(Dated: January 15, 2022)

The Petz recovery channel plays an important role in quantum information science as an operation that approximately reverses the effect of a quantum channel. The pretty good measurement is a special case of the Petz recovery channel, and it allows for near-optimal state discrimination. A hurdle to the experimental realization of these vaunted theoretical tools is the lack of a systematic and efficient method to implement them. This paper sets out to rectify this lack: using the recently developed tools of quantum singular value transformation and oblivious amplitude amplification, we provide a quantum algorithm to implement the Petz recovery channel when given the ability to perform the channel that one wishes to reverse. Moreover, we prove that our quantum algorithm’s usage of the channel implementation cannot be improved by more than a quadratic factor. Our quantum algorithm also provides a procedure to perform pretty good measurements when given multiple copies of the states that one is trying to distinguish.

Introduction—Pretty good measurements [1–5] and Petz recovery channels [6–10] are workhorses of quantum information theory: they are used ubiquitously to prove basic results in quantum communication and measurement [11]. Although important for attaining quantum channel capacities [12–16] and performing state discrimination [1–4, 9], these useful theoretical constructions are less common in experiment, for the simple reason that there has not been a systematic method for performing them efficiently in practice. One of the main goals of this paper is to fill this gap.

The Petz recovery channel was introduced in the context of quantum sufficiency in [6, 7] and later rediscovered in [9] in the context of quantum error correction. It can be understood as a critical part of a quantum version of the Bayes theorem [17, Section IV]. To review it, let us begin with the classical case. A classical channel with input system X and output system Y over the alphabets \mathcal{X}, \mathcal{Y} is a conditional probability distribution $\{p_{Y|X}(y|x)\}_{x \in \mathcal{X}, y \in \mathcal{Y}}$. We consider a probability distribution $p_X(x)$ over the alphabet \mathcal{X} as the input to the channel. It then follows from the Bayes theorem that $p_X(x)p_{Y|X}(y|x) = p_Y(y)p_{X|Y}(x|y)$, where $p_Y(y) = \sum_x p_X(x)p_{Y|X}(y|x)$. Hence, for all $x \in \mathcal{X}, y \in \mathcal{Y}$, we define the “reversal channel” via the formula

$$p_{X|Y}(x|y) = \frac{p_X(x)p_{Y|X}(y|x)}{\sum_x p_X(x)p_{Y|X}(y|x)}. \quad (1)$$

This channel acts on the output system Y . If the particular distribution $p_Y(y)$ defined above is “sent in” through this channel, then the input $p_X(x)$ is recovered perfectly: $p_X(x) = \sum_y p_{X|Y}(x|y)p_Y(y)$. The computation of the reversal channel $p_{X|Y}(x|y)$ requires a specification of the input probability distribution $p_X(x)$ and the forward channel $p_{Y|X}(y|x)$. The Petz

recovery channel is a quantum generalization of the reversal channel above: it is a function of a quantum channel \mathcal{N} and an input state σ to the channel, with the former generalizing $p_{Y|X}(y|x)$ and the latter $p_X(x)$. We discuss it in more detail later.

The Petz recovery channel appears often in quantum information as a proof tool, showing that near-optimal recovery from undesired quantum operations is possible. Ref. [9] demonstrated how this recovery channel can be an effective means for reversing the effects of noise. Thereafter, [18] showed that the Petz recovery channel (therein called “transpose channel”) is a universal recovery operation for approximate quantum error correction, which performs comparably to the best possible one in terms of worst-case fidelity (see also [19]). The Petz recovery channel also goes by the name “pretty good recovery,” as used in [20, 21], due to the result of [9]. Yet another application comes from the field of quantum communication: [16] showed explicitly how to use the Petz recovery channel in a decoder to achieve the coherent information rate of quantum communication. It has also found use in developing physically meaningful refinements of quantum entropy inequalities [22–26]. Most recently, it has been employed in the context of Gaussian quantum information [27, 28], the AdS/CFT correspondence [29, 30], and in black-hole physics [31].

As an application of our results, our quantum algorithm can be used to implement the pretty good measurement (PGM) [1–5] on a quantum computer (the PGM is also known as the square-root measurement [12]). This measurement was used in [12, 15] as part of a coding scheme to approach the Holevo information rate for classical communication over a quantum channel. It has also been instrumental in proving bounds for

quantum algorithms. Ref. [32] showed that the PGM is an optimal measurement for solving the dihedral hidden subgroup problem and that it is helpful in proving a lower bound on the sample complexity of this problem. Similar techniques have been used for quantum probably-approximately-correct learning [33].

