errors associated with approximating the expected utility could overwhelm the calculation of the optimal decision. Samples from \( p(\theta | d, a) \) will typically need to be recomputed for each pair \((d, a)\). In contrast, APS performs the expectation and optimization simultaneously, sampling \( d \) from regions with high utility with draws of \( \theta \) from the utility-tilted augmented distribution. This reduces MC error as optimization effort in parts of the parameter space with low utility values is limited, resulting in reduced sample sizes for the same precision. In problems with continuous decision sets, an extension of the proposed approaches could use MC to limit the area of the decision space where the optimum is located, and then switching to APS to search within that area in more detail. Exploiting gradient information of the utility functions (Naveiro and Insua 2019) could also be useful. Apart from computational issues, when the expected utility surface is flat, MC simulation may need many draws or result in poor estimates, being also inefficient for random variables with skewed distributions. APS could handle those cases better as it is based on sampling from the optimizing portions of the decision space. Moreover, APS could sample from a power transformation of the marginal augmented distribution, which is less flat and more peaked around the mode. Finally, in addition to sequential two stage games, these ideas could be extended to other game types such as simultaneous defend-attack games (Rios and Insua
2012) and general bi-agent influence diagrams (González-Ortega et al. 2019).

A Proofs of Propositions

Proposition 1: Under the hypothesis, for each $d$, $\pi_A(a, \theta \mid d)$ is a well-defined distribution and the samples generated within the inner APS loop in Algorithm 2 define a Markov chain with $\pi_A(a, \theta \mid d)$ as stationary distribution (Gamerman and Lopes 2006). Once convergence is detected (at iteration $K$), the remaining $M - K$ marginal samples $a^{(i)}$ of the Markov chain are approximate samples from $\pi_A(a \mid d)$. For large enough $M - K$, a consistent sample mode estimator (in the sense of Romano (1988)) converges almost surely to $a^*(d)$. Similarly, under the hypothesis, $\pi_D(d, \theta \mid a^*(d))$ is a well-defined distribution and the samples generated in the outer APS loop in Al-
Algorithm 2 define a Markov chain with stationary distribution $\pi_D(d, \theta | a^*(d))$. Once MCMC convergence is detected (at iteration $R$), the remaining $N - R$ marginal samples $d^{(i)}$ of the Markov chain are approximate samples from $\pi_D(d | a^*(d))$. Hence, their sample mode estimator converges to $d^*_{\text{GT}}$ almost surely (Romano 1988).

**Proposition 2:** Given our hypothesis about $U_A(a, \theta)$ and $P_A(\theta | d, a)$ for each $d$, the distributions $\pi_A(a, \theta | d) \propto \Pi_A(a, \theta | d)$ given by $\pi_A(a, \theta | d) \propto u_A(a, \theta)p_A(\theta | d, a)$ with $u_A \sim U_A$ and $p_A \sim P_A$, are well defined a.s. Moreover, the samples $a$ generated through **sample_attack** in Algorithm 5 are distributed according to $P_F[A^*(d) = a] = p_D(a | d)$. Indeed, as we are sampling $u_A(a, \theta) \sim U_A(a, \theta)$ and $p_A(\theta | d, a) \sim P_A(\theta | d, a)$; $\pi_A(a, \theta | d) \propto u_A(a, \theta)p_A(\theta | d, a)$, is a sample from $\Pi_A(a, \theta | d)$. Then, mode($\pi_A(a | d)$) is a sample from $A^*(d)^\omega$, whose distribution is $P_F[A^*(d) = a]$. To compute this mode, we sample $a, \theta \sim \pi_A(a, \theta | d)$ using MH, defining a Markov chain $\{a^{(i)}, \theta^{(i)}; i = 1, ..., M\}$ (loop in function **sample_attack**) whose stationary distribution is $\pi_A(a, \theta | d)$, (Roberts and Smith 1994). Once MCMC convergence is assessed, the first $K$ samples of $a$ are discarded as burn-in samples and the remaining $M - K$ marginal samples are approximate samples from $\pi_A(a | d)$. For large enough $M - K$, the mode of such marginal samples approximates the mode of $\pi_A(a, \theta | d)$, based on a consistent mode estimator (Romano 1988).