The diversity of applications makes a compelling case that the ability to implement the Petz recovery channel and pretty good measurement on a quantum computer will help to unleash the full potential of quantum computing. Moreover, the \star -product operation that enables quantum generalizations of Bayesian inference [17, 34] can also be implemented using the methods described herein.

We now begin the technical part of our paper, starting with an explicit description of the Petz recovery channel and the resources that we work with for its implementation.

Petz recovery channel—The Petz recovery channel is a function of a quantum state σ_A on a system A and a quantum channel $\mathcal{N}_{A \rightarrow B}$ taking system A to a system B . It is given explicitly as follows [10]:

$$\mathcal{P}_{B \rightarrow A}^{\sigma_A, \mathcal{N}}(\omega_B) := \sigma_A^{1/2} \mathcal{N}^\dagger(\mathcal{N}(\sigma_A)^{-1/2} \omega_B \mathcal{N}(\sigma_A)^{-1/2}) \sigma_A^{1/2}, \quad (2)$$

where \mathcal{N}^\dagger is the Hilbert–Schmidt adjoint [11] of the channel \mathcal{N} and we have omitted the system labels of $\mathcal{N}_{A \rightarrow B}$ for brevity. It is a composition of three completely positive (CP) maps:

$$(\cdot) \rightarrow [\mathcal{N}(\sigma_A)]^{-1/2} (\cdot) [\mathcal{N}(\sigma_A)]^{-1/2}, \quad (3)$$

$$(\cdot) \rightarrow \mathcal{N}^\dagger(\cdot), \quad (4)$$

$$(\cdot) \rightarrow \sigma_A^{1/2} (\cdot) \sigma_A^{1/2}. \quad (5)$$

None of these maps are trace preserving individually, but overall the map in (2) is trace preserving on the support of the state $\mathcal{N}(\sigma_A)$ [22].

Block-encoding—The Petz recovery channel depends on the state σ_A , and so our algorithm needs some form of access to it. In order to cover a wide range of scenarios, we employ the block-encoding formalism, which generalizes the most common input models for matrices used in quantum algorithms [35, 36].

Let $\|\cdot\|$ denote the spectral norm of a matrix (also known as the Schatten ∞ -norm). For any complex matrix A and $\alpha \geq \|A\|$, the matrix A/α can be represented as the upper-left block of a unitary matrix:

$$U = \begin{bmatrix} A/\alpha & \cdot \\ \cdot & \cdot \end{bmatrix} \iff A = \alpha(\langle 0| \otimes I)U(|0\rangle \otimes I). \quad (6)$$

The unitary matrix U is said to be a *block-encoding* of A . Henceforth, we do not write identity operators explicitly, but we instead include system subscripts as a guide. If the linear map A/α acts on a qubits, then the unitary U can be thought of as a probabilistic implementation of this map: given an a -qubit input state $|\psi\rangle$, applying the unitary U to the state $|0\rangle|\psi\rangle$, measuring the first system, and post-selecting on the $|0\rangle$ outcome, the second system contains a state proportional to $A|\psi\rangle/\alpha$.

This generalizes the two most relevant input models in our case. If we are given copies of the quantum state σ_A , then we can implement an (approximate) block-encoding of σ_A by using density matrix exponentiation [37, 38] and “taking the logarithm” of the time evolution [36]. Moreover, if we have access to a quantum circuit U_{RA}^σ that prepares a purification $|\psi^\sigma\rangle_{RA} := U_{RA}^\sigma|0\rangle_R|0\rangle_A$ of σ_A , such that $\text{Tr}_R[|\psi^\sigma\rangle\langle\psi^\sigma|_{RA}] = \sigma_A$, then we can directly implement an exact block-encoding of σ_A with only two uses of U_{RA}^σ as follows [35, 36]:

$$V_{RAA'}^\sigma := (U_{RA}^\sigma)^\dagger (I_R \otimes \text{SWAP}_{AA'}) U_{RA}^\sigma = \begin{bmatrix} \sigma_A & \cdot \\ \cdot & \cdot \end{bmatrix}, \quad (7)$$

where system A' is isomorphic to system A .

Assumptions—The resources that we use for implementing the Petz recovery channel are as follows:

1. Quantum circuits U^{σ_A} and $U^{\mathcal{N}(\sigma_A)}$ that are (approximate) block-encodings of σ_A and $\mathcal{N}(\sigma_A)$, respectively.
2. A quantum circuit $U_{E'A \rightarrow EB}^{\mathcal{N}}$ that implements the channel \mathcal{N} , in the sense that $U_{E'A \rightarrow EB}^{\mathcal{N}}|0\rangle_{E'} =: V_{A \rightarrow EB}^{\mathcal{N}}$, where $V_{A \rightarrow EB}^{\mathcal{N}}$ is an isometric extension of \mathcal{N} satisfying $\text{Tr}_E[V_{A \rightarrow EB}^{\mathcal{N}}(\omega_A)(V_{A \rightarrow EB}^{\mathcal{N}})^\dagger] = \mathcal{N}(\omega_A)$, for all input density operators ω_A .

We note that, given an efficient description of the channel \mathcal{N} in terms of its Kraus operators, the unitary $U_{E'A \rightarrow EB}^{\mathcal{N}}$ can be efficiently implemented on a quantum computer [39]. Also, given copies or “purified access” to σ_A , we can achieve the corresponding access to $\mathcal{N}(\sigma_A)$ after applying $U_{E'A \rightarrow EB}^{\mathcal{N}}$, which then results in an efficient block-encoding for $\mathcal{N}(\sigma_A)$.

Rewriting the Petz recovery channel—Eq. (4) calls for the application of the adjoint \mathcal{N}^\dagger of the channel \mathcal{N} . We now explain how this can be accomplished using $U_{E'A \rightarrow EB}^{\mathcal{N}}$. The action of the adjoint on an arbitrary operator ω_B is given by $\mathcal{N}^\dagger(\omega_B) = \langle 0|_{E'} U^{\mathcal{N}^\dagger} (I_E \otimes \omega_B) U^{\mathcal{N}} |0\rangle_{E'}$ [11]. Let $\Gamma_{E\tilde{E}} := |\Gamma\rangle\langle\Gamma|_{E\tilde{E}}$ denote an operator proportional to the maximally entangled state on E and a reference system \tilde{E} , where $|\Gamma\rangle_{E\tilde{E}} := \sum_{i=0}^{d_E-1} |i\rangle_E |i\rangle_{\tilde{E}}$ and d_E is the dimension of system E . Then extending the identity operator with $\Gamma_{E\tilde{E}}$, we rewrite the previous identity as

$$\mathcal{N}^\dagger(\omega_B) = \text{Tr}_{\tilde{E}}[\langle 0|_{E'} (U_{E'A \rightarrow EB}^{\mathcal{N}})^\dagger (\Gamma_{E\tilde{E}} \otimes \omega_B) U_{E'A \rightarrow EB}^{\mathcal{N}} |0\rangle_{E'}]. \quad (8)$$

Now the interpretation of the adjoint map as a probabilistic quantum operation is clear: the adjoint map \mathcal{N}^\dagger acting on the operator ω_B can be applied by tensoring in the maximally entangled state $\Gamma_{E\tilde{E}}/d_E$, performing the inverse of the unitary $U^{\mathcal{N}}$, measuring the system E' , accepting if the all-zeros outcome occurs, and finally, ignoring the system \tilde{E} (which corresponds to tracing it out).

Thus, our plan is to implement the linear extension of the adjoint map, as given in (8). Sandwiching this between the other two maps in (3) and (5) comprising the Petz recovery channel, we obtain the following isometric extension of the Petz recovery channel:

$$V_{B \rightarrow \tilde{E}A}^{\mathcal{P}} := (\langle 0|_{E'} \otimes I_{\tilde{E}A}) \sigma_A^{\frac{1}{2}} (U_{E'A \rightarrow EB}^{\mathcal{N}})^{\dagger} [\mathcal{N}(\sigma_A)]^{-\frac{1}{2}} (\Gamma)_{E\tilde{E}} \otimes I_B. \quad (9)$$

Tracing over \tilde{E} then implements the Petz recovery channel $\mathcal{P}_{B \rightarrow A}^{\sigma_A, \mathcal{N}}(\omega_B)$. Note that in the rewriting above, the implementation of the adjoint map discussed in the preceding paragraph is no longer contiguous. It proceeds in two phases: the application of the unitary $(U_{E'A \rightarrow EB}^{\mathcal{N}})^{\dagger}$ before multiplication by $\sigma_A^{1/2}$ (which applies (5)); and the measurement and post-selection after that step.