Next, as $u_D$ is positive and $u_D(d, \theta)p_D(\theta | d, a)p_D(a | d)$ integrable, $\pi_D(d, a, \theta)$ is well-defined and is the stationary distribution of the Markov chain defined by the outer APS in Algorithm 5. Once MCMC convergence is detected, the first $R$ samples of $d$ are discarded as burn-in and the remaining $N - R$ samples are approximately distributed as $\pi_D(d)$. Hence, a consistent mode
estimation of these samples approximates $d^*_\text{ARA}$.

B Proofs of Monte Carlo based approaches

We briefly present convergence of MC approximations in Algorithms 1 and 4.

B.1 Algorithm 1. Subgame perfect equilibria

Suppose that $A$ is a compact set in an Euclidean space; $\Theta$ is an Euclidean space; $u_A(a, \theta)$ is continuous in $a$ for each $\theta$ and measurable in $\theta$ for each $a$; there exists a function $h(\theta)$, integrable with respect to $p_A(\theta|d, a)$, such that $|u_A(a, \theta)| \leq h(\theta)$. Then, for almost all sequences $\{\theta_i\}$ forming a sample from $p_A(\theta|d, a)$, $\hat{\psi}_A(d, a) = \frac{1}{Q} \sum_{i=1}^{Q} u_A(a, \theta_i) \rightarrow \psi_A(d, a)$ when $Q \rightarrow \infty$ uniformly in $a$, as in Thm.2 in Jennrich (1969). Then, assuming that the best response $a^*(d)$ is unique, we can prove that $\arg \max_a \hat{\psi}_A(d, a)$ converges almost surely to $a^*(d)$ as $Q \rightarrow \infty$, with arguments similar to Thm.1 in Shao (1989).

Next, under similar conditions for $u_D(d, \theta)$, $p_D(\theta|d, a)$ and $D$, we have the almost sure uniform convergence of the Monte Carlo averages $\hat{\psi}_D(d) = \frac{1}{P} \sum_{i=1}^{P} u_D(d, \theta_i)$ to the expected utilities $\psi_D(d)$ as $P \rightarrow \infty$ and, therefore, the almost sure convergence of $\arg \max_d \hat{\psi}_D(d)$ to $d^*_{\text{GT}}$.

Several relevant comments are:

- When $A$ and $D$ are finite, the same argument applies.

- When $a^*(d)$ is not unique, corresponding to a case of alternative optima, convergence to the optima may not hold (although it would hold for the maximal expected utilities), but we may disentangle several convergent
subsequences to alternative best responses in case the set of alternative optima is finite. Then, the argument would hold for the inner loop. And similarly, for the outer loop. Note that with an infinite set of alternative optima we could have extreme cases, although we would estimate correctly the optimal expected utilities.

- The uniform convergence condition facilitates the use of regression metamodels (Chen et al. 2013) allowing to replace expected utilities in just a few values of $a$ or $d$ and then optimizing the metamodel as an alternative computational approach.

- Recall that $P$ and $Q$ are essentially dictated by the required precision. Based on the Central Limit Theorem (Chung 2001), MC sums approximate integrals with probabilistic bounds of the order $\sqrt{\frac{\text{var}}{N}}$ where $N$ is the MC sum size. To obtain a variance estimate, we run a few iterations and estimate the variance, then choosing the required size based on such bounds. In our case, in which there are multiple integrals to approximate associated to the various $a$ and/or $d$, we would run a few MC iterations at several $a$ or $d$ values and use the maximum variance to estimate the required MC simulation sizes $Q$ and $P$.

### B.2 Algorithm 4. ARA solutions

Convergence follows a similar path to B.1. Suppose that, almost surely, $U_{\omega A}(a, \theta)$ is continuous in $a$ for each $\theta$ and measurable in $\theta$; there is $h(\theta)$ integrable such that for each $a$ and $|U_{\omega A}(a, \theta)| \leq h(\theta)$; and $A$ is compact. Then, with the same argument $\arg \max_{a} \hat{\Psi}_{\omega A}(a, d)$ converges almost surely to $A^*(d)$. Next, by construction $p_{D}(a \mid d) = P(A^*(d) = a)$. Using the SLLN
\( \hat{p}_D(a \mid d) \) converges almost surely to \( p_D(a \mid d) \). The rest of the approximation follows by another application of a uniform version of the SLLN.