Quantum singular value transformation—Our implementation is based on quantum singular value transformation (QSVT) [36]. QSVT transforms the singular values of a block-encoded matrix and thus provides an efficient means of quantum matrix arithmetic. Often we need to rely on approximations, and so when doing so, we keep track of the error/precision δ , as well as the sub-normalization factor α : we say that U is an (α, δ) -block-encoding of A if $\|A - \alpha(\langle 0| \otimes I)U(|0\rangle \otimes I)\| \leq \delta$.

In what follows, we manipulate block-encodings U^{ρ} of density operators ρ . The power of QSVT is that it allows for transforming U^{ρ} to a block-encoding of $\tilde{f}(\rho)$, where \tilde{f} is a function applied to the singular values of its argument. More precisely, \tilde{f} denotes a polynomial approximation of some function f ; in view of the maps given in (3) and (5) above, the particular functions of interest here are $f_1(x) := x^{-1/2}$ and $f_2(x) := x^{1/2}$.

The complexity of realizing the transformed block-encoding unitary $U^{\tilde{f}(\rho)}$ is stated in terms of the number of uses of U^{ρ} (which dominates the overall gate complexity), and it depends on the parameters of the functional approximation \tilde{f} . For a function f , let $\|f(x)\|_J := \sup_{x \in J} |f(x)|$. Using techniques from [40], for the two functions above, one can find polynomial approximations \tilde{f}_1, \tilde{f}_2 such that $\frac{\theta^{1/2}}{2} \|\tilde{f}_1(x) - x^{-1/2}\|_{[\theta, 1]} \leq \delta$, and $\frac{1}{2} \|\tilde{f}_2(x) - x^{1/2}\|_{[\theta, 1]} \leq \delta$ for $\theta, \delta \in (0, 1/2]$. If ρ has minimum singular value λ_{\min} , then it suffices to set $\theta \leq \lambda_{\min}$. Since $1/\lambda_{\min}$ behaves like a ‘‘condition number’’ for ρ , being proportional to the difficulty of transforming ρ , we denote it with the symbol κ and employ this notation later. Indeed, using the functional approximations from [40], QSVT achieves the desired transformations up to the errors indicated above, with $\mathcal{O}\left(\frac{1}{\theta} \log \frac{1}{\delta}\right)$ uses of U^{ρ} .

The quantum algorithm—We implement the isometric extension of the Petz recovery channel given in (9). This consists of applying the maps in (3), (4), and (5) sequentially, with the first and third steps employing QSVT. Eq. (9) also has a measurement component as the final step, arising from the implementation of the map in (4). By exploiting the trace-preserving property of the Petz recovery channel, we amplify the probability of success of this measurement (i.e., the projection onto $|0\rangle_{E'}$) using oblivious amplitude amplification [41], which is a special case of QSVT [36]. Overall, the implementation is precise up to ε error in diamond distance [42] (see [11] for a definition of diamond distance). Theorem 1 below states the guarantees of this technique.

Theorem 1 *Let N_{σ} , $N_{\mathcal{N}(\sigma)}$ and $N_{\mathcal{N}}$ denote the number of elementary quantum gates needed to realize the unitaries U^{σ_A} , $U^{\mathcal{N}(\sigma_A)}$, and $U_{E'A \rightarrow EB}^{\mathcal{N}}$ respectively (noting that in our applications $N_{\mathcal{N}(\sigma)} \leq N_{\sigma} + N_{\mathcal{N}}$). Let κ_{σ} denote an upper bound on the reciprocal of the minimum non-zero eigenvalue of σ_A , and correspondingly, let $\kappa_{\mathcal{N}(\sigma)}$ denote the same for $\mathcal{N}(\sigma_A)$. There exists a quantum algorithm realizing the channel $\tilde{\mathcal{P}}_{B \rightarrow A}^{\sigma_A, \mathcal{N}}$, which is an approximate implementation of the ideal Petz recovery channel in (2), in the sense that*

$$\left\| \tilde{\mathcal{P}}_{B \rightarrow A}^{\sigma_A, \mathcal{N}} - \mathcal{P}_{B \rightarrow A}^{\sigma_A, \mathcal{N}} \right\|_{\diamond} \leq \varepsilon, \quad (10)$$

with gate complexity (up to poly-logarithmic factors)

$$\tilde{\mathcal{O}}\left(\sqrt{d_E \kappa_{\mathcal{N}(\sigma)}} \left(\kappa_{\mathcal{N}(\sigma)} N_{\mathcal{N}(\sigma)} + N_{\mathcal{N}} + N_{\sigma} \min\left(\kappa_{\sigma}, \frac{d_E \kappa_{\mathcal{N}(\sigma)}}{\varepsilon^2}\right)\right)\right). \quad (11)$$

In (11), d_E is the dimension of the system E , which is not smaller than the Kraus rank of the channel $\mathcal{N}(\cdot)$.