## C  Gibbs sampling based APS methods

Our core algorithms, Algorithms 2 and 5 are of the MH type. This section covers Gibbs sampler based APS versions. Gibbs sampling (GS) (Roberts and Smith 1994) can be utilized in cases where samples from full conditional distributions are available. This typically requires a more substantial preliminary analysis than MH, but tends to converge faster (when full conditionals are available). They iteratively sample from the conditional distributions resulting in samples from the joint distribution in the limit under mild conditions (Casella and George 1992).

### C.1 Subgame perfect equilibria

Based on the analysis in Section 2.2, Algorithm 6 summarizes a GS procedure. For each \( d \), the Attacker’s APS samples iteratively from \( \pi_A(a \mid \theta, d) \) and \( \pi_A(\theta \mid d, a) \), whereas the Defender’s APS samples iteratively from \( \pi_D(d \mid \theta, a^*(d)) \) and \( \pi_D(\theta \mid d, a^*(d)) \). Convergence of Algorithm 6 follows from arguments similar to Proposition 1. It requires \( 2 \times (|\mathcal{D}| \times M + N) \) samples plus the cost of convergence checks and \( |\mathcal{D}| + 1 \) mode approximations. The computational complexity of Algorithm 6 does not depend on the dimension of \( \mathcal{A} \), which could be crucial when \( |\mathcal{A}| \) is very large or \( \mathcal{A} \) is continuous.
**Algorithm 6:** Gibbs based APS to solve a game with complete information.

**C.2 ARA for incomplete information games**

Similarly, we consider a Gibbs sampler based APS approach for the ARA model in incomplete information games as an alternative to Algorithm 5.

The convergence of the Algorithm 7 follows similarly as from Proposition 2.

**D Further convergence results**

We present results referring to the convergence rate of the MCMC algorithms and the convergence of APS with several copies to peak the mode.
Algorithm 7: Gibbs based APS approach to solve the ARA problem

D.1 Convergence rate of MCMC for games with complete information

The geometric convergence rate of MCMC algorithms is widely studied in the Bayesian computation literature including Roberts and Polson (1994), Roberts and Tweedie (1996) and Mengersen and Tweedie (1996).

In our setup, for games with complete information, we define a discrete Markov chain in \((d, \theta)\) with target stationary distribution \(\pi_D(d, \theta | a^*(d))\). For the following discussion, assume \((d, \theta)\) to be finite. The transition probabilities are defined \(P_{ij}(n) = P(d_{n+1} = d', \theta_{n+1} = \theta' \mid d_n = d, \theta_n = \theta)\), on the space \((d, \theta)\) for \(i = (d, \theta)\) and \(j = (d', \theta')\) with stationary distribution \(\pi^*(d, \theta)\).

Suppose there exists a constant \(0 < a < \infty\) such that the proposal density satisfies \(p(d' \mid d) \geq a\) so that the chain is irreducible. This allows us to obtain
a bound on the transition kernel of the Markov chain related to the ergodicity coefficient \( \tau[P(n)] = 1 - \inf_{i,j} \sum_{m=1}^{n} \inf(P_{il}(n), P_{jl}(n)) \). The convergence rate of the samples from a Markov chain to the limiting distribution (target density) is characterized by \( \delta[P(n)] = 1 - \tau[P(n)] \), referred to as the delta coefficient of \( P(n) \) (Isaacson and Madsen 1976).