We now break the algorithm down into its four steps and analyze each step individually (assuming without loss of generality that $\varepsilon = \mathcal{O}(1)$). To simulate the first step of the Petz recovery channel, as described by (3), we transform the block-encoding of $\mathcal{N}(\sigma_A)$ to a $\left(2\sqrt{\kappa_{\mathcal{N}(\sigma)}}, \frac{\mathcal{O}(\varepsilon)}{\sqrt{d_E}}\right)$ -block-encoding $U_{R'B}^{\tilde{f}_1(\mathcal{N}(\sigma_A))}$ of $[\mathcal{N}(\sigma_A)]^{-1/2}$ using QSVT, which has gate complexity $\mathcal{O}\left(\kappa_{\mathcal{N}(\sigma)} N_{\mathcal{N}(\sigma)} \log \frac{d_E \kappa_{\mathcal{N}(\sigma)}}{\varepsilon}\right)$. Then the following error bound holds

$$\left\| \tilde{f}_1(\mathcal{N}(\sigma_A)) - (\mathcal{N}(\sigma_A))^{-1/2} \right\| \leq \frac{\mathcal{O}(\varepsilon)}{\sqrt{d_E}}, \quad (12)$$

which suffices for our purposes, as shown later.

Let \tilde{E} be a system with dimension equal to that of E . The second step of the algorithm is simply to prepare the maximally entangled state $|\Phi\rangle_{E\tilde{E}} := |\Gamma\rangle_{E\tilde{E}} / \sqrt{d_E}$ alongside the state prepared above, and then apply the unitary $(U_{A'E' \rightarrow BE}^{\mathcal{N}})^{\dagger}$. Note that $|\Phi\rangle_{E\tilde{E}}$ is a normalized quantum state, introducing an additional factor of $\frac{1}{d_E}$ in the output density operator, which resurfaces in the subnormalization factor of the overall unitary (see (15)). The maximally entangled state $|\Phi\rangle_{E\tilde{E}}$ is prepared by means of a unitary $U_{E\tilde{E}}^{\Phi}$ acting on the state $|0\rangle_{E\tilde{E}}$, so that $|\Phi\rangle_{E\tilde{E}} := U_{E\tilde{E}}^{\Phi} |0\rangle_{E\tilde{E}}$. Note that the unitary $U_{E\tilde{E}}^{\Phi}$ is easy to implement. For example, if systems E and \tilde{E} consist of qubits, one can apply Hadamard gates on the qubits of E and CNOT gates between pairs of qubits of E and \tilde{E} . In this step, we have described the first half of the procedure for implementing a linear extension of (4); the final part, which consists of measurement and post-selection, is deferred to the fourth step.

The third step of the algorithm is to apply an approximation of the map in (5) that conjugates the state by $\sigma_A^{1/2}$. Analogous to the first step, we transform the block-encoding of σ_A to a $\left(2, \frac{\mathcal{O}(\varepsilon)}{\sqrt{d_E \kappa_{\mathcal{N}(\sigma)}}}\right)$ -block-encoding $U_{R'A}^{\tilde{f}_2(\sigma_A)}$ of $\tilde{f}_2(\sigma_A)$ using QSVT, which has gate complexity $\mathcal{O}\left(\kappa_{\sigma} N_{\sigma} \log\left(\frac{d_E \kappa_{\mathcal{N}(\sigma)}}{\varepsilon}\right)\right)$. Then the

following error bound holds

$$\|\tilde{f}_2(\sigma_A) - \sigma_A^{1/2}\| \leq \frac{\mathcal{O}(\varepsilon)}{\sqrt{d_E \kappa_{\mathcal{N}(\sigma)}}}. \quad (13)$$

We can now apply the unitary $U_{R''A}^{\tilde{f}_2(\sigma_A)}$ to the output of Step 2. In detail, letting ρ_A denote the output state of Step 2, we tensor in the state $|0\rangle\langle 0|_{R''}$ to the input state ρ_A and perform the unitary $U_{R''A}^{\tilde{f}_2(\sigma_A)}$.

Let us summarize the algorithm up to this point. We have described the addition of auxiliary systems as happening separately in each step. However, we are free to tensor them in to the input state ω_B at the start, enlarging the input state to $|0\rangle\langle 0|_{R''} \otimes |0\rangle\langle 0|_{E\tilde{E}} \otimes |0\rangle\langle 0|_{R'} \otimes \omega_B$. Then to this state, we apply the following product of unitaries:

$$\tilde{W} := U_{R''A}^{\tilde{f}_2(\sigma_A)} \left(U_{E'A \rightarrow EB}^{\mathcal{N}} \right)^\dagger \left(U_{E\tilde{E}}^\Phi \otimes U_{R'B}^{\tilde{f}_1(\mathcal{N}(\sigma_A))} \right), \quad (14)$$

where $U_{R''A}^{\tilde{f}_2(\sigma_A)}$ and $U_{R'B}^{\tilde{f}_1(\mathcal{N}(\sigma_A))}$ are implemented using QSVT. The unitary \tilde{W} approximates the isometric extension in (9) and can be represented as the following block-encoding:

$$\tilde{W} = \begin{bmatrix} \frac{1}{4} \sqrt{\frac{1}{d_E \kappa_{\mathcal{N}(\sigma)}}} \tilde{V}_{B \rightarrow \tilde{E}A}^{\mathcal{P}} & \\ & \cdot \\ & \cdot \\ & \cdot \end{bmatrix}, \quad (15)$$

where the linear operator $\tilde{V}_{B \rightarrow \tilde{E}A}^{\mathcal{P}}$ is an approximate isometric extension of the Petz recovery channel and is defined through its action on a ket $|\psi\rangle_B$ as

$$\tilde{V}_{B \rightarrow \tilde{E}A}^{\mathcal{P}} |\psi\rangle_B := \tilde{f}_2(\sigma_A) \left(V_{A \rightarrow EB}^{\mathcal{N}} \right)^\dagger \tilde{f}_1(\mathcal{N}(\sigma_A)) |\Gamma\rangle_{E\tilde{E}} |\psi\rangle_B. \quad (16)$$

After applying \tilde{W} to the enlarged input state, we would like to measure the $R''E'R'$ systems and obtain the all-zeros state as the outcome (which corresponds to the top-left block of \tilde{W}). Receiving this outcome signals the successful implementation of the desired map $\tilde{V}_{B \rightarrow \tilde{E}A}^{\mathcal{P}}$, up to a sub-normalization factor of $4\sqrt{\kappa_{\mathcal{N}(\sigma)} d_E}$. To compare this to the ideal isometric extension in (9), we should account for the accumulated errors due to the approximate implementations of $\mathcal{N}(\sigma_A)^{-1/2}$ and $\sigma_A^{1/2}$ in \tilde{W} . It follows that

$$\|\tilde{V}_{B \rightarrow \tilde{E}A}^{\mathcal{P}} - V_{B \rightarrow \tilde{E}A}^{\mathcal{P}}\| \leq \mathcal{O}(\varepsilon), \quad (17)$$

where $\tilde{V}_{B \rightarrow \tilde{E}A}^{\mathcal{P}}$ is defined in (16) and $V_{B \rightarrow \tilde{E}A}^{\mathcal{P}}$ in (9). To see this, observe that the left-hand side of (17) can be bounded from above by the following quantity:

$$\begin{aligned} & \left\| \sigma_A^{1/2} - \tilde{f}_2(\sigma_A) \right\| \left\| \left(V_{A \rightarrow EB}^{\mathcal{N}} \right)^\dagger \mathcal{N}(\sigma_A)^{-1/2} |\Gamma\rangle_{E\tilde{E}} \right\| + \\ & \left\| \tilde{f}_2(\sigma_A) \left(V_{A \rightarrow EB}^{\mathcal{N}} \right)^\dagger \right\| \left\| |\Gamma\rangle_{E\tilde{E}} \right\| \left\| \mathcal{N}(\sigma_A)^{-1/2} - \tilde{f}_1(\mathcal{N}(\sigma_A)) \right\|, \end{aligned} \quad (18)$$

which follows from applying the triangle inequality and sub-multiplicativity of the spectral norm. Noting that $|\Gamma\rangle_{E\tilde{E}}$ is the

unnormalized maximally-entangled vector, we further bound the following terms:

$$\left\| \left(V_{A \rightarrow EB}^{\mathcal{N}} \right)^\dagger \mathcal{N}(\sigma_A)^{-1/2} |\Gamma\rangle_{E\tilde{E}} \right\| \leq \sqrt{d_E \kappa_{\mathcal{N}(\sigma)}}, \quad (19)$$

$$\left\| \tilde{f}_2(\sigma_A) \left(V_{A \rightarrow EB}^{\mathcal{N}} \right)^\dagger \right\| \left\| |\Gamma\rangle_{E\tilde{E}} \right\| \leq 2\sqrt{d_E}. \quad (20)$$