For a constant \( b \) such that \( 0 \leq b < \infty \), bounds are established, \( P_{ij}(n) \geq a \exp\{-b\} \), that results in geometric convergence with a rate characterized by \( \delta[P(n)] \). Assuming a bounded Defender utility function such that \( u_0 \leq u_D(d, \theta) \leq u_1 \), and setting \( b = \log(u_1/u_0 \epsilon) \) where \( \epsilon \) is an infinitesimal value; we have \( P_{ij}(n) \geq a(u_0 \epsilon/u_1) = a \exp\{-b\} \), which results in an irreducible and aperiodic Markov chain.

Overall, MCMC sampling can result in fast convergence such as geometric convergence in many cases and polynomial time in some cases in contrast to standard central limit theorem type convergence of MC estimation, as also detailed in Jacquier et al. (2007).

### D.2 Sampling from a power transformation of the marginal augmented distribution

One possibility to increase efficiency of APS in finding the mode (especially for the case of flat expected utility surfaces) is to sample from a power transformation of the marginal augmented distribution rather than sampling from the original distribution. Next, we provide a demonstration of such sampling and its convergence guarantees. For the sake of illustration, we just deal with the Attacker’s problem for a given defense \( d \).

Assume we are interested in maximizing the Attacker’s expected utility for
a given defense \(d\), \(\psi_A(a, \theta) = \int u_A(a, \theta)p_A(\theta|d, a)\ d\theta\). We define an augmented distribution \(\pi_H(a, \cdot)\) such that its marginal distribution in \(a\) is proportional to \(\psi_A^H(a, \theta)\), with \(H \geq 1\) defined as the augmentation parameter. Now, \(\psi_A^H(a, \theta)\) is more peaked around the optimal attack and, consequently the marginal on \(a\) of \(\pi_H(a, \cdot)\) will be more peaked around such mode, thus facilitating its identification. Let us define this augmented distribution creating \(H\) identical copies of the state \(\theta\) and using \(\pi_H(a, \theta_1, \ldots, \theta_H|d) \propto \prod_{i=1}^H u_A(a, \theta_i)p_A(\theta_i|d, a)\). Its marginal in \(a\) is \(\pi_H(a|d) \propto \left[\int u_A(a, \theta)p_A(\theta|d, a)\ d\theta\right]^H = \psi_A^H(a, \theta)\) as requested. Samples from this marginal will cluster tightly around the mode as \(H\) increases, since this distribution will be more peaked. To get those samples, for a given value of \(H\), we sample from \(\pi_H(a, \theta_1, \ldots, \theta_H|d)\) and just keep the samples of \(a\), using the following MH scheme: suppose the current state of the Markov chain is \((a, \theta_1, \ldots, \theta_H)\); generate a candidate \(\tilde{a}\) from a symmetric proposal \(g_A(\cdot|a)\), and propose \(\tilde{\theta}_i \sim p_A(\theta|d, \tilde{a})\) for \(i = 1, \ldots, H\); accept \(\tilde{a}, \tilde{\theta}_1, \ldots, \tilde{\theta}_H\) with probability

\[
\min \left\{ 1, \prod_{i=1}^H \frac{u_A(\tilde{a}, \tilde{\theta}_i)}{u_A(a, \theta_i)} \right\},
\]

(1) otherwise, maintain the current \((a, \theta_1, \ldots, \theta_H)\). This defines a Markov chain with stationary distribution \(\pi_H(a, \theta_1, \ldots, \theta_H|d)\) (Tierney 1994). Indeed, the acceptance probability of a Metropolis-Hastings scheme for a target distribution \(\pi_H(a, \theta_1, \ldots, \theta_H|d)\) with proposal distribution \(q(\tilde{a}, \tilde{\theta}_1, \ldots, \tilde{\theta}_H|a, \theta_1, \ldots, \theta_H) =

46
Thus, samples from $\pi_H(a, \theta_1, \ldots, \theta_H|d)$ can be generated running this MH scheme for a certain number of iterations, and discarding the initial ones as burn-in samples.

Direct application of this approach might not be feasible when the decision sets are high dimensional, as mode identification becomes more challenging. Müller et al. (2004) offer a solution for this issue that consists of embedding the previous MH scheme within an annealing schedule. Thus, within each APS iteration we increase $H$ using an appropriate cooling schedule. This produces an inhomogeneous Markov chain that converges to the mode of $\pi_H(a|d)$ (the optimal attack). A proof could be found in Müller et al. (2004).