The second bound follows because $\tilde{f}_2(\sigma_A)$ is a block-encoding with norm at most 2. Putting (18)–(20) together with the bounds in (12) and (13), we conclude an overall error of $\mathcal{O}(\varepsilon)$.

Finally, we move on to the last step, which is a measurement of the $R''E'R'$ systems. Eq. (15) makes it clear that the probability p_{success} of measuring the all-zeros state, at this point, is approximately $\frac{1}{16d_E \kappa_{\mathcal{N}(\sigma)}}$. We would like to amplify this probability, and so we use oblivious amplitude amplification to implement an approximate projection onto this state. This too can be achieved using QSVT techniques [36] and requires a number of repetitions of \tilde{W} that scales as $\mathcal{O}(1/\sqrt{p_{\text{success}}})$, which in this case is $N_{\text{rep}} := \mathcal{O}(\sqrt{d_E \kappa_{\mathcal{N}(\sigma)}})$. After applying (robust) oblivious amplitude amplification [43, Theorem 28], we obtain a unitary that is a $(1, \mathcal{O}(\varepsilon))$ -block-encoding of the isometric extension $V_{B \rightarrow \tilde{E}A}^{\mathcal{P}}$ providing an $\mathcal{O}(\varepsilon)$ -approximate implementation of the Petz recovery channel.

The complexity of our algorithm is given by N_{rep} times the complexity of implementing \tilde{W} . As we discussed previously, the cost of implementing the first step in \tilde{W} is $\mathcal{O}(\kappa_{\mathcal{N}(\sigma)} N_{\mathcal{N}(\sigma)} \log \frac{d_E \kappa_{\mathcal{N}(\sigma)}}{\varepsilon})$. The complexity of implementing the second step is $\mathcal{O}(N_{\mathcal{N}} + \log(d_E))$, where the logarithmic term is the cost of implementing $U_{E\tilde{E}}^\Phi$. Finally, the complexity of the third step is $\mathcal{O}(\kappa_{\sigma} N_{\sigma} \log \frac{d_E \kappa_{\mathcal{N}(\sigma)}}{\varepsilon})$. An alternative for this last step is to consider choosing a threshold θ higher than $1/\kappa_{\sigma}$, and approximating the square root function by constant zero below the threshold. Indeed, then choosing $\theta \approx \varepsilon^2/(d_E \kappa_{\mathcal{N}(\sigma)})$ suffices, resulting in the alternative complexity $\mathcal{O}(\frac{d_E \kappa_{\mathcal{N}(\sigma)}}{\varepsilon^2} N_{\sigma} \log \frac{d_E \kappa_{\mathcal{N}(\sigma)}}{\varepsilon})$ of the third step.

Lower bounds—Our algorithm uses the forward channel unitary $U_{E'A \rightarrow EB}^{\mathcal{N}}$ about $\mathcal{O}(\sqrt{d_E \kappa_{\mathcal{N}(\sigma)}})$ times. We now prove that any generally applicable algorithm must use $U_{E'A \rightarrow EB}^{\mathcal{N}}$ at least $\Omega(d_E^{\frac{1}{2}-\alpha} \kappa_{\mathcal{N}(\sigma)}^\alpha)$ times, for any $\alpha \in [0, \frac{1}{2}]$, thereby ruling out the possibility of large improvements on our algorithm.