E Illustrative examples

We provide further insights about our illustrative examples that are presented in Sections 2.2 and 3.2.
E.1 Checking the optimal solution

As can be seen in Figure 3 from Section 2.2, while $d = 8$ is declared optimal, the expected utilities of decisions 8 and 9 are very close. APS is useful in checking that, indeed, $d^*_{GT} = 8$. Something similar happens with the ARA solution in Figure 7.

We repeat both experiments using APS but, as in Section 5, replacing the defender’s marginal augmented distribution $\pi_D$ by its power transformation $\pi^H_D$, which is more peaked around the mode. In addition, as in simulated annealing, within each APS iteration we increase $H$ using an appropriate cooling schedule (Müller et al. 2004). Figure 12 displays the results showing that, indeed, the game-theoretic solution under complete information is $d^*_{GT} = 8$, while ARA would recommend $d^*_{ARA} = 9$.

![Graph](image1.png)

(a) Game with complete information

![Graph](image2.png)

(b) ARA

Figure 12: Defender optimal solutions for the game with complete information (a) and ARA (b)
E.2 ARA robustness

We repeat the experiment in Section 3.2 to test the robustness of the ARA solution with respect to our uncertainty level about the attacker. The random probability of success for the Attacker is modeled again as $P_A(\theta = 1 \mid d, a = 1) \sim Beta(\alpha_d, \beta_d)$ but, instead of using parameter values of $\alpha_d$ and $\beta_d$ from Table 1d, we divide both by 100. That way, the variances of the resulting beta distributions are more than 50 times larger. The resulting $p_D(a \mid d)$, obtained with MC and APS, is shown in Figures 13a and 13b, respectively. As expected, these $p_D(a \mid d)$ distributions are more spread than those in Section 3.2, reflecting the fact that the Defender is more uncertain about the Attacker’s behaviour. However, the optimal ARA solution ($d^*_{ARA} = 9$) remains stable, as can be seen in Figures 14a and 14b.

![Figure 13: Estimation of $p_D(a \mid d)$ through ARA](image)

F Details of cybersecurity case study

We provide the comprehensive details of the cybersecurity case study in Section 5, structuring the information according to the nodes in the BAID.
Figure 14: ARA solutions for the Defender

Security controls:
The Defender has to determine the security controls, the protection level of a cloud-based DDoS protection system, with choices including 0 (not subscribing), 5, 10, 15, \ldots, 190, and 195 gbps.

Security controls cost:
Subscription costs $c_s$ are presented in Figure 15.

Competitor attack:
The Attacker must decide about the number of days that he will attempt to launch a DDoS attack, his possible alternatives being \{0, 1, \ldots, 30\}.

Duration DDoS:
The duration $l$ in hours of all DDoS attacks depends on both $d$, the cloud-based protection hired by the organization, and the number of attacking
Figure 15: Costs of DDoS protection given protection hired

attempts, $a$. We model the length $l_j$ of the $j$-th individual attack as a $\Gamma(4, 1)$ distribution (its average duration is 4 hours). This duration is conditional on whether the attack actually saturates the target, which depends on the capacity of the attacker’s DDoS platform minus the absorption of the cloud-based system. We assume that the Attacker uses a professional platform capable of producing attacks of 5 gbps, modelled through a $\Gamma(5, 1)$ distribution. We then subtract the traffic $d$ absorbed by the protection system to determine whether the attack was successful which happens when its traffic overflows the protection system. Thus, the total duration is $l = \sum_{j=1}^{a} l_j$, with $l_j \sim \Gamma(4, 1)$ when $\Gamma(5, 1) - d > 0$ and $l_j = 0$, otherwise.

To model the Attacker random beliefs about the duration of the attack, we base our estimate on that of the Defender. We model the length of the $j$-th individual DDoS attack as a random gamma distribution $\Gamma_{\text{length}}(v, v/\mu)$ with $v \sim \mathcal{U}(3.6, 4.8)$ and $v/\mu \sim \mathcal{U}(0.8, 1.2)$ so that we add uncertainty about the average duration (between 3 and 6 hours) and the dispersion. Similarly, we model the attack gbps through a random gamma distribution $\Gamma_{\text{gbps}}(\omega, \omega/\eta)$.
with \( \omega \sim U(4.8, 5.6) \) and \( \omega/\eta \sim U(0.8, 1.2) \). Next, we subtract the protection \( d \) from \( \Gamma_{gbps} \) to determine whether the DDoS is successful. We then use \( l = \sum l_j \), with \( l_j \sim \Gamma_{\text{length}} \) if \( \Gamma_{gbps} - d > 0 \), and \( l_j = 0 \) otherwise.

**Impact on market share:**

The DDoS duration might cause a reputational loss that would affect the organisation market share. The current market share is 50% valued at 1,500,000 €. We assume that all market share is fully lost at a linear rate until lost in, say, 5 – 8 days of unavailability (120 – 192 hours of DDoS duration): in the fastest case the loss rate would be \( 0.5/120 = 0.00417 \) per hour, whereas in the slowest one it would be 0.0026. We model this with a uniform distribution \( U(0.0026, 0.00417) \). Thus, the monetary loss \( m \) due to a reduced market share is \( m \sim \min[1500000, 3000000 \times l \times U(0.0026, 0.00417)] \).

For the Attacker, we base our estimate on that of the Defender, adding some uncertainty. The market share value and percentage are not affected by uncertainty, as this information is available to both agents. However, we model the uncertainty in the market loss rate so that the fastest one (5 days in the Defender problem) is between 4 and 6 days in the Attacker problem and the slowest one (8 for Defender) is between 7 and 9. Therefore, the random distribution describing the market loss \( m \) is \( m \sim \min \left[ 1500000, 3000000 \times l \times U(\alpha, \beta) \right] \) with \( \alpha \sim U(0.0021, 0.0031) \) and \( \beta \sim U(0.00367, 0.00467) \).

**Total costs:**

The costs \( c_d \) suffered by the Defender include the security control (subscription) costs \( c_s \), and the market share lost: \( c_d = m + c_s \).
Defender utility:

The organisation is constant risk averse over costs. Its utility function is strategically equivalent to \( u(c_d) = a - b \exp(k(c_d)) \). We rescale the costs to the (0,1) range and calibrate the utility function to \( u(c_d) = \frac{1}{e-1} \left[ \exp \left( 1 - \frac{c_d}{7000000} \right) - 1 \right] \).

Attacker earnings:

Being the sole competitor, the Attacker gains \( e \) in terms of market share is \( e = m \), all the market share lost by the Defender.

Attacker detection:

The Attacker runs the risk of being detected with significant costs. Detection probability is estimated via expert judgment at 0.2%, should the Attacker attempt a DDoS attack. Should there be \( a \) attacks, the detection has a binomial distribution \( B(a, 0.002) \). To add some uncertainty, we model the detection probability for each attack through a \( \beta e(2, 998) \) (Its’ mean is 0.002.). Thus, we model attacker’s detection \( t \) through a random binomial distribution that outputs \( detected \) if \( B(a, \phi) > 0 \) with \( \phi \sim \beta e(2, 998) \), and \( not detected \), otherwise.

Costs when detected:

If the attack is detected, there is a further cost for the Attacker deriving from legal issues, discredit, etc. We assume that \( c_t \mid t = 1 \sim \mathcal{N}(2430000, 400000) \) for the detection costs, where \( t = 1 \) indicates that attack is detected. If \( t = 0 \),
there are no further costs.

Result of the attack:

Regarding costs, using a botnet to launch the DDoS attack would cost on average 792 € per day. Overall, the Attacker gains are $c_a = e - c_t - 792a$.

Attacker utility:

The Attacker utility function is strategically equivalent to $u_A(c_a) = (c'_a)^{k_a}$, where $c'_a$ are the $c_a$ costs normalised to $[0, 1]$, and $k_a$ is the risk proneness parameter. We add uncertainty on $k_a$ assuming it follows a $U(8, 10)$ distribution.