We consider solving the problem of unstructured search of $N \geq 2$ elements with only a single marked element. Let O be a search oracle that recognizes the single marked element. Let the input state σ_A be the maximally mixed state representing a uniformly random index $i \in [N]$. The forward channel $\mathcal{N}_{A \rightarrow B}$ applies the search oracle and outputs its output, which is equal to 1 if i is the marked element and is equal to 0 otherwise. Hence $\mathcal{N}_{A \rightarrow B}(\sigma_A) = \text{diag}(1 - \frac{1}{N}, \frac{1}{N})$ and $\kappa_{\mathcal{N}(\sigma)} = d_E = N$. Let $\mathcal{P}^{\mathcal{N}, \sigma_A}$ be the Petz recovery channel defined from \mathcal{N} and σ_A as specified above. Now applying the exact channel $\mathcal{P}^{\mathcal{N}, \sigma_A}$ on the state $\omega_B = |1\rangle\langle 1|$ finds the marked element with certainty. Thus, for any constant $c < 1$, applying a c -approximate channel $\tilde{\mathcal{P}}^{\mathcal{N}, \sigma_A}$ on ω_B still finds a marked element with probability at least $1 - c$. This requires $\Omega(\sqrt{N}) = \Omega(d_E^{\frac{1}{2}-\alpha} \kappa_{\mathcal{N}(\sigma)}^\alpha)$ uses of O ,

as the well known quantum search lower bound states [44].

Eq. (11) also depends on the parameter d_E . By modifying the procedure for applying the adjoint map, we can obtain a complexity that is independent of this parameter. We will discuss this modified procedure in a companion paper, to be released later.

Pretty good measurement—One can use our algorithm to implement the *pretty good measurement* [1–5]. In this application, one is given a set $\{\sigma_B^x\}_x$ of states and a probability distribution p_X . Let σ_{XB} denote the following classical–quantum state: $\sigma_{XB} := \sum_x p_X(x) |x\rangle\langle x|_X \otimes \sigma_B^x$. Let $\mathcal{N}_{XB \rightarrow B} := \text{Tr}_X$ be the partial trace channel that discards system X .

We now plug these choices into (2). The adjoint map $(\mathcal{N}_{XB \rightarrow B})^\dagger$ appends the identity on system X . Let $\bar{\sigma}_B := \mathcal{N}_{XB \rightarrow B}(\sigma_{XB}) = \sum_x p_X(x) \sigma_B^x$. The resulting Petz recovery channel is as follows:

$$\mathcal{P}_{B \rightarrow XB}^{\sigma_{XB}, \text{Tr}_X}(\omega_B) := \sum_x |x\rangle\langle x|_X \otimes p_X(x) (\sigma_B^x)^{\frac{1}{2}} (\bar{\sigma}_B)^{-\frac{1}{2}} \omega_B (\bar{\sigma}_B)^{-\frac{1}{2}} (\sigma_B^x)^{\frac{1}{2}}, \quad (21)$$

which is known as the “pretty good instrument” [22]. This is a generalization of the pretty good measurement that has a quantum output in addition to the usual classical measurement output; the PGM is obtained by discarding the quantum output.

We check the necessary assumptions for our technique against what is potentially available for experiments. The isometric extension of the channel $\text{Tr}_X(\cdot)$ is simply the identity. If we have copies of σ_{XB} then our algorithm is applicable, but it is more efficient in the case when we can prepare a purification of σ_{XB} . Applying Theorem 1, we arrive at a quantum algorithm implementing the pretty good instrument with performance guarantees as in (10) and (11), where

$$d_E = |X|, \quad \kappa_{\mathcal{N}(\sigma)} = \kappa_{\bar{\sigma}}, \quad \kappa_\sigma = \min_x p_X(x) \kappa_{\sigma_B^x}. \quad (22)$$

Conclusion and open problems—We have developed a quantum algorithm for implementing the Petz recovery channel and the pretty good measurement. This solves an important open problem in quantum computation, and more generally, it opens up a new research paradigm for realizing fully quantum Bayesian inference on quantum computers.

In future work, it would be interesting to explore certain special channels, potentially allowing for simplifications or speed-ups. For instance, if the forward channel is a unitary channel, then the recovery map consists of simply applying its inverse, amounting to a total gate complexity of N_N . In this very special case, we have $d_E = 1$, enabling the simplification. This hints at the possibility of more efficient implementations when a channel \mathcal{N} is close to a channel $\tilde{\mathcal{N}}$ with small d_E and/or $\kappa_{\mathcal{N}(\sigma)}$. On the other hand, there also seems to be room for tightening our general lower bound, which could provide a better understanding of the ultimate resource requirements of Petz recovery channels and pretty good measurements.

We gratefully acknowledge the Simons Institute for the Theory of Computing, where part of this work was conducted.

AG acknowledges funding provided by Samsung Electronics Co., Ltd., for the project “The Computational Power of Sampling on Quantum Computers.” Additional support was provided by the Institute for Quantum Information and Matter, an NSF Physics Frontiers Center (NSF Grant PHY-1733907).
